**Notice**

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our knowledge, changes in practice, treatment and drug therapy may become necessary or appropriate. Readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of the practitioner, relying on their own experience and knowledge of the patient, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions. To the fullest extent of the law, neither the Publisher nor the Editors assume any liability for any injury and/or damage to persons or property arising out of related to any use of the material contained in this book.

ELSEVIER BOOK AID International Sabre Foundation

To our patients whom we treat as family, and to our families for their patience.

I would like to thank my wife, Edie, and our sons, Brandon and Andrew, for continuing to support my academic endeavors and for providing a loving environment from which to grow professionally and personally. Also to my parents, George and Audrey, who taught me to “reach for the stars.” To the many mentors who have had such a profound impact on my life—to them I am forever indebted. Finally, I would like to recognize my coeditors, IH and JS. Their friendship has made this project enjoyable from the onset; their exemplary professionalism is a credit to our field of medicine.

—EB

I dedicate this book to my family: Patricia, my wife, and our children, Angela, Andrea, and Luke for their unending enthusiasm and support for all my academic ventures. To my mother, who in her ninetieth year continues to remind me how “she is responsible for it all.” Finally as noted in the preface, behind every successful professional is one other key person, *viz.* their Administrative Assistant. This book could not have been completed without the capable assistance of Doreen Smith, whose tireless hours addressed the entire “attention to detail” prerequisite to what you have in your hands today.

—JS

I dedicate this text to my wife, Julie, and daughters, Andrea and Rebecah. It is through their support and sacrifice that I have been able to pursue my academic career. In addition to my family, I would like to recognize the mentors who have assisted me in my academic pursuits. As mentioned in the preface, my participation in preparing this text would not have been possible without my Administrative Assistant, Julie Cook. It is my hope that this text will provide physicians with an evidence-based approach to gynecology.

—IH

# Contributors

## Rony A. Adam, MD

Director, Division of Gynecologic Specialties, Department of Gynecology and Obstetrics, Emory University School of Medicine, Atlanta, GA

*Diagnosis and Treatment of Fistulas; Nonsurgical Treatment of Urinary Incontinence*

## Raedah Al-Fadhl, MD

Fellow, Reproductive Endocrinology and Infertility, McGill University, Montreal, Quebec, Canada

*Laparoscopic Instrumentation*

## Zoyla Almeida-Parra, MD

Gynecologic Oncologist, Department of Obstetrics and Gynecology, Memorial Miramar Hospital; Gynecologic Oncologist, Department of Obstetrics and Gynecology, Memorial West Hospital, Miramar, FL  
*Cervical Carcinoma*

## Rudi Ansbacher, MD, MS

Professor Emeritus, Obstetrics and Gynecology, University of Michigan Medical Center, Ann Arbor, MI  
*Geriatric Gynecology*

## Gloria Bachmann, MD

Professor, Departments of Obstetrics and Gynecology and Medicine; Associate Dean for Women's Health, Women's Health Institute; UMDNJ-Robert Wood Johnson Medical School; Attending, Obstetrics and Gynecology, Robert Wood Johnson University Hospital, New Brunswick, NJ  
*Sexual Function and Disorders*

## Patricia E. Bailey-Sarnelli, MD

Department of Obstetrics and Gynecology, Baystate Health Systems, Longmeadow, MA  
*Contraception*

## Randall B. Barnes, MD

Associate Professor, Department of Obstetrics and Gynecology, Northwestern University, Chicago, IL  
*Abnormal Uterine Bleeding*

## Jack Basil, MD

Associate Director, Department of Gynecologic Oncology, TriHealth, Tristate Gynecologic Oncology, Cincinnati, OH  
*Vaginal Carcinoma*

## John Bennett, MD

Department of Radiology, St. Joseph's Health Care, London, Ontario, Canada  
*Uterine Leiomyomas*

## Inbar Ben-Shachar, MD

Lecturer, Faculty of Medicine, Hebrew University; Attending, Division of Gynecologic Oncology, Department of Obstetrics and Gynecology, Hadassah University Medical Center, Jerusalem, Israel  
*Gestational Trophoblastic Disease*

## Jonathan S. Berek, MD, MMSc

Professor and Chair, College of Applied Anatomy; Executive Vice Chair, Department of Obstetrics and Gynecology; Chief, Division of Gynecologic Oncology and Gynecology Service; Director, UCLA Women's Reproductive Cancer Program, David Geffen School of Medicine at UCLA, UCLA Center for the Health Sciences, Los Angeles, CA  
*Cancer Genetics*

## Sarah L. Berga, MD

James Robert McCord Professor and Chair, Department of Gynecology and Obstetrics, Emory University School of Medicine; Department of Gynecology and Obstetrics, Emory Healthcare, Atlanta, GA  
*Physiology of the Menstrual Cycle*

## Eric J. Bieber, MD, MHCM

Chair, Department of Obstetrics and Gynecology; Medical Director, Women's Service Line; Chief Medical Officer, Geisinger Wyoming Valley and Geisinger South Wilkes-Barre; Senior Vice President; Geisinger Health Systems; Wilkes-Barre and Danville, PA  
*Hysteroscopic Instrumentation; Hysteroscopic Procedures; Laparoscopic and Hysteroscopic Complications; Laparoscopic Instrumentation*

*Hysteroscopic Instrumentation*

**Howard A. Zaccur, MD, PhD**

Theodore and Ingrid Baramki Professor and Director of Reproductive Endocrinology and Infertility, Department of Gynecology and Obstetrics, The Johns Hopkins University School of Medicine, Baltimore, MD  
*Hyperprolactinemia*

# Preface

The stage is set as this segment of a textbook is always written, but may not always be read. The editors conceptualized this textbook almost a decade ago. While several popular gynecologic texts existed, we were unable to find a substantive reference text that had all of the qualities we envisioned. We spent many months debating format options that we believed would optimize the educational experience of you our audience. This final version is the distillation of those many discussions.

The three editors come from distinct and vastly different backgrounds: Eric Bieber's greatest interest lies in minimally invasive surgery (MIS), reproductive endocrinology and infertility (REI), and general gynecology; Ira Horowitz is interested in gynecologic oncology, pelvic surgery, and anatomy; and Joseph Sanfilippo is integrally involved with REI, MIS, and pediatric and adolescent gynecology. Each of us has directed fellowships, residencies, and departments over the years and each of us has also completed master's degrees in business administration or healthcare management. These disparate, yet singularly motivated interests, were an excellent nidus and most appropriate prerequisite for the text genesis.

The planning of this book has the basic tenets of combing the literature, pursuing the shelves of libraries, and arriving at a conclusion focused on what is needed for all sectors of female healthcare provision. The editors felt it was of paramount importance to provide for our readers a well-illustrated text in full color that was visually interesting but that also spanned the spectrum of gynecology. The text is thus divided into the following sections:

- 1 Ambulatory office practice
- 2 General gynecology
- 3 Gynecologic infectious disease
- 4 Urogynecology
- 5 Pediatric and adolescent gynecology
- 6 Minimal invasive surgery
- 7 Gynecologic oncology
- 8 Reproductive endocrinology and infertility
- 9 Coding and office management

We tapped into the expertise of leading authorities to provide the most current information in a succinct and easily understood format. This allows each chapter to be a "stand alone" entity, although there is continuity of style from chapter to chapter. However, given how we have intentionally structured the text, there are areas where we have allowed seeming incongruencies to stand as written. This allows the reader a panoramic understanding regarding some topics where there are inherent multiplicities of opinions and data.

The reader will note the increased breadth given to the topic of minimal invasive surgery. In addition, we address other areas such as compliance and the regulatory environment that are typically not covered in other texts.

In an effort to bring the most up-to-date and relevant information to the reader, we asked the chapter authors to provide references with coding of the level of strength of study design. Furthermore, they were requested to limit their citations to references that were particularly important. While several quality-of-evidence paradigms exist, we chose one that has been internationally accepted and widely used for evaluating strength of data. This format will help the reader who desires to pursue more in-depth information on a particular topic. We have also asked each chapter author to highlight key points that are presented at the beginning of each chapter.

Clinical decision making represents collating the clinical circumstance, research evidence, and patient preference after learning alternative management strategies. Back in 1992, evidence-based medicine proponents focused on a new paradigm in which provision was made how to best utilize research in clinical correlation. We have requested all contributors to grade the strength of the study design and its implementation. This classification is as follows:

## Quality of evidence

- Ia Evidence obtained from meta-analysis of randomized controlled trials
- Ib Evidence obtained from at least one randomized controlled trial
- Ila Evidence obtained from at least one well-designed controlled study without randomization
- IIb Evidence obtained from at least one other type of well-designed quasi-experimental study
- III Evidence obtained from well-designed non-experimental descriptive studies, such as comparative studies, correlation studies, and case studies
- IV Evidence obtained from expert committee reports or opinions and/or clinical experience of respected authorities

## Strength of recommendation

- A At least one randomized controlled trial as part of a body of literature of overall good quality and consistency addressing the specific recommendation (Evidence levels Ia, Ib)
- B Well-controlled clinical studies available but no randomized clinical trials on the topic of recommendations (Evidence levels IIa, IIb, III)
- C Evidence obtained from expert committee reports or opinions and/or clinical experiences of respected authorities. Indicates an absence of directly applicable clinical studies of good quality (Evidence level IV)

Haynes RB: What kind of evidence is it that evidence-based medicine advocates want health care providers and consumers to pay attention to? <http://www.biomedcentral.com/1472-6963/2/3>. Accessed Feb. 8, 2004

We want to express our appreciation to the administrative and secretarial staff for the tireless effort in seeing the textbook to completion. We are indebted to Doreen Smith and Julie Cook among many individuals who were helpful in this regard. We would also like to thank Elsevier for their incredible effort in seeing this very large project from genesis to completion. Without their belief in the project we would be unable to produce this heavily illustrated text. Specifically, we would like to thank Dee Simpson, Todd Hummel, and Mary Stermel.

We hope for you, as the reader, that we have accomplished our goal of providing a single authoritative reference text for the broad area of gynecology. Significant effort has been put into making this the most visually interesting and distinct text available. We hope this aids you in managing your patients and con-

tinuing to be enthusiastic about providing them with the latest gynecologic care.

Happy reading and care providing!

## Osteoporosis

Tamara J. Vokes, MD, and Murray J. Favus, MD

### KEY POINTS

- Osteoporosis is asymptomatic until a fracture occurs; making the diagnosis and initiating treatment in the presymptomatic stage may prevent fractures.
- Measurement of bone mineral density (BMD) is a good but not perfect predictor of fractures; additional risk factors, such as previous fractures (particularly vertebral), family history of osteoporosis and fractures, and presence of other diseases or use of medications that affect bone, should be considered in assessing fracture risk and making therapeutic decisions.
- Secondary causes of osteoporosis (such as osteomalacia or hyperparathyroidism) should be considered in the evaluation of a patient with low BMD and fractures.
- Several effective therapies that improve BMD and reduce fracture risks are available; the choice of the drug should be individualized.
- The T-score is the number of standard deviations (SD) above or below the young adult mean. It is a better measure than the Z-score for predicting fracture risk.
- Pregnancy and lactation are associated with demineralization of the mother's skeleton, which is fully restored after weaning; consequently, multiparity is not a risk factor for osteoporosis.

### INTRODUCTION

Osteoporosis is a systemic skeletal disorder characterized by low bone mass and microarchitectural deterioration of bone tissue (Fig. 1-1), with a consequent increase in bone fragility and susceptibility to fracture.<sup>1</sup> The definition encompasses several essential characteristics of this disease: one is the susceptibility to fractures that occur at considerably lower levels of trauma in osteoporotic subjects than in those with normal bone. Although the typical osteoporotic fractures are those of the wrist, vertebrae, and hip, almost any fracture is dependent on the quantity and quality of bone.<sup>2,3</sup> The problem with the fracture-based definition of osteoporosis is that fractures occur relatively late in the course of the disease and have long-term consequences that are largely irreversible. This leads to recognition of the other aspect of osteoporosis that is captured by the current definition: the finding of low bone mass, which usually is present during the long asymptomatic phase of the disease. Introducing this concept into the definition and understanding of osteoporosis

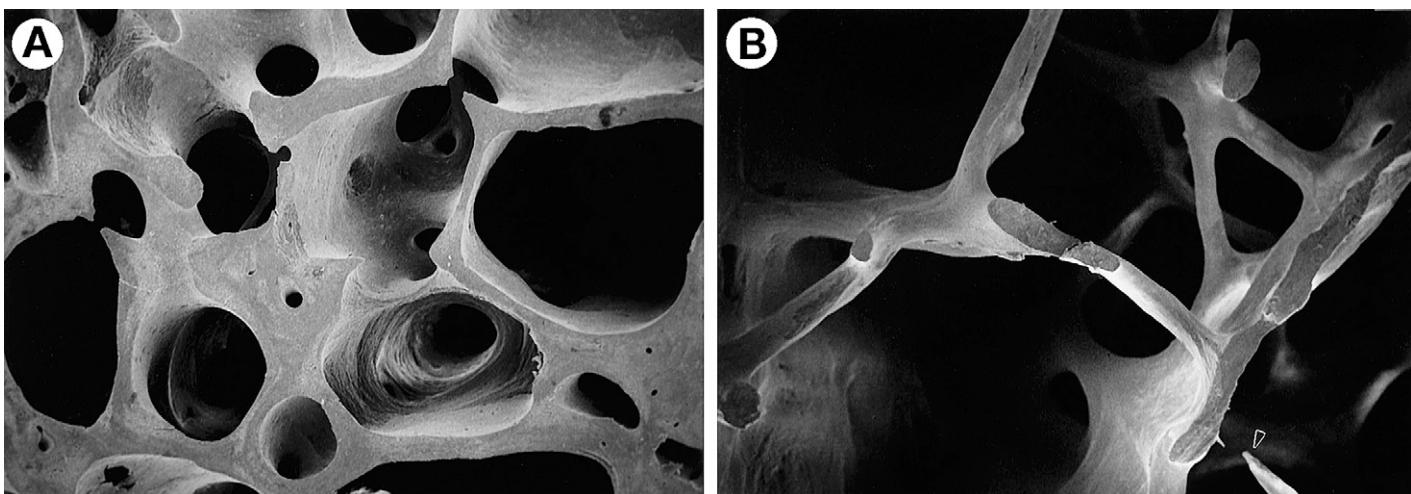

allows recognition of the disease before fracture occurs and the use of bone density-based diagnostic criteria for osteoporosis<sup>4</sup> (Table 1-1). The third aspect of the osteoporosis definition is the microarchitectural deterioration of bone tissue. Changes in bone microarchitecture cannot be assessed easily using currently available methods, yet represent an important aspect of this disease and an active area of research.<sup>5</sup>

The evolution of the human skeleton has resulted in bones that are light enough to allow adequate mobility and strong enough to avoid disabling fractures during the reproductive years. However, with advancing age in both sexes, and particularly after the menopause in women, bone becomes weaker and neuromuscular function declines. These changes produce a dramatic increase in the risk of fracture, which is the only symptom of osteoporosis. Osteoporotic fractures are a major public health problem as they are a significant cause of disability in the aging population and a major contributor to the cost of health care in many countries.<sup>6</sup>

### EPIDEMIOLOGY AND CLINICAL PRESENTATION

Osteoporosis is a common disease. Approximately 44 million persons in the United States have low bone mass, and the number is likely to increase substantially during the next several decades as the proportion of elderly people in the population increases.<sup>6</sup> It is estimated that a Caucasian woman aged 50 years has a 40% chance of having at least one of the typical osteoporotic fractures during her lifetime and a 70% chance if fractures other than spine, hip, and wrist are considered (such as pelvic, humeral, tibial, and other fractures). The probability of fracture in men is about one third that of women. Because women have a higher fracture risk and because they live longer, they account for 80% of all hip fractures. Osteoporosis occurs more frequently with increasing age as bone tissue is progressively lost. In women, there is accelerated bone loss after menopause such that most women meet the World Health Organization (WHO) bone density criteria for osteoporosis (see Table 1-1) by age 70 years.

Hip fractures are the most devastating and costly consequence of osteoporosis. Most hip fractures occur in individuals with reduced bone mass, after a fall from standing height or less. Most require hospitalization and surgical intervention, which are often associated with thromboembolic, cardiovascular, and infectious complications. The high rate of these complications is due at least in part to the advanced age of the subjects who sustain hip fractures. As a result, during the first year following

**Figure 1-1 Scanning electron micrographs of normal (A) and osteoporotic (B) cancellous bone from human iliac crest.** Note that the osteoporotic bone has both lower mass and altered bone microarchitecture. (From Dempster DW: The contribution of trabecular architecture to cancellous bone quality. *J Bone Miner Res* 2000;15:20–23. Reproduced with permission from the American Society for Bone and Mineral Research.)

hip fractures there is an increase in mortality of about 36% in men and 21% in women, greater in older men and in persons with higher level of comorbidities or declining cognitive function. In those who survive, there is often residual disability or decline in functional status, resulting in loss of independence that necessitates nursing home admission in almost 50% of patients. The degree of functional recovery is inversely proportionate to age and prefracture functional status.

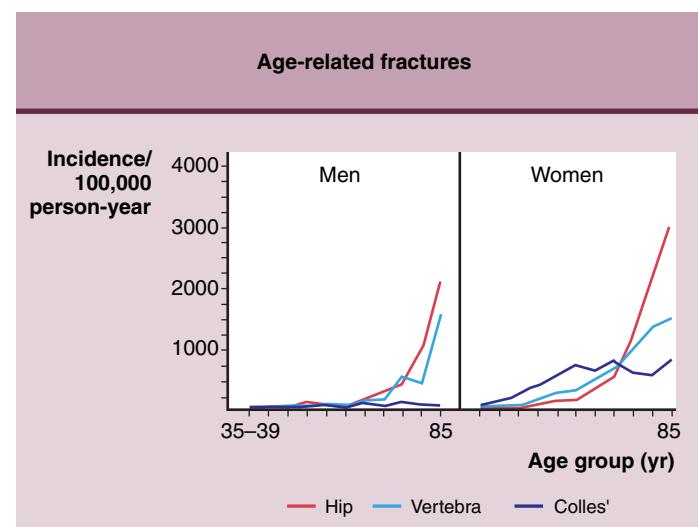

The incidence of hip fractures increases exponentially with age<sup>6</sup> (Fig. 1-2). Worldwide, an estimated 1.66 million hip fractures occurred in 1990. In the United States, about 300,000 hip fractures occur annually, most of which require hospital admission and surgical intervention. The current cost resulting from hip fractures is more than \$11.5 billion per year in the United States alone. There is significant geographic variation in the rates of hip fractures (Fig. 1-3). In addition, the rates are higher in urban than in rural areas, probably because urbanization results in decline in physical activity and because change from softer ground to hardwood, tile, concrete, and asphalt surfaces

increases the impact of falling. The rates of hip fracture are increasing worldwide, because of the aging population and because of an absolute increase in age-adjusted hip fracture rates.<sup>7</sup> The most likely explanation for this is a decline in physical activity and possibly increased frailty of the aging population.

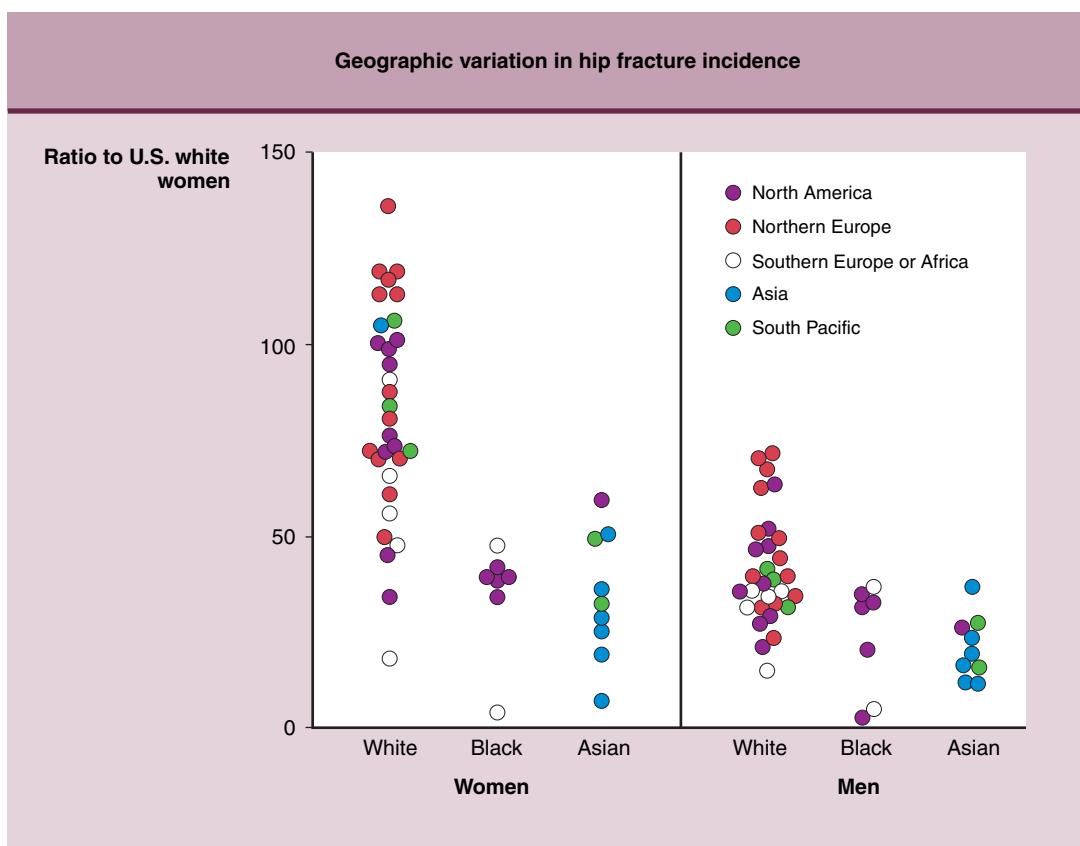

Vertebral fractures usually occur in the course of routine daily activities, with only one quarter resulting from a fall. Although approximately 500,000 vertebral fractures occur each year in the United States, most are asymptomatic; only about one third of fractures that are found on radiographs come to medical attention and less than 10% require hospital admission. Interestingly, even when a vertebral fracture is present on the

Table 1-1 WHO Definition of Osteoporosis Based on BMD Measurement		
Category	Defined as BMD That Is	T-Score
Normal	No more than 1 SD below the young adult mean	>-1
Osteopenia	Between 1 and 2.5 SD below the young adult mean	-1 to -2.5
Osteoporosis	More than 2.5 SD below the young adult mean	<-2.5
Severe (established) osteoporosis	More than 2.5 SD below the young adult mean and at least one fragility fracture	<-2.5

**Figure 1-2 Age-specific incident rates for hip, vertebral, and distal forearm fractures in men and women.** (From Melton LJ: Epidemiology of fractures. In Riggs BL, Melton LJ [eds]: Osteoporosis: Etiology, Diagnosis and Management. New York, Raven Press, 1988, pp 133–154.)

**Figure 1-3 Geographic variation in hip fracture incidence.** (From Melton LJ III: Differing patterns of osteoporosis across the world. In Chesnut CH III [ed]: New dimensions in osteoporosis in the 1990s—proceedings of the Second Asian Symposium on Osteoporosis, Nov 10, 1990. Hong Kong, Asia Pacific Congress Series No. 125, Excerpta Medica, 1991, pp 13–18.)

radiograph it often is not mentioned by the radiologist, is not noted in the chart, and does not lead to diagnosis or treatment of osteoporosis. Although vertebral fractures are often undiagnosed, they are commonly associated with significant morbidity and increased mortality.<sup>8</sup> Multiple fractures lead to height loss and kyphosis, chronic pain resulting from altered biomechanics of the kyphotic back, restrictive lung disease resulting from decreased thoracic cavity, and digestive complaints of early satiety, gastroesophageal reflux, and constipation resulting from decreased volume of the abdominal cavity<sup>8</sup> (Fig. 1-4). Vertebral fractures should be suspected in older people with kyphosis or height loss of at least 4 to 5 cm (1.5 to 2 in.), changes that many patients and physicians fail to recognize as a sign of disease and erroneously attribute to effects of aging. Although often asymptomatic, vertebral fractures are associated with a significant risk of additional vertebral and nonvertebral fractures.<sup>8,9</sup>

Because vertebral fractures are often asymptomatic, their epidemiology is less clear than that of hip fractures. In addition, studies of prevalence of radiographic vertebral fractures have been complicated by lack of consensus about what constitutes a vertebral fracture. It is clear, nevertheless, that the incidence of vertebral fractures increases with age, with the curve being steeper in women (see Fig. 1-2). Although the risk of vertebral fractures is about three times higher in women over age 65, the prevalence is similar in men and women aged 50 to 60 years,

possibly reflecting a higher risk of traumatic vertebral fractures in younger men as a result of greater occupational and recreational physical activity. There is less geographic variability in the risk of vertebral fractures compared with hip fractures.<sup>6</sup>

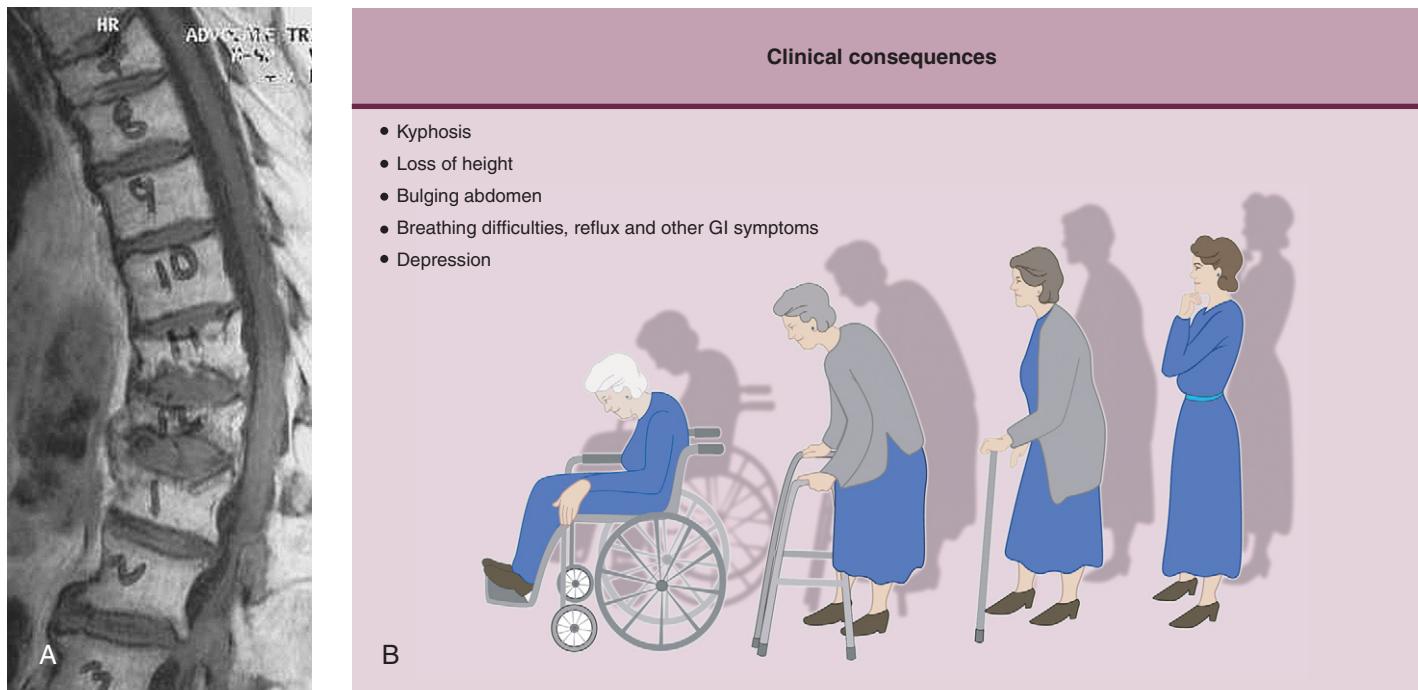

Distal forearm fractures almost always follow a fall on the outstretched arm. Because this pattern of falling is seen in younger people (in comparison with the elderly, who tend to fall to the side or backward and sustain a hip fracture), the peak incidence of these fractures in Caucasian women is between ages 40 and 65 (see Fig. 1-2). The main importance of wrist fracture is that it often is a first manifestation of osteoporosis, which should prompt appropriate evaluation and therapy.

### Risk Factors

Many conditions increase the risk of fracture by either causing decreased bone mass or increasing the risk of falling (Table 1-2). Among these, the most significant are the history of fracture as an adult, maternal history of hip fracture (or other fractures), cigarette smoking, and low body weight (below 58.5 kg [129 lb]).<sup>10</sup>

### PATHOGENESIS

Osteoporosis or low bone mass can result from inadequate accumulation of bone in young adulthood (low peak bone mass)

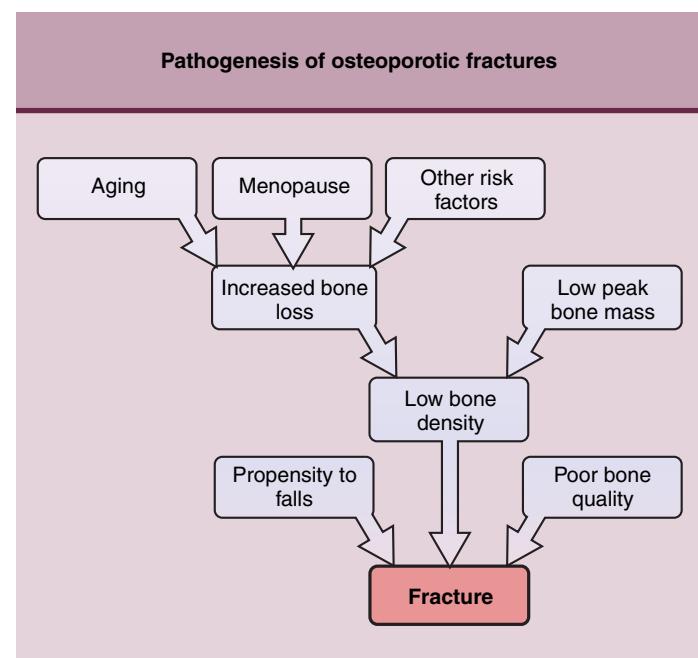

**Figure 1-4 Vertebral fractures.** A, MRI of the thoracic and lumbar spine showing multiple vertebral fractures (T7, T11, T12, L1, and L2). B, Clinical consequences of vertebral fractures. (B, From Gallagher JC, Hedlund LR, Stone S, et al: Vertebral morphometry: normative data. Bone Miner 1988;4:189–196.)

or excessive bone loss later in life<sup>11,12</sup> (Fig. 1-5). The increase in bone mass that occurs during childhood and puberty results from a combination of bone growth at the endplates (endochondral bone formation) and change in bone shape (modeling). The rapid increase in bone mass during puberty associated with an increase in sex hormone levels continues for 3 to 4 years and

then slows down with the closure of growth plates. Further increase in BMD in the next several years is relatively modest and the consequence of periosteal apposition (modeling). The peak bone mass is achieved by age 20 to 30 and is greater in men than in women and greater in African American than in Caucasian, Asian, or Hispanic populations. Genetic factors are

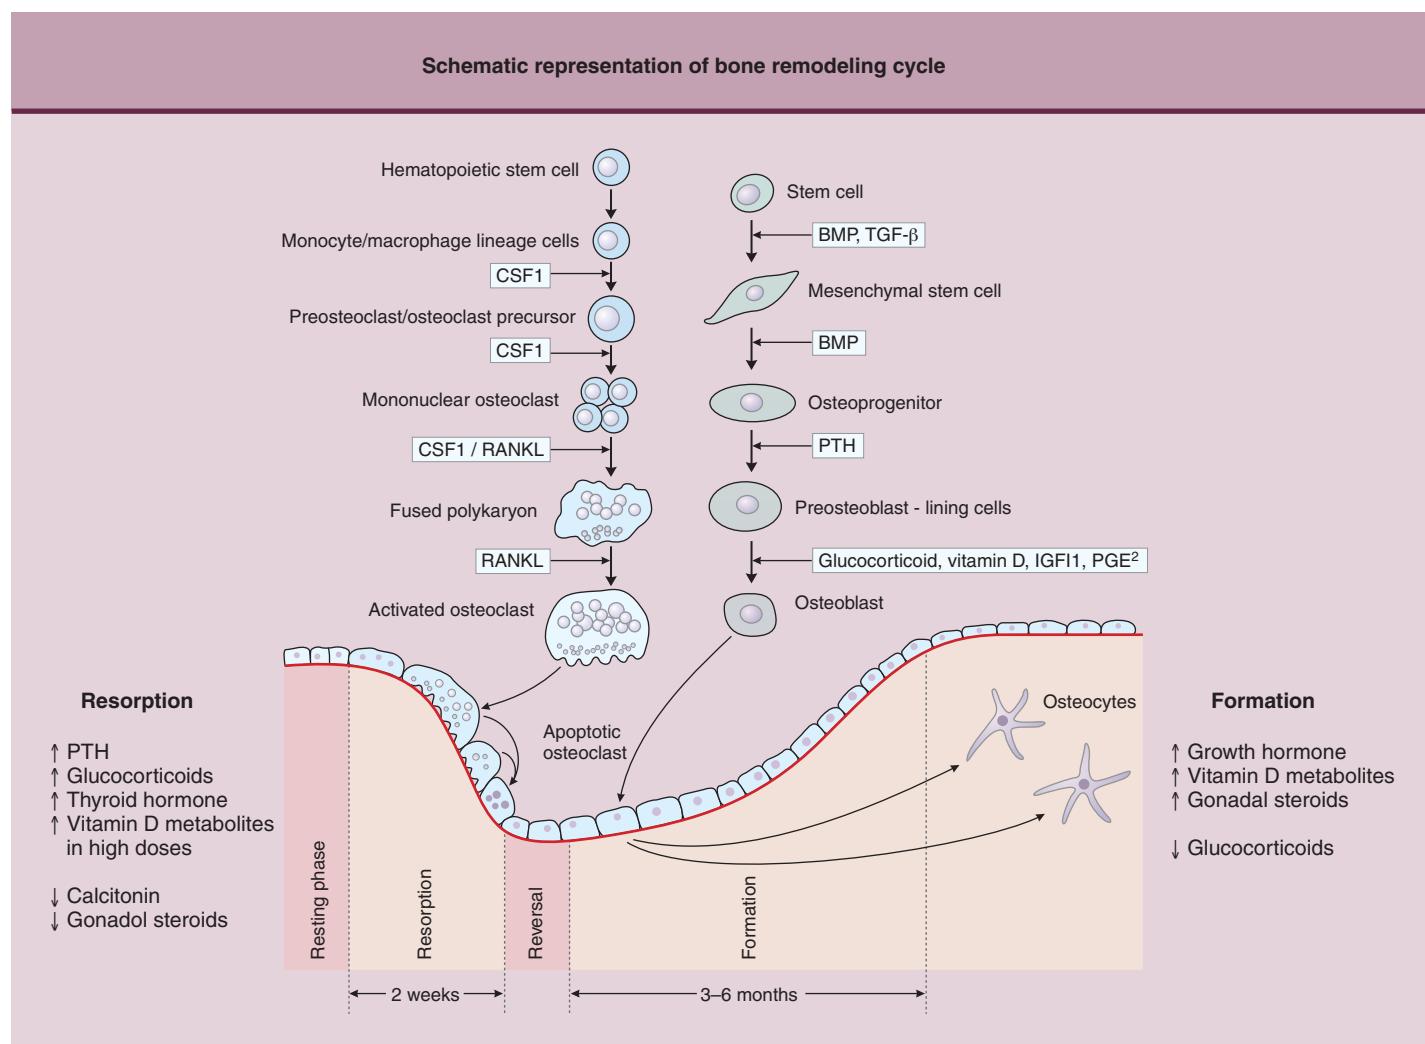

**Figure 1-5 Pathogenesis of osteoporotic fractures.**

the main determinants of peak bone mass and account for 50% to 85% of the variance in bone density and size. It is likely that several genes regulate bone mass, each with modest effect. Nongenetic factors associated with low peak bone mass include low calcium intake during childhood, low body weight, sedentary lifestyle, chronic disease, and delayed puberty.

After the peak bone mass is attained, further changes in bone, including bone loss associated with aging and menopause, are determined by bone remodeling (Fig. 1-6). Bone remodeling is responsible for repair of microdamage of bone, maintenance of skeletal strength, and supply of calcium from the skeleton when needed to maintain normal serum calcium. Bone remodeling involves osteoclast-mediated bone resorption followed by

osteoblastic bone formation. The initial stimulus is often a micro-crack, which leads to *activation*—recruitment and fusion of osteoclast precursors into mature osteoclast. The mature osteoclast then attaches to the bone surface by binding with the ruffled border. *Resorption* of bone trapped by the osteoclast produces a cutting cone (cortical bone) or a trench (trabecular bone). Bone resorption is followed by *bone formation*, the process during which osteoblasts synthesize bone matrix that subsequently mineralizes. After the matrix fills a resorption cavity, osteoblasts remain trapped in the bone and become osteocytes. The latter are believed to be responsible for mechanotransduction and bone response to mechanical loading. While the process of osteoclastic bone resorption of a single

**Figure 1-6 Bone remodeling.** Note that the resorption phase lasts approximately 2 weeks, whereas the formation phase requires 3 to 6 months for completion. As a result, conditions associated with increased bone turnover often result in a net loss of bone. Osteoclast is a tissue-specific macrophage polykaryon created by the differentiation of the monocyte/macrophage precursor cells at or near bone surface. One of the main physiologic regulators of osteoclast differentiation and function is RANKL, which binds to RANK on the surface of the osteoclast and its precursors. RANKL is transmembrane protein expressed on osteoblasts, which also produce a soluble factor osteoprotegerin (OPG), which acts as a decoy receptor for RANKL and decreases osteoclast-mediated bone resorption. OPG is under investigation as a possible pharmacologic agent for treatment of osteoporosis. BMP, bone morphogenic protein; CSF, colony stimulating factor; IGF-I, insulin-like growth factor-I; PGE<sub>2</sub>, prostaglandin E<sub>2</sub>; PTH, parathyroid hormone; RANKL, receptor activator of nuclear factor kappaB ligand; TGF-β, transforming growth factor-β.

cavity usually takes approximately 2 weeks, osteoblastic bone formation requires 3 to 6 months to fill in a resorption pit. Consequently, any physiologic or pathologic process (such as decrease in estrogen level during menopause) that increases activation frequency (rate of initiation of new bone remodeling cycle) results in a net loss of bone. Numerous circulating or locally produced factors influence bone remodeling (see Fig. 1-6). Imbalance in bone remodeling, i.e., greater resorption than formation, results in bone loss. This manifests as increased cortical porosity in cortical bone and perforation of trabecular plates in trabecular bone. These processes greatly diminish the biomechanical competence of the aging skeleton. Multiple diseases and medications are associated with these processes (Table 1-3). Therapeutic agents used to treat osteoporosis act primarily by either decreasing bone resorption ("antiresorptive agents") or increasing bone formation ("anabolic agents").

## DIAGNOSIS

Because osteoporosis is largely asymptomatic, it is necessary to diagnose bone fragility before fractures occur. This can be approached through assessment of bone mass (widely used in clinical practice and in research), assessment of bone structure (used only in research), and assessment of bone turnover (widely used in research, beginning to be used in clinical practice).

### Assessment of Bone Mass

Currently available methods used to assess bone mass can be grouped according to the site scanned or the scanning method used (Table 1-4). There are multiple indications to assess bone mass, which continue to be reevaluated on the basis of new information and studies (Table 1-5).

The standard method used for assessment of bone mass in both clinical practice and the research setting is dual energy x-ray absorptiometry (DXA) of the central sites, i.e., lumbar spine and proximal femur.<sup>13,14</sup> Measuring bone mass at peripheral sites such as distal radius, calcaneus, and phalanges are widely available and less costly.<sup>13</sup> Although peripheral measurements can be used for assessment of fracture risks in population studies, their use in making a diagnosis of osteoporosis in an individual is problematic because their fracture prediction ability is lower than that of central BMD and because the proportion of patients with T-score less than -2.5 varies considerably from one type of device to another (Fig. 1-7).<sup>15</sup> Peripheral measurements are best used as screening tools to identify patients who are unlikely to have osteoporosis at central sites or increased fragility. To properly select patients who do not need further testing by central densitometry device, specific cut-off points should be established for each device. It should be noted, however, that subjects with significant risk factors such as chronic corticosteroid therapy or history of fractures, should have central densitometry regardless of the results of peripheral testing. Because of lower precision and lack of adequate prospective data, peripheral measurements should not be used for monitoring therapy.<sup>16</sup>

Quantitative computed tomography (CT) scans of the spine can also be used for assessing bone mass.<sup>13</sup> The advantage of CT scans is that they are three-dimensional, permitting a separate assessment of trabecular and cortical bone. In addition, arthritic

**According to method**

DXA (spine, hip, heel, forearm)  
Ultrasound (heel)  
qCT—quantitative CT (spine, radius)  
Radio-absorptiometry (phalanges)

changes of the spine, which falsely elevate DXA, do not affect CT measurement. The disadvantages of CT include high cost and high radiation exposure, and its ability to predict fracture is not well studied. Applying WHO BMD criteria for osteopenia and osteoporosis to CT measurements leads to a tendency to overdiagnose osteoporosis in younger women. All the difficulties associated with CT measurements largely limit its application to that of a research tool. When CT measurements are used in clinical practice, care should be taken that WHO criteria are not strictly applied.

Numerous studies have documented a strong inverse relationship between fracture risk and central, particularly hip, BMD, making DXA measurement the gold standard for assessing bone mass and predicting fracture risk (Table 1-6).<sup>13,14</sup> BMD is measured at the lumbar spine and proximal femur.

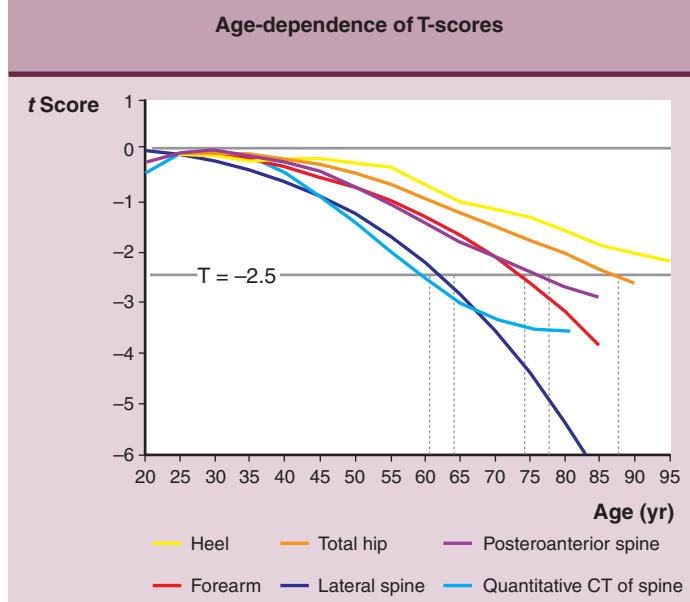

Spine DXA measures BMD of the L1–L4 vertebrae. Since vertebrae are composed primarily of metabolically active trabecular bone, this site is more likely to show the earliest

**Table 1-5****Indications for Bone Mineral Density Testing\*†**

- Women aged 65 and older
- Postmenopausal women under age 65 with risk factors
- Men aged 70 and older
- Adults with a fragility fracture
- Adults with a disease or condition associated with low bone mass or bone loss
- Adults taking medications associated with low bone mass or bone loss
- Anyone being considered for pharmacologic therapy for bone loss
- Anyone being treated for bone loss, to monitor treatment effect
- Anyone not receiving therapy in whom evidence of bone loss would lead to treatment

\*Women discontinuing estrogen should be considered for bone density testing according to the indications listed in the table.

† As recommended by International Society for Clinical Densitometry (ISCD), 2003 consensus conference.<sup>16</sup>

**Figure 1-7 Prevalence of osteoporosis, defined as T-score of  $-2.5$  and below, depends on the site and technique used to assess bone mass.**

(From Faulkner KG, von Stetten E, Miller P: Discordance in patient classification using T-scores. J Clin Densitom 1999;2:343–350.)

**Table 1-6****Use of Central DXA for Diagnosis of Osteoporosis\*****Skeletal sites to measure**

Measure BMD at both posteroanterior spine and hip in all patients  
Forearm BMD should be measured under the following circumstances:  
Hip or spine cannot be measured or interpreted  
Patient has hyperparathyroidism  
Very obese patient (over weight limit for DXA table)

**Spine region of interest**

Use posteroanterior L1–L4 for spine BMD measurement  
Use all evaluable vertebrae and exclude only vertebrae affected by local structural change or artifact; use three vertebrae if four cannot be used, and two if three cannot be used  
Lateral spine should not be used for diagnosis, but may have a role in monitoring

**Hip region of interest**

Use total proximal femur, femoral neck, or trochanter, whichever is lowest  
BMD may be measured at either hip  
Do not use Ward's area for diagnosis  
There are insufficient data to determine whether mean T-scores for bilateral hip BMD can be used for diagnosis  
The mean hip BMD can be used for monitoring, with total hip being preferred

**Forearm region of interest**

Use 33% radius (sometimes called one-third radius) of the nondominant forearm for diagnosis  
Other forearm regions of interest are not recommended

BMD, bone mineral density; DXA, dual energy x-ray absorptiometry.

\*As recommended by International Society for Clinical Densitometry (ISCD), 2003 consensus conference.<sup>16</sup>

The proximal femur (hip) is composed of more cortical bone than the spine is, and it is less likely to show large changes with therapy. Since hip BMD is not affected by the artifacts that may affect spine BMD, it may be a more reliable site for measuring BMD in patients over 65 years of age. Bone density of the hip is the best predictor of the risk of hip fractures and indeed of overall fracture risk.<sup>13,14</sup> Several regions of interest of the proximal femur can be used for diagnosis (see Table 1-6).<sup>16</sup>

For each patient, BMD is compared with two sets of normative data. First, it is compared with BMD obtained in the healthy young adult Caucasian population, which yields a T-score (the number of standard deviations above or below the young adult mean). The T-score is used for diagnosing osteopenia and osteoporosis because it is the best predictor of fracture risk. The second comparison is to age, race, and sex-matched population and is the basis for calculating the Z-score (the number of standard deviations above or below the mean of age, race, and sex-matched population). While a low Z-score (below -1.5 or -2) is thought to suggest the presence of secondary causes of osteoporosis, no studies support that belief.

WHO criteria for diagnosing osteoporosis and osteopenia based on BMD measurements (see Table 1-1) is applicable only to postmenopausal women (see Table 1-7 for BMD interpretation in other populations<sup>16</sup>). In premenopausal women with low bone mass, particularly if associated with fracture, a thorough search for secondary causes should be undertaken.

### Assessing Non-Bone Mineral Density Aspects of Fragility

BMD accounts for 85% of fracture risk in population studies, and in vitro biomechanical testing confirms the importance of bone mass in determining bone strength. However, BMD is not the sole predictor of fragility, as evidenced by a large overlap in BMD values between subjects with and without fractures (Fig. 1-8). Among the non-BMD factors that predict fragility, the paramount variable is age (Fig. 1-9): at any level of BMD, fracture risk is considerably higher in older subjects.<sup>17</sup>

Vertebral fractures, and to a lesser degree other low trauma fractures, also strongly predict future fractures.<sup>2,9</sup> Although vertebral fractures herald future fractures, they often are asymptomatic and require radiographs for detection. However, radiographs usually are not a part of standard patient evaluation for osteoporosis. Recently, imaging of the thoracic and lumbar spine has become possible using the same DXA equipment used for measuring BMD (Fig. 1-10). With this methodology, termed vertebral fracture assessment (VFA), detection of vertebral fractures and measurement of BMD is possible at the same visit.<sup>18</sup> The presence of atraumatic vertebral fractures, even in a patient who does not have BMD criteria for osteoporosis, is considered diagnostic of osteoporosis and should prompt a more aggressive evaluation and treatment.

### Assessment of Bone Structure

Assessment of bone structure is not available clinically at present but has significant potential as a tool for determining non-BMD aspects of bone fragility. The methods under development include three-dimensional evaluations using magnetic resonance imaging (MRI) and micro-CT, and two-dimensional techniques such as fractal analysis of bone radiographs.<sup>5</sup>

**Table 1-7**  
**Definition of T-Scores and Diagnosis of Osteoporosis in Various Populations\***

#### Reference database for T-scores

Use a uniform Caucasian (non-race-adjusted) female normative database for women of all ethnic groups  
Use a uniform Caucasian (non-race-adjusted) male normative database for men of all ethnic groups

#### Diagnosis in postmenopausal women

Use the WHO criteria (normal, T-score -1.0 or above; osteoporosis, T-score -2.5 or below; osteopenia, t score between -1.0 and -2.5)  
Select the lowest T-score of posteroanterior spine, femoral neck, total hip, trochanter, or the 33% radius, if measured

#### Diagnosis in men (aged 20 yr and older)

The WHO criteria should not be applied in their entirety to men  
In men aged 65 yr and older, T-scores should be used and osteoporosis diagnosed if the T-score is at or below -2.5  
Between ages 50 and 65 yr, T-scores may be used and osteoporosis diagnosed if the T-score is at or below -2.5 and other risk factors for fracture are identified  
Men at any age with secondary causes of low BMD (e.g., glucocorticoid therapy, hypogonadism, hyperparathyroidism) may be diagnosed clinically with osteoporosis supported by findings of low BMD  
The diagnosis of osteoporosis in men under age 50 yr should not be made on the basis of densitometric criteria alone

#### Diagnosis in premenopausal women (aged 20 yr to menopause)

The WHO criteria should not be applied to healthy premenopausal women  
Z-scores rather than T-scores should be used  
Osteoporosis may be diagnosed if there is low BMD with secondary causes (e.g., glucocorticoid therapy, hypogonadism, hyperparathyroidism) or with risk factors for fracture  
The diagnosis of osteoporosis in premenopausal women should not be made on the basis of densitometric criteria alone

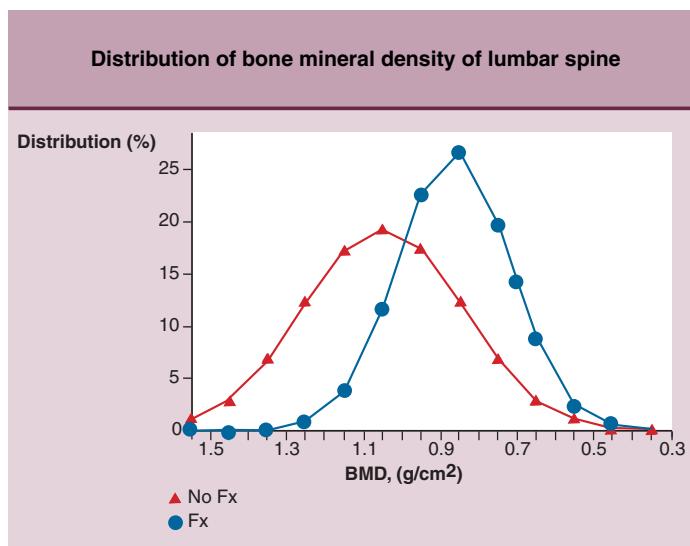

#### Diagnosis in children (male or female < aged 20 yr)

T-scores should not be used in children; Z-scores should be used instead  
T-scores should not appear in reports or on DXA printouts in children  
The diagnosis of osteoporosis in children should not be made on the basis of densitometric criteria alone  
Terminology such as low bone density for chronologic age may be used if the Z-score is below -2.0  
Z-scores must be interpreted in light of the best available pediatric databases of age-matched controls; the reference database should be cited in the report  
Spine and total body are the preferred skeletal sites for measurement  
The value of BMD to predict fractures in children is not clearly determined  
There is no agreement on standards for adjusting BMD or bone mineral content (BMC) for factors such as bone size, pubertal stage, skeletal maturity, and body composition; if adjustments are made, they should be clearly stated in the report  
Serial BMD studies should be done on the same machine using the same scanning mode, software, and analysis method when appropriate; changes may be required with growth of the child  
Any deviation from standard adult acquisition protocols, such as use of low-density software and manual adjustment of region of interest, should be stated in the report

\*As recommended by International Society for Clinical Densitometry (ISCD), 2003 consensus conference.<sup>16</sup>

### Biochemical Markers of Bone Turnover

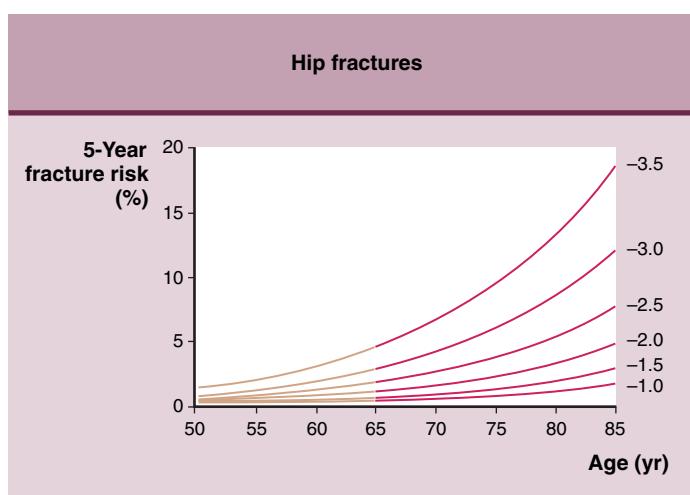

Biochemical markers of bone turnover also assess non-BMD aspects of bone fragility.<sup>19</sup> Currently available markers of bone formation and resorption are listed in Table 1-8. Because bone formation and resorption usually are coupled, measuring any

**Figure 1-8** Distribution of bone mineral density (BMD) of the lumbar spine in women with and without vertebral fractures. (From Melton LJ III, Kan SH, Frye MA, et al: Epidemiology of vertebral fractures in women. Am J Epidemiol 1989;129:1000–1011.)

Rights were not granted to include this figure in electronic media.  
Please refer to the printed publication.

marker is likely to yield similar information. In epidemiologic studies, markers of bone resorption are more consistent predictors of future fractures. Biochemical markers of bone turnover may be useful in clinical evaluation of osteoporosis as a way of predicting fracture risk. Thus, subjects with high markers of bone resorption have higher fracture risk than those with similar BMD and low levels of bone markers (Fig. 1-11). Although widely used in research, biochemical markers are of limited use in clinical practice at present because of relatively

**Figure 1-9** Five-year risk of hip fractures as a function of age and bone mineral density (BMD). Note that at any level of BMD, the fracture risk is considerably higher in older than in younger subjects. The hip fracture risk for women over age 65 is observed in Study of Osteoporotic Fractures (SOF), which included women over age 65 only. The fracture risk in younger women is extrapolated. (From Cummings SR, Bates D, Black DM: Clinical use of bone densitometry: scientific review. JAMA 2002;288:1889–1897.)

high analytical and biological variability and the lack of guidelines regarding the selection of markers and their practical application. The potential application of bone markers is in patients who have borderline BMD values in whom finding a high marker will prompt a therapeutic intervention. Bone markers are also used to assess response to therapy. Changes in bone markers during therapy predict subsequent increase in bone density and reduction in fracture rate. In the future, it also may be possible to use biochemical markers of bone turnover to select therapeutic agents that either reduce bone resorption or stimulate bone formation.

#### Monitoring Changes in Bone Status

BMD can be used to monitor bone loss in early menopause, during corticosteroid therapy, or in the course of diseases that may have detrimental effects on bone. Increased bone mass occurs in response to osteoporosis therapy, during the resolution

of a disease, and upon discontinuing medications associated with bone loss. The frequency with which bone density testing should be repeated depends on the expected rate of change in bone mass and the precision of the DXA instrument.<sup>16</sup> The “least significant change,” which is the smallest difference between two measurements that can be considered a true change with 95% confidence, is calculated as 2.7 (approximated to 3) times the precision error of the measurement. Since the precision of the lumbar spine BMD measurement is 1%, the least significant change is 3%. Hip precision of 1.5% requires the least significant change to be greater than 4.5% to 5%. On the basis of this information, bone density can be repeated every 1 to 2 years in early menopause, when the rate of bone loss is the greatest. In

late menopause, the time between two BMD measurements should be at least 2 years. Corticosteroid therapy induces rapid bone loss during the first 6 months of therapy, which can be monitored by repeating BMD at 6 to 12 months after long-term treatment is begun, and yearly thereafter. Pharmacologic treatment of osteoporosis can be monitored by repeating BMD 1 year after the initiation of therapy and every 2 years thereafter. Stable or increased BMD, greater than the least significant change, indicates a satisfactory response to therapy. A decrease in BMD greater than the least significant change should prompt a search for secondary causes, particularly if this was not done prior to initiation of therapy, and a reassessment of the patient’s compliance, including adequate intake of calcium and vitamin D.

**Routine Laboratory Evaluation and Workup  
for Secondary Causes of Osteoporosis**

No laboratory abnormalities are diagnostic of postmenopausal osteoporosis. However, laboratory evaluation might be helpful in determining whether the patient has secondary causes of osteoporosis, i.e., conditions other than age and menopause that contribute to bone loss. There are no clear guidelines regarding screening for secondary causes of osteoporosis, primarily because there is relatively little information regarding the proportion of patients with osteoporosis who have evidence of secondary causes.<sup>20</sup> In a study from a tertiary referral center in Canada,<sup>21</sup> more than half of patients with a T-score less than -2.5 had a history of diseases or medications contributing to bone loss (Table 1-9). Among the 173 women with no history of any bone-related disorder or medication, more than 30% were found to have secondary causes on laboratory testing (see Table 1-9). Interestingly, there was no significant difference in T-scores or Z-scores between patients with and without secondary causes. The authors of that study concluded that the most cost-effective approach is to measure 24-hour urine calcium, serum calcium, and parathyroid hormone (PTH) in all patients and thyroid-stimulating hormone (TSH) in those receiving exogenous thyroid hormone. It is also reasonable to obtain a chemistry panel, looking for evidence of renal or hepatic disease or elevation of alkaline phosphatase. Low urinary calcium suggests deficient intake or absorption of calcium or vitamin D. Idiopathic hypercalciuria and primary hyperparathyroidism both are associated with high urinary calcium, and can be differentiated by serum calcium and PTH, which are normal in the former disease and elevated in the latter. In all patients with elevated PTH, renal function should be assessed to exclude renal insufficiency and accompanying secondary hyperparathyroidism and renal osteodystrophy.

While some secondary causes of low bone mass explain low BMD, other causes have important therapeutic implications. For example, osteomalacia often presents with low BMD and fractures. Osteomalacia results from vitamin D deficiency, which decreases calcium absorption and induces secondary hyperparathyroidism, which in turn increases excretion of phosphate and decreases excretion of calcium in the urine. Consequently, hypophosphatemia is more common than hypocalcemia, which is seen only in advanced cases. High PTH increases bone turnover, which raises serum alkaline phosphatase, particularly its bone fraction, which is normal in postmenopausal osteoporosis.

**Figure 1-11** Hip fracture risk is better assessed by a combination of bone mineral density (BMD) and bone resorption rate in a cohort of elderly (mean age, 82.5 years) French women. Low BMD was defined by a value below 2.5 SD of the young adult mean and high bone resorption by urinary CTx values above 2.0 SD of the young adult mean. CTx, C-terminal telopeptide of type I collagen.

Osteomalacia requires treatment with calcium and vitamin D to normalize bone mass and structure. Importantly, the ensuing increase in BMD is far greater than observed with antiresorptive therapy in osteoporosis. Use of potent antiresorptive agents such as bisphosphonates is contraindicated in osteomalacia and may result in severe hypocalcemia caused by inhibition of osteoclastic bone resorption, which previously had maintained eucalcemia in the face of deficient intestinal absorption.

Idiopathic hypercalciuria is also important to detect because it may explain in part the low BMD and because it requires a different therapeutic approach. Calcium intake should be limited to 600 to 800 mg/day (rather than the 1500 recommended for postmenopausal women) and be supplied by food. Higher intake of calcium, particularly if obtained from calcium supplements, aggravates hypercalciuria and increases risk of kidney stones. On the other hand, severe restriction in calcium intake (as was recommended in the past to patients with kidney stones) does not eliminate hypercalciuria but increases calcium recruitment from bone, resulting in further bone loss. Hypercalciuria may be controlled by administration of thiazide diuretics, particularly the longer acting chlorthalidone.

## TREATMENT

### Lifestyle Changes

The goal of treating osteoporosis is prevention of fractures. Since most fractures are associated with trauma, it is important to prevent falls by adapting the environment (removing loose carpeting, cables, and other objects that increase the risk of falling), avoiding medication that is associated with orthostatic hypotension or sedation, and correcting visual problems. Smoking and excessive alcohol intake should also be discouraged.<sup>10</sup>

### Nutritional Recommendations

Adequate calcium intake is a necessary part of the treatment plan for all patients with osteoporosis and for postmenopausal women and other patients at risk of developing osteoporosis. Recommended calcium intake is a 1000 mg/day for premenopausal women and 1200 to 1500 mg/day for postmenopausal women.<sup>10</sup> Calcium can be taken from food or from calcium supplements (Table 1-10). It is important to limit the amount of elemental calcium taken at one time to no more than 600 mg, since the calcium absorption fraction decreases with higher doses. Calcium supplements are best taken with food, particularly in the case of calcium carbonate, which requires an acid environment for the dissociation of calcium from carbonate and for its absorption. For this reason, patients who take proton pump inhibitors or have low gastric acid production should receive calcium citrate. Calcium citrate may be also preferable for patients who are prone to constipation, which tends to worsen with carbonate preparations.

Vitamin D, which is necessary for intestinal calcium absorption, is synthesized in the skin under the influence of ultraviolet light. Vitamin D insufficiency is common particularly among the elderly and in those living in northern latitudes. Because few food sources contain a significant amount of vitamin D, it often is necessary to use vitamin D supplementation at the recommended dose of 200 IU for adults less than 50 years of age, 400 IU for adults between 50 and 70 years of age, and 600 to 800 IU for adults over 70 years of age. A multivitamin tablet usually contains 200 to 400 units, as do many calcium supplements. Patients who have very low serum levels of 25-OH-vitamin D should be treated with high vitamin D doses (50,000 IU/wk) until the deficiency is corrected. In the frail elderly, it also is important to provide adequate caloric and protein intake. Caffeine and salt intake should be limited because they increase urinary calcium excretion.

### Exercise

By itself, exercise can not maintain or increase bone mass in postmenopausal women. However, regular physical activity should be a part of the therapeutic approach because it is beneficial to patients with osteoporosis.<sup>11,12</sup> Since gravity enhances bone formation, weight-bearing exercise (e.g., walking, dancing, cross country skiing) is thought to decrease bone loss in the elderly and promote maintenance of peak bone mass in younger subjects. In addition, exercise improves muscle strength and coordination, thereby decreasing the risk of falling and minimizing the severity of injury upon a fall. Even for those who cannot walk, swimming and water exercise are beneficial for improving muscle function. Exercising at least three times a week should be a consistent and long-term habit.

Table 1-10 Calcium Content of Food and Supplements		
Calcium Content of Some Common Food Items		
Food	Portion	Amount of Calcium (mg)
<b>Milk and milk products</b>

<b>Calcium citrate</b>		
Citracal	950	200
Citracal Caplets + D	1500	315 + 200 IU vitamin D

Hip protectors decrease the risk of hip fractures and should be recommended to all frail elderly subjects who are at high risk of hip fracture.<sup>22</sup>

### Pharmacologic Therapies

Selection of patients for pharmacologic therapy should be based on their risk of fracture and the efficacy of the proposed therapy. National Osteoporosis Foundation (NOF) guidelines recommend pharmacologic therapy in postmenopausal women based on BMD measurement, as follows: initiate therapy if the T-score is below -2.0 by hip DXA with no risk factors, if the T-score is below -1.5 by hip DXA with one or more risk factors, or if there is a prior vertebral or hip fracture.<sup>10</sup> The most important risk factors are chronic corticosteroid therapy, older age, history of osteoporotic fracture in a first-degree relative, personal history of fracture as an adult, smoking, and low body weight. The best time to start therapy is a subject of debate. Because age is an independent risk factor for fractures, the short-term risk of fractures is considerably higher in older than in younger subjects at any level of BMD. Consequently, treatment is likely to result in greater appreciable short-term fracture reduction in older subjects. Younger postmenopausal women with low bone density do not need to be treated urgently because their immediate fracture risk is low. However, because they have a higher lifetime risk of fractures and many more years during which further bone loss may occur, intervention that would prevent bone loss is warranted at some point. Patients with high markers of bone resorption also have an increased fracture risk and may be considered for antiresorptive therapy at higher BMD levels (T-score -1.5).

Pharmacologic agents used to treat osteoporosis (Table 1-11) can be classified based on their mechanism of action as anti-resorptive or anabolic agents.<sup>23</sup> The former reduce fractures by inhibiting bone resorption, which usually is increased in postmenopausal osteoporosis. They produce modest increases in the measured BMD, primarily by promoting greater mineralization of existing bone. The only currently available anabolic agent is 1-34 fragment of human PTH (teriparatide), which stimulates bone formation and increases bone size. Despite the difference in their mechanism of action, the antifracture efficacy of anabolic and the more potent anti-resorptive agents is similar. The choice of therapy should be individualized according to the patient's BMD, fracture history, and other health problems.<sup>24,25</sup> Very few studies have performed a head-to-head comparison of the effects of different agents on BMD, and none have done so in terms of fracture efficacy. Consequently, a meaningful comparison of relative potency of different agents is not possible. Indirectly, some conclusions about relative efficacy may be arrived at by meta-analyses of the published trials, such as shown in Figures 1-12 to 1-15.<sup>25</sup>

### Bisphosphonates

Bisphosphonates are bone-specific agents that bind to hydroxylapatite crystals on the bone surface, particularly at the site of bone remodeling, and inhibit bone resorption by reducing activity of osteoclasts in part by accelerating their apoptosis. Two bisphosphonates (alendronate and risedronate) have been approved for treatment of postmenopausal and steroid-induced osteoporosis and osteoporosis in men. In addition, ibandronate

Table 1-11 Pharmacologic Agents for Osteoporosis Approved for Use in the United States				
Pharmacologic	Dosing	Cost*	Advantages	Disadvantages
<b>Antiresorptive agents</b>				
Bisphosphonates			Bone specific (no effects on other organs) Reduces vertebral and other fractures Easy weekly or monthly dosing Long duration of effect in bone	GI upset (infrequent) Cannot be used in renal insufficiency (creatinine clearance <35 mL/min) Dosing regimen (on an empty stomach with nothing by mouth and upright posture for at least 30 minutes)
Alendronate (Fosamax)	70 mg/wk	\$67		
Risedronate (Actonel)	35 mg/wk	\$68		
Ibandronate (Boniva)	150 mg/mo	\$76		
Estrogen, various			Improves hot flashes Reduces vertebral and nonvertebral fractures	Increases risk of breast cancer Increases risk of thromboembolic events Increases risk of cardiovascular events
CEE, oral	0.625 mg/day	\$28		
Estradiol, oral	0.5 mg/day	\$8		
Transdermal	0.05 mg/day	\$20		
Raloxifene (Evista)	60 mg/day	\$85	Reduces vertebral fractures	No effect on nonvertebral fractures Increases hot flashes Increases risk of thromboembolic events Not as potent as estrogen and bisphosphonates
Calcitonin (Miacalcin)	200 IU/day nasally	\$93	Reduces vertebral fractures Well tolerated Pain relief in some patients	No effect on nonvertebral fractures Low potency
<b>Anabolic agents</b>				
1,34 rh PTH teriparatide (Forteo)	20 µg/day SC injection	\$590	Builds new bone rather than mineralizes existing bone Greater increase in BMD than with antiresorptive agents Reduces vertebral and nonvertebral fractures	Has to be taken by daily injection High cost Associated with osteosarcoma in rats

\*Approximate retail price in U.S. \$/mo in 2005 from [www.drugstore.com](http://www.drugstore.com).

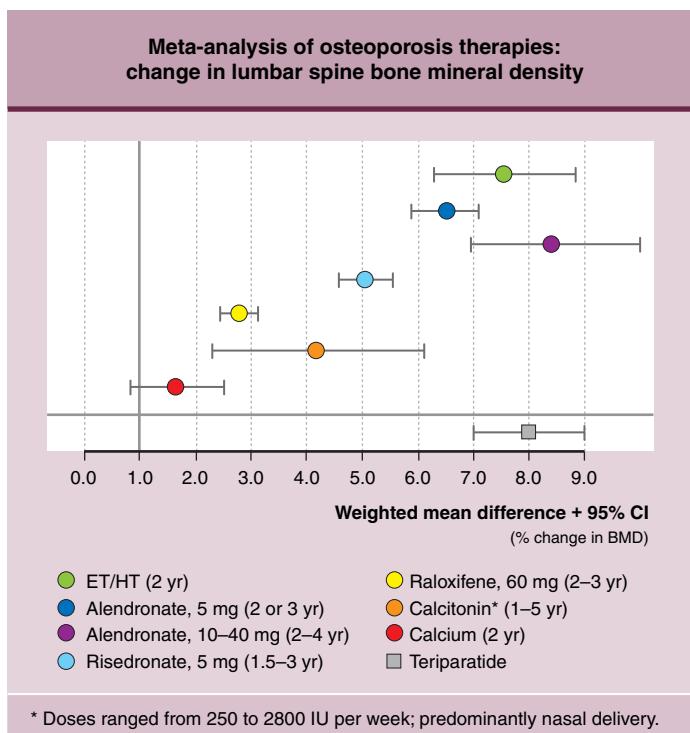

given once a month has recently been approved for postmenopausal osteoporosis. Bisphosphonates increase BMD of the spine and to a lesser degree of the hip (see Figs. 1-12 and 1-13) and decrease bone turnover, thereby reducing the risk of vertebral and nonvertebral fractures (see Figs. 1-14 and 1-15). The antifracture effect is demonstrable after only 6 to 12 months of therapy. Alendronate and risedronate are generally well tolerated, but gastrointestinal side effects such as heartburn, abdominal pain, and nausea may occur. Because of poor absorption rates and high affinity for foods, liquids, and medications, bisphosphonates are taken on an empty stomach with 150 to 250 mL (6 to 8 oz) of water followed by no other food or drink for 30 to 60 minutes. During this time, the patient should remain upright to prevent movement of the bisphosphonate tablet into the esophagus, where it can cause perforation or ulceration. The inconvenience associated with the use of oral bisphosphonates is minimized by the once weekly or monthly dosing regimen, which is associated with a lower incidence of gastrointestinal side effects. In an occasional patient who cannot take one of the approved oral bisphosphonates, oral etidronate (400 mg/day for 14 days every 3 months) or intravenous pamidronate (30 to 60 mg infused over 1 to 2 hours

every 3 months) or zoledronate (4 mg infused over 10 minutes once a year) are used, although they have not been approved for osteoporosis by the U.S. Food and Drug Administration (FDA).

Bisphosphonates are the first choice for treatment of osteoporosis in most patients because they are bone specific agents that have no other hormonal or metabolic effects, are easy to take, and have documented antifracture efficacy and long-term safety. The duration of therapy is debatable. A recent analysis of 10-year treatment with alendronate showed a progressive increase in BMD for all 10 years. In those patients who stopped alendronate after 5 years, there was preservation of bone mass in the spine but not at the hip during the next 5 years. This observation raises the possibility of a “drug holiday” for patients who have taken bisphosphonates for several years. There is no information regarding the effect of either prolonged therapy or periodic discontinuation of bisphosphonates on fracture rates.

#### Estrogen and Selective Estrogen Receptor Modulators

For many years estrogen was the sole therapeutic agent available for postmenopausal osteoporosis. Estrogen was a logical choice

**Figure 1-12 Changes in lumbar spine bone mineral density (BMD) during treatment with currently available pharmacologic agents.**

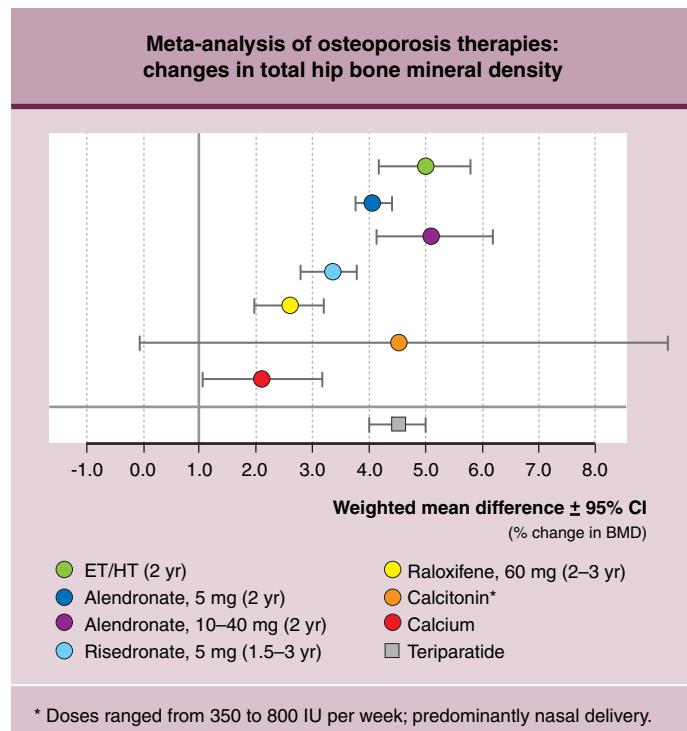

Changes are expressed relative to placebo controls. The effects of antiresorptive agents are taken from the meta-analysis,<sup>25</sup> which was performed before teriparatide was available. The effect of teriparatide is from a single randomized placebo controlled trial.<sup>27</sup> Please note that meta-analysis is not to be used for direct comparison of different agents, which is only possible from head-to-head trials. Such trials have not been performed. ET/HT, estrogen therapy/hormone therapy. (From Cranney A, Guyatt G, Griffith L, et al: Meta-analyses of therapies for postmenopausal osteoporosis IX: summary of meta-analyses of therapies for postmenopausal osteoporosis. *Endocr Rev* 2002;23:570–578; and Neer RM, Arnaud CD, Zanchetta JR, et al: Effect of parathyroid hormone [1–34] on fractures and bone mineral density in postmenopausal women with osteoporosis. *N Engl J Med* 2001;344:1434–1441.)

based on the observation that bone loss accompanied menopause as well as conditions associated with estrogen loss in younger women. In postmenopausal women, estrogen produces dose-dependent increases in BMD. The high dose of estradiol is 2 mg orally or 100 µg transdermally, and for conjugated equine estrogen (CEE) 1.25 mg orally. The intermediate dose is 1 mg of oral or 50 µg of transdermal estradiol, and 0.625 mg of CEE. The low dose corresponds to 0.5 mg of oral or 25 µg of transdermal estradiol, and 0.3 mg of CEE. Addition of progesterone does not have an appreciable effect on bone.

In the Women's Health Initiative (WHI) trial, the intermediate dose reduced vertebral and hip fractures by 34% and all osteoporotic fractures by 23%<sup>26</sup> (Fig. 1-16). The fracture protection of estrogen in the WHI trial is particularly significant, since the study population was not selected for osteoporosis. However, the WHI trial revealed that estrogen/progestin therapy was associated with increases in breast cancer and cardiovascular morbidity,<sup>26</sup> which has led to a significant decrease in the use of

estrogen. On the basis of currently available information, the use of estrogen for osteoporosis should be limited to a short course (a few years) given to early postmenopausal women who have hot flashes (hot flushes) and are at low risk of breast cancer and other undesirable effects of estrogen. This recommendation may change as information regarding lower doses or alternative delivery becomes available. Estrogen may be a reasonable therapeutic alternative for women who cannot tolerate oral bisphosphonates. It should be noted, however, that the effect of estrogen on bone is lost rapidly upon its discontinuation, in contrast to the bisphosphonates, whose effect may persist for several years. In women who are discontinuing estrogen therapy, BMD should be measured, and in those found to be at risk for osteoporotic fractures, the use of other bone active agents, such as bisphosphonates, should be considered.

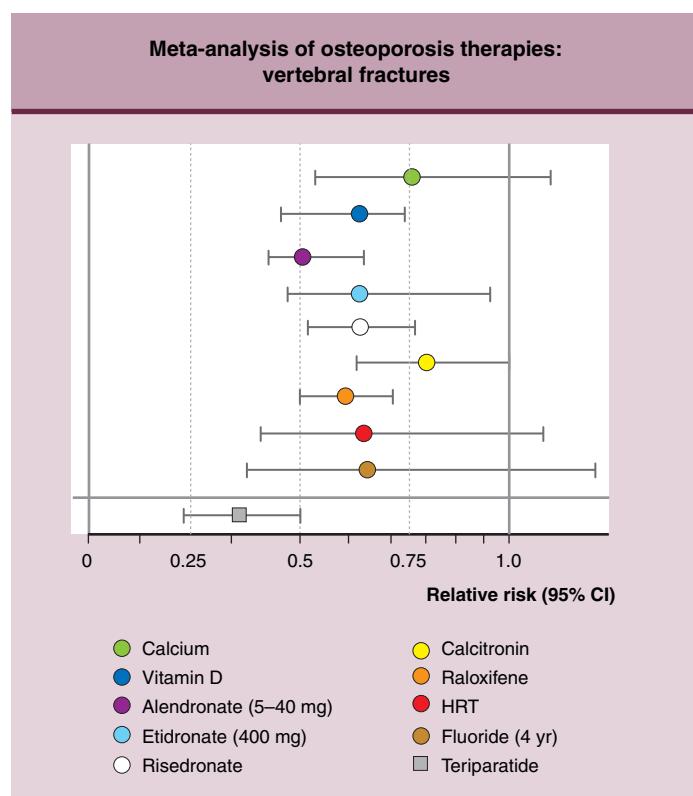

Two selective estrogen receptor modulators (SERMs) are available in the United States: tamoxifen and raloxifene. Tibolone is available in several European countries. Tamoxifen, which is approved for prevention and treatment of breast cancer, has a mild antiresorptive effect that prevents bone loss at the lumbar spine. No studies have been undertaken to assess its effect on fractures. Tamoxifen is not as potent as estrogen in preventing bone loss. However, it causes less bone loss than the

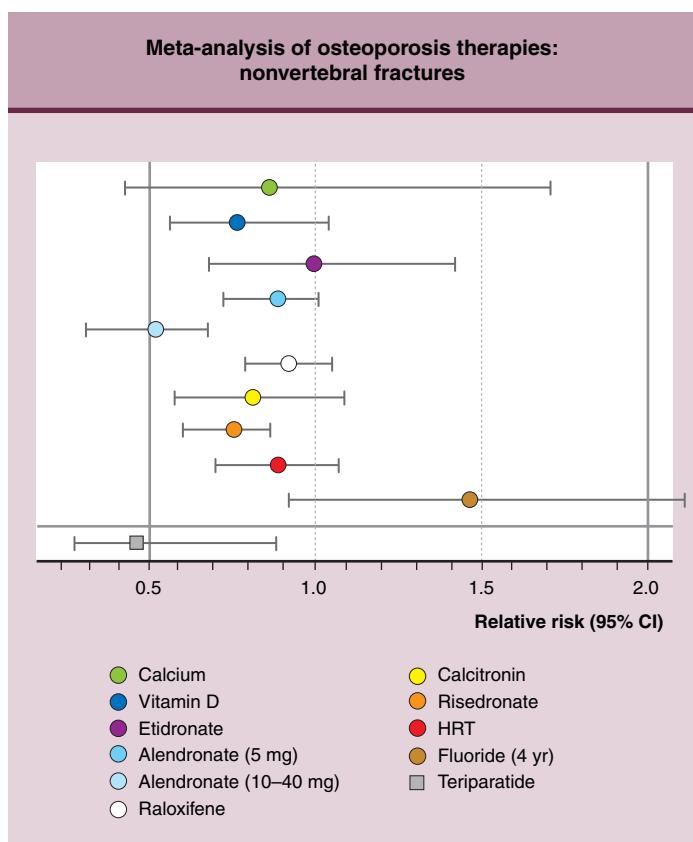

**Figure 1-13 Changes in hip bone mineral density (BMD) during treatment with currently available pharmacologic agents.** For explanation, see Figure 1-12. (From Cranney A, Guyatt G, Griffith L, et al: Meta-analyses of therapies for postmenopausal osteoporosis IX: summary of meta-analyses of therapies for postmenopausal osteoporosis. *Endocr Rev* 2002;23:570–578; and Neer RM, Arnaud CD, Zanchetta JR, et al: Effect of parathyroid hormone [1–34] on fractures and bone mineral density in postmenopausal women with osteoporosis. *N Engl J Med* 2001;344:1434–1441.)

aromatase inhibitors. The bone actions of these agents should be considered when deciding which drug to choose for prevention and treatment of breast cancer.

Raloxifene is the first SERM that received FDA approval for the treatment of postmenopausal osteoporosis. While raloxifene has estrogen-like effects on the bone, its effect on the breast is antiestrogenic, which accounts for the observed decrease in the risk of estrogen receptor-positive breast cancer in subjects receiving raloxifene for the treatment of osteoporosis. The skeletal effect of raloxifene is less potent than that of estrogen, as evidenced by the effects on BMD (see Figs. 1-12 and 1-13). Raloxifene reduces bone markers by about 34% compared with a decrease of 50% with an intermediate dose of estrogen and a 60% to 75% decrease with alendronate. Raloxifene reduces vertebral fractures but not nonvertebral fractures (see Figs. 1-14 and 1-15). The side effects of raloxifene include an increase in hot flashes, muscle cramps, and thromboembolic events. The effect of raloxifene on cardiovascular risk is under study. It appears that good candidates for raloxifene therapy are women with a family history or risk of breast cancer and moderate osteoporosis of the spine (since raloxifene reduces vertebral but not nonvertebral, particularly hip, fractures). Raloxifene may

**Figure 1-14 Effects of different agents on vertebral fracture.** Meta-analysis of effects of different agents on nonvertebral fracture. For explanation, see Figure 1-12. N Engl J Med 2001;344:1434–1441.)

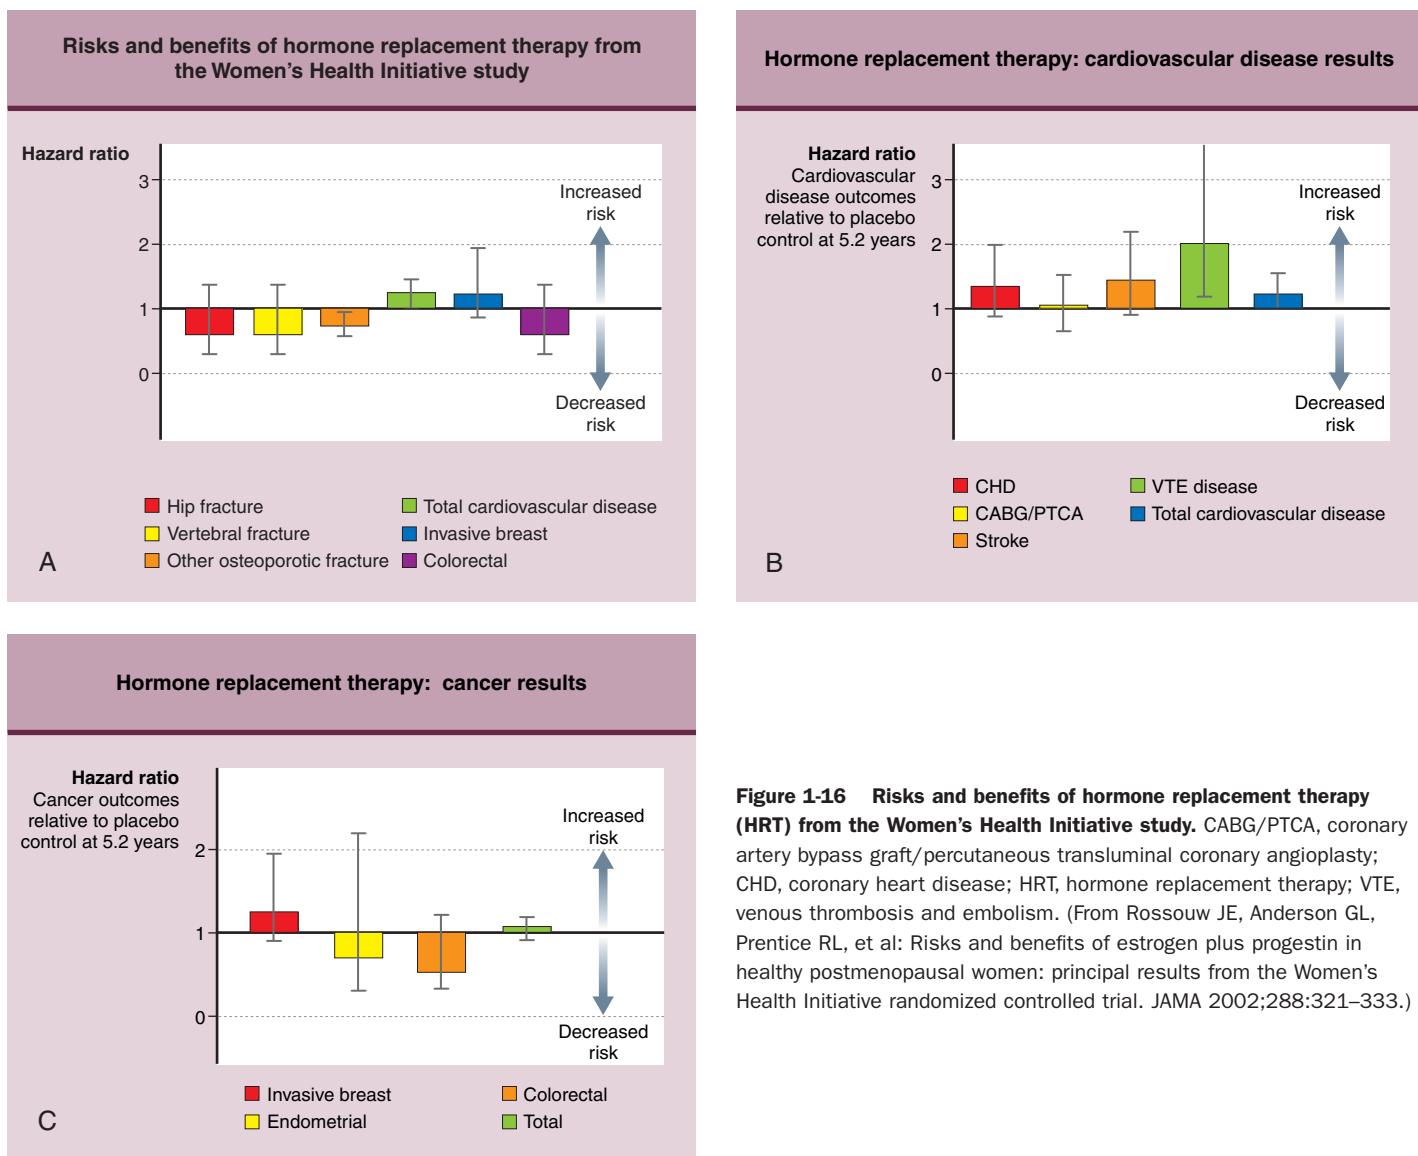

**Figure 1-15 Effects of different agents on nonvertebral fracture.** For explanation, see Figure 1-12. (From Cranney A, Guyatt G, Griffith L, et al: Meta-analyses of therapies for postmenopausal osteoporosis IX: summary of meta-analyses of therapies for postmenopausal osteoporosis. Endocr Rev 2002;23:570–578; and Neer RM, Arnaud CD, Zanchetta JR, et al: Effect of parathyroid hormone [1–34] on fractures and bone mineral density in postmenopausal women with osteoporosis. N Engl J Med 2001;344:1434–1441.)

not be a good choice for women with hot flashes or those who are discontinuing estrogen and likely to develop hot flashes.

### Calcitonin

Calcitonin, a hormone secreted by the C cells of the thyroid gland, is used for treatment of hypercalcemia and osteoporosis because it inhibits osteoclastic bone resorption. It has mild antiresorptive activity and only minor effects on BMD (see Figs. 1-12 and 1-13) and only a 12% reduction in bone resorption markers. Calcitonin reduces vertebral fractures by about 30% to 40% (see Fig. 1-14), but the effect may be highly variable. Calcitonin does not reduce the rates of hip and other nonvertebral fractures (see Fig. 1-15). Calcitonin causes mild side effects usually limited to occasional irritation of the nasal mucosa and facial flushing. In some patients calcitonin has an analgesic effect, making it particularly suitable for patients with painful acute vertebral fractures who cannot or should not receive other pharmacologic agents for osteoporosis.

The beneficial effects of estrogen, SERMs, and calcitonin on bone are likely to dissipate quickly after their discontinuation, suggesting that these drugs need to be taken either indefinitely or, if stopped, replaced by another active agent.

**Figure 1-16** Risks and benefits of hormone replacement therapy (HRT) from the Women's Health Initiative study. CABG/PTCA, coronary artery bypass graft/percutaneous transluminal coronary angioplasty; CHD, coronary heart disease; HRT, hormone replacement therapy; VTE, venous thrombosis and embolism. (From Rossouw JE, Anderson GL, Prentice RL, et al: Risks and benefits of estrogen plus progestin in healthy postmenopausal women: principal results from the Women's Health Initiative randomized controlled trial. JAMA 2002;288:321-333.)

### Teriparatide (rhPTH [1-34])

Chronic elevation of PTH such as occurs in hyperparathyroidism typically is associated with decreased bone mass and increased risk of fracture. In contrast, intermittent daily injection of small doses of PTH activates bone formation without concurrent activation of bone resorption. Teriparatide, given by subcutaneous injection, produces a dramatic increase in BMD, particularly at the spine (see Fig. 1-12).<sup>27</sup> This anabolic therapy also increases bone size, which is not reported with antiresorptive agents. During an 18 month clinical trial, teriparatide reduced the rate of vertebral fractures by 60% to 65% and nonvertebral fractures to a lesser extent (see Figs. 1-14 and 1-15).<sup>27</sup> The effect of teriparatide on hip fractures specifically is not known. The increase in osteosarcoma in rats given teriparatide raises some concerns. However, the higher doses and longer duration of treatment may be responsible for this effect. While the appearance of osteosarcoma remains a theoretical concern in human use, it is reassuring that there have not been reports of osteosarcoma in humans treated to date and no increased incidence of these tumors in subjects with chronic elevation of endogenous PTH

of primary, secondary, or tertiary hyperparathyroidism. The subcutaneous injections are generally well tolerated with the most common side effects being nausea, dizziness, and mild transient hypercalcemia, and hypercalciuria. Teriparatide is contraindicated in patients with hypercalcemia or hypercalciuria, renal insufficiency, Paget's disease, or history of bone tumors. It currently is not clear who are the best candidates for treatment with teriparatide or how it should be added to or combined with other agents. A reasonable suggestion is to reserve teriparatide for patients who cannot tolerate bisphosphonates or show inadequate response to antiresorptive agents (i.e., fracturing during bisphosphonate therapy). Since the anabolic response to teriparatide is diminished in subjects pretreated with alendronate,<sup>28,29</sup> it may also be reasonable (although no data support this position) to use teriparatide in previously untreated subjects with very low bone density of the spine or prevalent vertebral fractures. The effect of teriparatide dissipates upon its discontinuation, suggesting that this treatment should be followed by an antiresorptive agent such as a bisphosphonate to preserve the increases in bone mass.

### **Combination Therapy**

The combination of antiresorptive agents such as estrogen or raloxifene and alendronate produces only a slightly greater increase in BMD than alendronate alone.<sup>29</sup> Although there are no clear guidelines, it seems prudent to use one antiresorptive agent and to add a second only if there is documented lack of response to the first. The theoretical concern about combining several antiresorptive agents is that profound suppression of bone resorption may lead to “dead bone,” which theoretically may increase the risk of fracture because of failure to repair microcracks. Although no increase in fractures has been observed with prolonged use of a single agent (alendronate) for up to 10 years, it is not clear if a combination of antiresorptive drugs increases fracture risk. A combination of teriparatide and bisphosphonate is not recommended, since it has been shown that the increase in bone density seen with teriparatide is attenuated by concurrent or prior administration of alendronate.<sup>28</sup>

### **Skeletal Changes during Pregnancy and Lactation**

Pregnancy and lactation place a demand on the calcium homeostasis of the mother. During pregnancy, the increased demand for calcium necessary for formation of the fetal skeleton is met primarily by increased intestinal absorption.<sup>30</sup> This is due to the increased circulating levels of 1,25-dihydroxyvitamin D, probably mediated by increased renal or placental 25(OH)-vitamin D<sub>1α</sub>-hydroxylase under the influence of the PTH-related protein (PTHRP), estradiol, prolactin, or placental lactogen. Little information is available regarding the changes in bone mass during pregnancy because of the need to avoid ionizing radiation. However, one study found proximal femur BMD to decline during pregnancy and then rapidly increase in the months following delivery. Thus, it seems that pregnancy itself is not associated with dramatic bone loss. In contrast, a significant bone loss of 3% to 10% may occur after 2 to 6 months of lactation. The bone loss is primarily due to the increased maternal bone resorption necessary to provide 300 to 400 mg, and up to 1000 mg, of calcium that is secreted in the milk daily. The main mediator of lactation-related changes in calcium homeostasis appears to be PTHR<sub>P</sub>, which is produced by the lactating breast. PTHR<sub>P</sub> makes more calcium available for milk production by increasing bone resorption and decreasing urinary calcium excretion. In contrast to pregnancy, there is no elevation of serum 1,25-dihydroxyvitamin D during lactation and no increase in intestinal calcium absorption. Thus, loss of calcium from the mother’s skeleton is not prevented by increasing dietary calcium and vitamin D intake beyond the usual requirements. The loss of bone mass resulting from lactation is rapidly reversed upon weaning with an increase in BMD of 0.5% to 2% per month. Consequently, multiparity or breastfeeding does not increase the risk of osteoporosis and fracture.

Fragility fractures and low BMD have been reported during pregnancy and during lactation. It is likely that many of these women had low BMD before pregnancy, with further bone loss due to increased bone turnover in pregnancy and particularly during lactation. An exaggeration of normal lactation-associated skeletal effects might cause excessive demineralization and increased bone fragility. No specific treatment for bone loss under these conditions exists; however, it is important to exclude secondary causes of osteoporosis, provide adequate calcium and

vitamin D intake, and consider discouraging breastfeeding to allow restoration of the mother’s skeletal health.

## **CONTROVERSY AND FUTURE CHALLENGES**

Recent years have seen dramatic increases in the understanding of the pathophysiology of osteoporosis, the development of diagnostic modalities, and more effective treatment options. However, several challenges remain in approaching this disease. One is the economic issue.<sup>7</sup> With the number of patients with osteoporosis increasing as a result of the aging population and the increased secular trend in fracture incidence, the financial challenge of diagnosing and treating osteoporosis needs to be addressed on a national scale. In developing countries, health care resources likely will best be used for large population measures to prevent osteoporosis and fractures. In more developed countries, a case finding approach such as that used in the United States is more likely to predominate. With increased health care expenditure and competition with other significant diseases, allocation of resources for diagnosing and treating osteoporosis will most certainly generate intense debate.

The second challenge in osteoporosis therapy is that even the most potent currently available therapeutic agents reduce fracture risk by only half. It is not clear whether earlier diagnosis and treatment of patients with low bone mass will prevent subsequent bone loss and osteoporotic fractures. If that is the case, it might be more economical to treat patients earlier and thereby prevent development of very low levels of bone mass. However, identifying patients who would most benefit from treatment requires identifying which factors other than BMD predict fracture, since nonselectively treating everyone with osteopenia is likely to be prohibitively expensive. Finally, it will be necessary to develop treatment strategies that are individualized according to a patient’s specific clinical characteristics to ensure tolerability and efficacy of the chosen therapy. Further exploration of the effects of combination therapy is necessary to determine how to optimize currently available agents. Despite these challenges, it is possible that in the future osteoporosis will no longer be considered an inevitable feature of aging and prevention and treatment will reduce it to an infrequent disorder.

## KEY POINTS

- Premenstrual syndrome (PMS) is characterized by psychological and physical symptoms occurring before menses; premenstrual dysphoric disorder (PMDD) is a more severe form of PMS with significant mood symptoms and disability.
- Standard criteria and prospective symptom calendars should be used in diagnosing women with PMS or PMDD.
- Lifestyle changes such as diet, exercise, sleep hygiene, stress reduction, and patient education should be a part of treatment regimens.
- SSRIs and venlafaxine are the treatments of choice for severe PMS and PMDD.
- Oral contraceptives and GnRH agonists are second-line agents used when first-line agents are ineffective or when symptoms are primarily physical.
- Scientific evidence does not support the use of natural progesterone and primrose oil, and the risks of surgical oophorectomy outweigh its benefits.
- The most crucial factor in establishing the diagnosis of PMS/PMDD is ascertaining that the patient does not have another underlying medical or psychiatric diagnosis that is showing premenstrual exacerbation in symptoms.

## EPIDEMIOLOGY

PMS is a condition of recurrent physical and psychological symptoms occurring in a cyclic fashion during the 1- to 2-week period preceding a woman's menstrual period. Most surveys find that as many as 85% of menstruating women report one or more mild premenstrual symptoms. Severe symptoms that meet the criteria for PMS, however, are much less common, with only 10% of women reporting significant impairment in lifestyle.<sup>1</sup> PMDD, a variant of PMS that entails more severe psychologic symptoms and impairment of functioning, occurs in 2% to 9% of women of reproductive age.<sup>2</sup>

## RISK FACTORS

The only proven risk factor for PMS and PMDD is ovulatory cycles. Women with a prior history of a depressive disorder, including postpartum depression, or with a family history of PMS may represent high-risk groups.<sup>3</sup> There appears to be an increased risk with age and increased parity.<sup>4</sup> Dalton proposed that tubal ligation, oral contraceptive use, pre-eclampsia, and

absence of dysmenorrhea were associated with increased risk for premenstrual symptoms.<sup>5</sup> However, none of these factors have been shown empirically to have an association. PMS has been reported among women in diverse geographic locations, cultural and ethnic groups, and historical periods. Racial, socioeconomic, or marital status differences have not been identified. Finally, risk factors such as increased imposed stress and specific personality profiles are not helpful in differentiating women with PMS/PMDD from those without the disorder.<sup>1</sup>

## PATHOGENESIS

Although the etiology of PMS is incompletely understood, considerable progress has been made in understanding its pathophysiology. The most common theories are serotonergic dysregulation, fluctuating sex steroid levels, and genetic predisposition.<sup>1</sup> Most likely, central nervous system neurotransmitters, such as serotonin, interact with sex steroids in genetically vulnerable women.<sup>6</sup>

### Serotonin

A number of experimental models have consistently demonstrated an important role for serotonin in the pathophysiology of PMS/PMDD. PMS/PMDD patients have lower whole blood serotonin levels<sup>7</sup> and lower platelet serotonin uptake<sup>8</sup> during the premenstrual phase. Challenges with serotonergic agents, such as L-tryptophan, fenfluramine, and buspirone, also have provided evidence of serotonin dysfunction in women with PMS/PMDD.<sup>9-11</sup> Finally, the finding that serotonergic drugs, particularly the selective serotonin reuptake inhibitors (SSRIs), rapidly treat PMS/PMDD and at low doses, strongly supports the hypothesis that serotonin is involved in the etiology of PMS/PMDD. However, it is notable that only 60% of PMS/PMDD patients respond to treatment with SSRIs,<sup>12</sup> suggesting that serotonin may not be the primary etiologic variable in all PMS/PMDD patients.

### Sex Steroids

Although there is a temporal relationship between symptoms of PMS/PMDD, female sex hormones, and phases of the menstrual cycle, the relationship is unclear. Women with PMS/PMDD show no consistent diagnosis-related differences in basal levels of ovarian hormones.<sup>13</sup> However, suppression of ovarian function by pharmacotherapy or through surgical menopause eliminates the symptoms of PMS/PMDD.<sup>14</sup> The most likely explanation is that women with PMS/PMDD are in some way vulnerable to the normal physiologic changes associated with the

menstrual cycle.<sup>13</sup> This hypothesis is supported in one study in which women with PMS/PMDD developed depressed mood in response to challenge with physiologic levels of estrogen and progesterone compared with controls.<sup>15</sup>

Allopregnanolone, a centrally active progesterone metabolite, has been implicated in PMS/PMDD. Though the results have been contradictory, there is some evidence that low plasma allopregnanolone concentrations are correlated with depressive symptoms during the luteal phase.<sup>16</sup> Changes in allopregnanolone concentrations have also been associated with improvement in response to pharmacotherapy for PMDD.<sup>17</sup> Allopregnanolone's hypothesized site of action is the GABA<sub>A</sub> receptor, the receptor that also affects the pharmacologic activity of benzodiazepines. PMS/PMDD patients have been shown to be more sensitive than control subjects to the anxiogenic effects of the benzodiazepine antagonist flumazenil<sup>18</sup> and less sensitive than controls to a number of benzodiazepines.<sup>19</sup>

Androgens have been investigated in PMD/PMDD because of the prominence of irritability in the symptom profile. Elevated testosterone levels have been reported in women with severe premenstrual irritability,<sup>20</sup> and a positive correlation has been observed between free testosterone concentrations and irritability.<sup>21</sup> Moreover, some success has been reported in treating PMS/PMDD with androgen antagonists.<sup>20</sup>

### Genetic Risk

Genetics appears to play a role in PMS. The concordance rate of PMS is twice as high among monozygotic twins as among dizygotic twins.<sup>22</sup> A study including more than 1000 female twins estimated heritability of premenstrual symptoms at approximately 56%, with no substantial role for familial environmental factors.<sup>23</sup>

### CLINICAL FEATURES

More than 150 different symptoms have been attributed to PMS.<sup>4</sup> Psychological symptoms are the most common reason for seeking help, and the hallmark symptom is irritability. Others include easily precipitated crying spells, low self-esteem, anxiety, and depression. The full range of depressive symptoms, including low mood, sleep disturbance, and abnormal eating are more commonly encountered with PMDD. The cognitive problems, although less frequently reported, can have a significant impact, particularly on a woman's work efficiency. These symptoms include short-term memory problems, difficulty concentrating, and "fuzzy" thinking. Finally, the somatic, or physical, symptoms are more characteristic of PMS than PMDD, and include breast tenderness, bloating, fluid retention, hot flashes (hot flushes), headaches, and musculoskeletal discomfort (Table 2-1).

No feature of the definition of PMS/PMDD is more important to a clinically useful understanding than the level of severity. The majority of menstruating women experience symptoms that are qualitatively similar to those associated with "mild" PMS. The difference between these normal symptoms, also referred to as "molimina," and PMS or PMDD, is quantitative. Molimina symptoms are typically present for a few days prior to the onset of menses and do not interfere with daily functioning. Severe PMS and PMDD, in contrast, begin 2 weeks or so before menses and result in difficulties with daily function-

**Table 2-1**  
**Symptoms of Premenstrual Syndrome/Premenstrual Dysphoric Disorder**

Psychological Symptoms	Cognitive Symptoms	Physical Symptoms
Irritability	Forgetfulness	Breast tenderness
Mood swings	Decreased concentration	Bloating
Depressed mood		Fluid retention
Crying spells		Weight gain
Low self-esteem		Constipation
Anxiety		Hot flashes
Sleep disturbance		Headaches
Increased appetite		Musculoskeletal discomfort
Lethargy or fatigue		Acne
		Rhinitis
		Palpitations

ing. PMDD is most likely to present with mood symptoms and the most severe disability. The percentage of women reporting mood symptoms in one study of PMDD was as follows: anger/irritability (76%), anxiety/tension (71%), tired/lethargic (58%), mood swings (58%), sad/depressed (54%), interpersonal conflicts (54%), bloated/breast swelling (54%), less interested in activities (49%), sensitive to rejection (47%), and poor concentration (43%).<sup>24</sup> Although most women clearly fall into one of these three groups, there is a spectrum of experience in between.

In this chapter, the term *PMS/PMDD* refers to the more severe premenstrual symptoms that interfere with functioning and require medical management.

### DIAGNOSIS

The key clinical features of both PMS and PMDD include (1) restriction of symptoms to the luteal phase of the menstrual cycle, (2) affective and somatic symptoms, (3) impairment in function, and (4) exclusion of other diagnoses that may better explain the symptoms.<sup>1</sup> PMDD represents the more severe end of the diagnostic spectrum of premenstrual syndromes and is characterized by severe mood symptoms. This difference is observed by comparing the diagnostic criteria for PMDD created by the American Psychiatric Association to the diagnostic criteria for PMS developed by the American College of Obstetricians and Gynecologists (Table 2-2). To be diagnosed with PMDD, a woman must have at least five affective symptoms, of which one must be irritability, affective lability (mood swings), depressed mood, or anxiety.<sup>25</sup> In PMS, only one symptom (either an affective or a somatic symptom) is necessary to meet diagnostic criteria.<sup>1</sup>

The diagnosis of PMS/PMDD should be based on prospective symptom diaries, because as many as half of women reporting a luteal-phase pattern will be found to have some other pattern when the diaries are examined. Because some women experience cycle-to-cycle variability in symptoms, reviewing 2 to 3 months of prospective charting is preferable to reviewing a single cycle.<sup>26</sup> A number of valid and reliable diagnostic instruments are available to document symptoms in PMS/PMDD, including the Calendar of Premenstrual Experiences<sup>27</sup> and the Daily Record of Severity of Problems.<sup>28</sup> Patients record emotional,

**Table 2-2**  
**Comparison of Diagnostic Criteria for Premenstrual Syndrome/Premenstrual Dysphoric Disorder**

Please refer to the printed publication.

From American College of Obstetricians and Gynecologists (ACOG): Premenstrual Syndrome. ACOG Practice Bulletin No. 15, Apr 2000, and American Psychiatric Association Diagnostic and Statistical Manual of Mental Disorders, 4th ed DSM-IV, text revision. Washington, DC, American Psychiatric Association, 2000.

physical, and functional symptoms daily using one of these tools to assess the presence, timing, and severity of symptoms. The diagnosis of PMS/PMDD is confirmed if there is evidence of a relative absence of symptoms during the follicular phase of the menstrual cycle; a substantial increase in emotional symptoms, physical symptoms, or both during the luteal phase of the menstrual cycle; and functional impairment during the luteal phase.<sup>29</sup>

### Differential Diagnosis

Establishing a diagnosis of PMS/PMDD can be difficult because of the wide and variable range of symptoms and because there are no confirmatory laboratory tests or signs on physical examination. Nevertheless, a comprehensive history and physical examination are required to rule out other possible causes of the emotional and physical symptoms.

The most crucial factor in establishing the diagnosis of PMS/PMDD is making sure that the patient does not have another underlying medical or psychiatric diagnosis that is showing premenstrual exacerbation in symptoms. More than 50% of patients suffering from major depression report a clear-cut premenstrual exacerbation in their depressive symptoms.<sup>30</sup> Other psychiatric conditions that may be magnified are bipolar disorder (manic-depressive illness), panic disorder, generalized anxiety disorder, eating disorders, and psychosocial conditions resulting from sexual and physical abuse. Prospective rating

of daily diaries can facilitate making a differential diagnosis. Women who report symptoms across all phases of the cycle, but with increasing severity during the premenstrual period, should be treated for the underlying disorder.

Table 2-3 summarizes the medical and psychiatric conditions that most frequently present with premenstrual exacerbation, or whose symptoms mimic some of the typical symptoms of PMS/PMDD. Medical disorders that may mimic premenstrual syndromes include hypothyroidism, diabetes, autoimmune conditions, anemia, chronic fatigue syndrome, and endometriosis. As a rule, these disorders should be treated first before treatment of PMS/PMDD is initiated, unless one drug has proven efficacy in both conditions.

Other medical disorders subject to premenstrual exacerbation are migraine and seizure disorders, irritable bowel syndrome, asthma, chronic fatigue syndrome, and allergies. The diagnosis of these conditions usually is straightforward because the symptoms are not part of the typical PMS/PMDD symptom set and emotional symptoms are not prominent, as they are in PMS/PMDD.

Finally, women in the period of transition to menopause may have symptoms typical of PMS/PMDD, especially mood disturbance, fatigue, and hot flashes. Because menstrual periods are often less predictable, these women may be less aware of the relationship of the symptoms to the menstrual cycle. Considering the patient's age, a history of recent menstrual cycle changes,

**Table 2-3**  
**Differential Diagnosis of Premenstrual Syndrome/  
 Premenstrual Dysphoric Disorder**

From American College of Obstetricians and Gynecologists: Premenstrual Syndrome. ACOG Practice Bulletin No. 15, Apr 2000, and Freeman EW, Sondheimer SJ: Premenstrual dysphoric disorder: recognition and treatment. J Clin Psychiatry 2003;5:30–39.

and a symptom diary showing sporadic or daily occurrence of symptoms usually can help make the correct diagnosis.

### Clinical Course and Progression

Little is known about the natural history of PMS/PMDD. Most women who seek help for premenstrual symptoms are in their mid-thirties, although often symptoms have been present for several years.<sup>3</sup> The longitudinal course of PMS/PMDD is not well defined, particularly the extent to which spontaneous remissions occur. Clinical experience suggests that many women have recurrent symptoms until menopause.

### NONPHARMACOLOGIC TREATMENT

A wide variety of supportive, lifestyle, and dietary supplementation approaches have been recommended to treat premenstrual symptoms, and some have demonstrated real benefit. Therefore, these strategies can be recommended to women with mild to moderate symptoms as primary therapy and to women with severe symptoms as adjunctive therapy. Table 2-4 lists these nonpharmacologic treatments and the evidence supporting their efficacy and safety.

#### Lifestyle

For women with mild symptoms, education about the condition, supportive counseling, and general healthy lifestyle measures, such as a regular exercise and healthy diet, may be sufficient to

\*Strength of recommendation: A, at least one randomized controlled trial as part of a body of literature of overall good quality and consistency addressing the specific recommendation;

B, well-controlled clinical studies available but no randomized clinical trials on the topic of recommendations; C, evidence obtained from expert committee reports or opinions and/or clinical experiences of respected authorities; indicates an absence of directly applicable clinical studies of good quality.

†Quality of evidence: Ia, evidence obtained from meta-analysis of randomized controlled trials; Ib, evidence obtained from at least one randomized controlled trial; IIb, evidence obtained from at least one other type of well-designed quasi-experimental study; III, evidence obtained from well-designed nonexperimental descriptive studies, such as comparative studies, correlation studies, and case studies; IV, evidence obtained from expert committee reports or opinions and/or clinical experience of respected authorities.

‡Efficacy: A, effective; B, conflicting data; C, insufficient data; D, ineffective.

§Adverse effects: A, minimal/mild; B, moderate; C, major; D, unknown.

result in symptom improvement. Lifestyle modifications should be the first approach taken in all women with premenstrual complaints and can be conveniently given during a 2-month trial while the patient completes the prospective daily ratings necessary to confirm the diagnosis of PMS/PMDD.<sup>12,31,32</sup>

### **Exercise**

Several studies support the efficacy of exercise in reducing PMS/PMDD symptoms. In a 3-month randomized trial of 23 women with prospectively diagnosed PMS/PMDD, the group taking regular moderate aerobic exercise reported more improvement than the control group, who did nonaerobic exercise.<sup>33</sup> In another small prospective but not randomized study, two groups of women who exercised aerobically reported fewer premenstrual symptoms at the end of a 6-month trial than did a nonexercising comparison group.<sup>34</sup> Therefore, aerobic exercise for 20 to 30 minutes, three to four times per week, is recommended.<sup>32</sup> Reduction of body weight to within 20% of ideal, where possible, is an appropriate goal.<sup>14</sup>

### **Diet**

Dietary modification can have a noticeable impact on symptom severity. Women should be encouraged to reduce or eliminate intake of salty foods, sugar, caffeine (especially coffee), and alcohol. Increased consumption of fruits, vegetables, legumes, whole grains, and water is recommended. Finally, eating smaller, more frequent meals that are high in carbohydrates may specifically improve symptoms of tension and depression.<sup>32</sup>

### **Sleep Hygiene**

For many women, PMS/PMDD is associated with sleep irregularities.<sup>35</sup> To alleviate the associated distress and discomfort, adoption of a regular sleep-wake pattern may be helpful. Women should be encouraged to adhere to consistent bedtime and waking times during the premenstrual period and ideally across the menstrual cycle.<sup>32</sup>

### **Stress Reduction**

Encouraging women to avoid planning stressful activities for the premenstrual period whenever possible can be helpful. Women should be encouraged to review their own daily diaries and identify triggers for symptom exacerbation.<sup>14</sup>

### **Psychotherapy and Group Support**

#### **Supportive Therapy and Patient Education**

Group support can be effective in managing PMS and PMDD. A recent controlled trial of psychoeducational group intervention with a focus on positive reframing of women's perceptions of their menstrual cycles found that women with PMS/PMDD who received the intervention had reduced premenstrual symptoms and premenstrual impairment, though there were no differences in posttreatment depression or anxiety scores.<sup>36</sup> Several other studies also noted efficacy of group support in managing symptoms of PMS/PMDD.<sup>37</sup>

#### **Cognitive Behavioral Therapy**

Several small studies have investigated the effectiveness of cognitive therapy in alleviating negative symptoms in women with PMS/PMDD. A 12-week study comparing women

randomized to weekly cognitive behavioral therapy (CBT) with a group of controls allocated to a waiting group list found CBT was significantly more effective in reducing psychological and somatic symptoms as well as impairment of functioning.<sup>38</sup> In another study,<sup>39</sup> women using CBT with relaxation instructions had significantly reduced PMS symptoms compared with women randomized to a nonactive control group during two menstrual cycles. In a study<sup>40</sup> of 367 women with severe premenstrual symptoms randomly assigned to CBT, a nonspecific treatment, or a waiting-list group, CBT significantly reduced premenstrual symptoms compared with both control groups at posttreatment and at the 9-month follow-up evaluation. However, lack of a true placebo group makes these results difficult to interpret.

One randomized 6-month trial showed equal efficacy of CBT compared with fluoxetine (20 mg) in treating 60 women with PMS/PMDD.<sup>41</sup> However, women responded more quickly to fluoxetine but had better maintenance of treatment effects at 1-year follow-up with CBT. Fluoxetine was more effective in alleviating symptoms of anxiety, whereas CBT was associated with increased use of more effective coping strategies.<sup>42</sup> There was no apparent benefit of combining the treatments.<sup>41</sup> The results of this study support earlier findings that individual CBT is of benefit for women with PMS in improving partner relationships, daily functioning, and mood.<sup>38</sup>

### **Dietary Supplements**

#### **Calcium**

A 3-month multicenter trial of 497 women reported that calcium carbonate 1200 mg/day was significantly more effective than placebo in reducing premenstrual symptoms.<sup>43</sup> Several similar clinical trials have suggested that calcium supplementation can improve mood and somatic symptoms in PMS/PMDD.<sup>44</sup> Moreover, increased calcium intake has benefits beyond those associated with reduction of premenstrual symptoms, particularly with respect to prevention of osteoporosis, and is not associated with adverse effects with doses of up to 1500 mg/day.<sup>32</sup>

#### **Magnesium**

Two small trials have found that magnesium 200 to 400 mg may decrease premenstrual pain.<sup>45,46</sup> A possible biological rationale for the effectiveness of magnesium is the inhibition of PGF<sub>2α</sub> and the promotion of muscle relaxation and vasodilatation.<sup>47</sup>

#### **Vitamin E**

Vitamin E has been recommended as a treatment for mastalgia. Vitamin E 400 IU/day significantly improved affective and somatic symptoms in PMS/PMDD patients in one randomized, double-blind, controlled study.<sup>48</sup> Although its effectiveness probably is minimal, no serious side effects are reported with vitamin E 400 IU/day, and as an antioxidant it has other beneficial effects.

#### **Vitamin B<sub>6</sub> (Pyridoxine)**

Vitamin B<sub>6</sub> is a water-soluble vitamin that may improve premenstrual symptoms by its effects on serotonin.<sup>47</sup> Results of a systematic review suggest that doses of up to 100 mg/day may improve premenstrual symptoms, including depression. Higher doses have been associated with peripheral neuropathy.<sup>49</sup>

**Herbal Products****Chasteberry (*Vitex agnus-castus*)**

The fruit of the chasteberry tree is a botanical commonly used for PMS/PMDD. Active constituents in chasteberries are the essential oils, iridoid glycosides, and flavonoids.<sup>44</sup> The mechanism of action is unclear, but it may involve decreasing estrogen and increasing progesterone, prolactin, and dopamine levels.<sup>47</sup> In a study of 1542 women with PMS/PMDD, 33% reported total relief of their symptoms and 57% reported partial relief. A 3-month, randomized, double-blind, placebo-controlled study of 217 PMS/PMDD subjects found chasteberry (600 mg 3 times daily) alleviated only restlessness.<sup>50</sup> Another study showed that chasteberry and vitamin B<sub>6</sub> groups had similar reductions in PMS scores (77% and 66%, respectively).<sup>51</sup> In general, the data show conflicting results but appear promising.

**St. John's Wort (*Hypericum perforatum*)**

The use of serotonin reuptake inhibitors for the mood symptoms of PMS/PMDD is well established.<sup>52</sup> Consequently, St. John's wort is often used as a botanical alternative for treating premenstrual mood symptoms. A number of reviews have suggested that St. John's wort can be useful for mild depression but not severe depression.<sup>53</sup> In a pilot study, 19 women with PMS/PMDD were treated with 300 mg of hypericin standardized to 0.3% hypericin. The results showed a reduction of 51% in PMS/PMDD scores between baseline and the end of the trial, with more than two thirds showing at least a 50% decrease in symptom severity.<sup>54</sup> Patients taking protease inhibitors (for HIV), cyclosporine, or other medications that are metabolized by the cytochrome P-450 enzyme system should avoid using St. John's wort because it reduces serum levels of these medications.<sup>44</sup> The dose recommended for mild depression in most clinical trials is 300 mg of a standardized product to hypericin at 0.3% three times daily.<sup>44</sup>

**Black Cohosh (*Cimicifuga racemosa*)**

Most studies looking at black cohosh have been for treatment of menopausal symptoms. The mechanism of action is somewhat unclear but may involve suppressing luteinizing hormone secretion.<sup>47</sup> A number of studies using Remifemin, a proprietary extract of black cohosh, show efficacy in treating menopausal symptoms (hot flashes, profuse sweating, sleep disturbance, and depressive moods).<sup>52</sup> Because women with PMS/PMDD often have these symptoms, many clinicians have recommended the use of black cohosh in this population. Further clinical studies are needed to determine its efficacy. The recommended dose is 40 to 80 mg of a standardized extract twice daily providing 4 to 8 mg of triterpene glycosides.<sup>52</sup>

**Evening Primrose Oil (*Oenothera*)**

Seven clinical trials have been conducted to determine the efficacy of evening primrose in PMS/PMDD.<sup>47</sup> Five of the seven trials were randomized studies, but none found a beneficial effect. However, the sample sizes in all might have been too small to detect a modest benefit.<sup>55</sup> Nevertheless, at this time it does not appear that evening primrose improves premenstrual symptoms.

**PHARMACOLOGIC TREATMENT**

Women with severe symptoms or symptoms resistant to non-medical approaches should be considered for drug therapy. Table 2-5 lists pharmacologic agents used to treat PMS/PMDD and the evidence supporting their efficacy and safety.

**Selective Serotonin Reuptake Inhibitors****Efficacy**

Selective serotonin reuptake inhibitors (SSRIs) are the initial choice for severe PMS/PMDD. Both continuous and intermittent dosing are effective. A recent meta-analysis of 15 randomized, placebo-controlled trials of the use of SSRIs for PMS/PMDD found no significant difference in symptom reduction between the two dosing methods.<sup>56</sup> Intermittent administration has many advantages. It is less expensive, reduces the overall rate of side effects, limits exposure to medications, may reduce tolerance, and is more acceptable to many women. Moreover, no studies have reported discontinuation symptoms with the luteal-phase regimen in PMS/PMDD. The drug is started between 7 and 14 days before the next menstrual period, with the start day individualized to begin at or just before the expected onset of symptoms.

**Fluoxetine**

Fluoxetine has U.S. Food and Drug Administration (FDA) approval for continuous and luteal-phase administration for PMS/PMDD and is sold as Sarafem for this use. One large, multicenter trial<sup>57</sup> and six smaller randomized, double-blind, placebo-controlled studies<sup>58-63</sup> have reported efficacy for fluoxetine administered daily for the treatment of PMS/PMDD. Luteal-phase administration with fluoxetine was recently reported in a large, multicenter study<sup>64</sup> in which 260 women were randomly assigned to receive fluoxetine either 10 or 20 mg/day from ovulation (midcycle) to menses for three menstrual cycles. Fluoxetine 20 mg/day was superior to placebo in reducing the total symptoms, depressed mood, and physical symptom clusters and improving social functioning as assessed by daily ratings. The 10 mg/day dose improved mood and social functioning but not the physical symptom cluster. In the first month after stopping the medication, there was no longer a drug-placebo difference, which was interpreted as an indication of the rapid return of symptoms when mediation was discontinued.

Another large, multicenter, randomized, placebo-controlled study examined the efficacy of enteric-coated fluoxetine 90 mg administered once on day 14 and/or at day 21 of the menstrual cycle for PMS/PMDD.<sup>65</sup> Women who received both doses of fluoxetine showed significant improvement compared with placebo as assessed by total daily symptom scores, the mood symptom cluster, functioning, and several other outcome measures. The single dose of fluoxetine at day 21 was not significantly better than placebo. Fluoxetine was well tolerated; only 5 of 257 subjects (2%) discontinued, all as a result of nonserious adverse events.

A nonrandomized study compared fluoxetine 20 mg/day as continuous and luteal-phase administration in a group of 48 women with PMS/PMDD.<sup>66</sup> Seventy-five percent of the

continuous administration group and 67% of the luteal-phase administration group were rated as responders, a nonsignificant difference. Reported adverse events included headache, insomnia, muscle pain, and nausea. The results suggested that the regimens were similarly effective, although nonrandomization limited the conclusions that can be drawn from these data. A more extensive review of fluoxetine and its applications to PMS/PMDD concluded that fluoxetine is generally a well-tolerated treatment for PMS/PMDD.<sup>67</sup>

### Sertraline

Sertraline has been used in a number of luteal-phase administration studies<sup>68–73</sup> and has FDA approval for continuous and luteal-phase administration for PMS/PMDD. In a 3-month, double-blind, placebo-controlled trial in 281 women with PMS/PMDD, sertraline (50–100 mg/day) administered for the last 2 weeks of the menstrual cycle was significantly more effective than placebo in reducing premenstrual symptoms.<sup>73</sup> The superiority of sertraline compared with placebo was shown in the endpoint daily symptom rating scores, Clinical Global Impression (CGI) improvement ratings, and measures of functioning and quality of life. However, premenstrual physical symptoms did not improve significantly more with sertraline compared with placebo in this study. The luteal-phase administration regimen was well tolerated, with only 8% (11/142) of subject discontinuing as a result of adverse events. There were no reports of discontinuation symptoms.

Multiple preliminary studies of luteal-phase administration of sertraline were consistent with the above results. In a double-

blind crossover study, 79% (11/14) of women with PMS/PMDD who had responded to continuous treatment with sertraline 100 mg/day responded equally well to the same dosage administered only in the luteal phase.<sup>68</sup> In another double-blind crossover study of 11 women, sertraline at a dosage of 50 mg/day in the luteal phase was significantly better than placebo as assessed by daily symptom scores. Both the behavioral and physical symptom clusters improved with sertraline significantly more than with placebo.<sup>70</sup> In a third crossover study of 57 women with PMS/PMDD, which used a flexible dosage of sertraline 50 to 100 mg/day only in the luteal phase, improvement was significantly greater with sertraline compared with placebo for total symptoms and behavioral and physical symptom clusters as assessed by daily symptom reports.<sup>69</sup> This study showed that most of the women improved at the 50 mg/day dosage although 25% had greater improvement with 100 mg/day dosage. Insomnia was the only adverse event reported by 10% or more of the women in the sertraline group.

In a preliminary double-blind study to compare continuous and luteal-phase administration, 31 subjects with PMS/PMDD were randomized to receive either full-cycle or luteal-phase sertraline.<sup>71</sup> The results showed no statistically significant difference between the two administration regimens for the total daily symptom report scores, although the mood factor was significantly more improved in the luteal-phase administration group. Flexible dosages ranged from 50 to 150 mg per luteal day, but 42% remained at the 50 mg/day dosage after three cycles of treatment. Adverse events did not differ between the two administration regimens; no subjects reported discontinuation

symptoms. These preliminary studies consistently indicated that luteal-phase administration of sertraline was more effective than placebo and that response was achieved with dosages of 50 to 100 mg/day. Some studies reported an improvement in physical as well as emotional symptoms.

#### **Paroxetine**

A controlled-release formulation of paroxetine was recently approved by the FDA for continuous (daily) and intermittent (each day for 2 weeks before menses) administration for PMS/PMDD. As yet, there are no fully published studies of luteal-phase administration of paroxetine for the treatment of PMS/PMDD. However, data presented in abstracts indicate that both continuous and intermittent administration of the controlled-release formulation at dosages of 12.5 and 25 mg/day were more effective than placebo in the treatment of PMS/PMDD.<sup>74,75</sup> In addition, the efficacy of continuous administration of immediate-release paroxetine (10 to 30 mg/day) was reported in one controlled trial of 65 women with PMS/PMDD<sup>76</sup> and in an unblended study of 14 women with PMS/PMDD at average dosage of  $22 \pm 10$  mg/day.<sup>77</sup>

#### **Citalopram**

Luteal-phase administration of citalopram was reported in one randomized, placebo-controlled trial.<sup>78</sup> Sixty-seven women with PMS/PMDD were randomized to one of four parallel treatment arms: continuous, luteal-phase, or low follicular dose increased in the luteal-phase administration of citalopram or placebo. The luteal-phase administration group received citalopram 10 to 30 mg per luteal day for the 3 months of treatment. Both the continuous administration group and the luteal-phase administration group reported significantly more improvement compared with placebo. Ratings of irritability, which the researchers considered the cardinal symptom of PMS/PMDD, were superior in all drug-treated groups compared with placebo. These data indicated that luteal-phase administration of citalopram was more effective than either continuous or semi-intermittent administration for PMS/PMDD. The researchers suggested that the intermittent administration regimen, with its regular and repeated drug-free intervals, averted the possible development of tolerance to the medication, thus favoring luteal-phase administration of the drug.<sup>78</sup>

Citalopram was well tolerated. Adverse events were generally mild and transient. Only 8 of the 67 subjects (12%) discontinued, all as a result of nonserious adverse events. The three most frequently reported adverse events in the citalopram-treated group were reduced libido, dry mouth, and sweating. The reports of reduced libido decreased by the third treatment cycle (39% [in the first treatment cycle] and 6% [in the third treatment cycle]), in contrast to previous reports indicating that the sexual adverse effects of other SSRIs do not decrease with time.<sup>76,79</sup> Whether this was related to intermittent administration or other unidentified factors could not be determined. It is noteworthy that the subjects included in the trial had marked irritability as the cardinal symptom of the PMS/PMDD and no major depression or dysthymia (which can affect sexual function) within the previous 2 years.

A small preliminary study of citalopram compared luteal-phase with continuous administration in 17 women who had not

improved with an initial SSRI for the treatment of severe PMS/PMDD.<sup>80</sup> Flexible dosages ranged from 20 to 40 mg/day. Both administration regimens significantly improved symptoms as assessed by total premenstrual scores from daily symptom reports. The majority of subjects (59%) responded at the 20 mg/day dosage. Reported adverse events were mild and transient and did not differ between the full-cycle and luteal-phase administration groups. There were no reports of discontinuation symptoms with luteal-phase administration.

#### **Fluvoxamine**

At present, no studies of luteal-phase administration of fluvoxamine have been reported. Information on continuous administration is limited to two very small studies with conflicting results. In open-label treatment with fluvoxamine at 100 mg/day, 10 women with PMS/PMDD showed significant improvement from baseline.<sup>81</sup> In a randomized study of 20 women with self-described PMS/PMDD, fluvoxamine at 150 mg/day did not differ significantly from placebo.<sup>82</sup> The latter is the only negative report in the literature of SSRIs for PMS/PMDD; however, the small sample size and likelihood of type II error, the lack of daily symptom ratings and other screening criteria to confirm the diagnosis, and the low dose of fluvoxamine may have contributed to the results.

#### **Adverse Effects**

The adverse events associated with SSRIs when administered in the luteal phase are similar to those that occur with continuous administration. Overall in the treatment of PMS/PMDD, adverse events that occur with SSRIs are generally mild and transient and decrease or abate with adjustment of the medication. In controlled clinical trials, discontinuation rates of SSRIs due to nonserious adverse effects ranged from 2% to 12%.<sup>64,65,73,78,83,84</sup> A meta-analysis of SSRI treatments for PMS/PMDD indicated that the most common adverse effects are nausea, insomnia, dizziness/lightheadedness, fatigue, dry mouth, gastrointestinal problems, sweating, headache, and decreased libido/delayed orgasm.<sup>56</sup> Although no studies have directly compared the adverse effects among SSRIs and venlafaxine in the treatment of PMS/PMDD, the comparative effects in depressive disorders are known (Table 2-6).<sup>85</sup>

#### **Sexual Side Effects**

Decreased libido or sexual dysfunction was reported as an adverse event by about 9% to 16% of participants receiving SSRIs in PMS/PMDD studies. This is notably lower than the rates in the population of SSRI users in trials of the use of the drugs in depression, which were recently reported to be 36% to 43%.<sup>86</sup> This same study also examined the prevalence of decreased libido or sexual dysfunction in the subpopulation of SSRI users deemed unlikely to have predisposing factors for these conditions and found a much lower rate of 7% to 30%. This latter group may be a more appropriate comparator for PMS/PMDD patients who do not have a history of depressive disorders and are otherwise healthy.

A baseline assessment of sexual function rarely is available prior to the use of treatments for PMS/PMDD, which makes it difficult to determine the actual extent of disturbance in sexual functioning that results from the medication. The importance

of baseline information was shown in a study of luteal-phase administration of fluoxetine, where fluoxetine-treated subjects were significantly more likely than placebo-treated subjects to report decreased libido as an adverse effect (9% vs. 0% for placebo-treated patients), but an analysis of change from baseline sexual functioning to treatment endpoint showed no statistically significant differences in libido among the study groups.<sup>64</sup> For patients who experience sexual dysfunction when receiving an SSRI, a shift to another SSRI may be beneficial<sup>80</sup> although there are no scientific guidelines. Bupropion is associated with lower rates of sexual dysfunction than SSRIs or venlafaxine,<sup>85</sup> and buspirone may also be a useful alternative<sup>87</sup>; however, the efficacy of these medications for PMS/PMDD is less studied and appears to be modest. Some other management strategies for sexual dysfunction have been reviewed,<sup>88</sup> but none have consistent evidence of efficacy.

Intermittent administration may reduce troublesome adverse effects compared with continuous administration, possibly owing to lower exposure or reduced risk of development of tolerance<sup>89</sup> although there is no conclusive evidence for this at present. However, in support of this possibility, fewer subjects reported treatment-emergent adverse events with luteal administration<sup>73</sup> than with continuous administration<sup>83</sup> in multicenter studies of sertraline for PMS/PMDD, although the study designs and samples were not directly comparable and the studies were not designed to definitively answer questions about adverse effects. In contrast, in a randomized, double-blind, placebo-controlled study that compared luteal-phase and continuous administration for PMS/PMDD, adverse events that commonly diminish with adjustment to medication were more likely to decrease in the continuous administration group than in the luteal administration group.<sup>72</sup> In a study of luteal-phase administration with fluoxetine, only decreased libido was reported significantly more frequently with active medication compared with placebo.<sup>64</sup> With luteal-phase administration of weekly fluoxetine, nausea, diarrhea, and breast pain were reported significantly more often with the drug than with placebo, possibly a result of the higher dose used in the weekly regimen.<sup>65</sup>

#### Discontinuation Effects

Discontinuation symptoms have been reported after SSRI therapy is interrupted in patients with depression. However, there have

been no reports of discontinuation symptoms in the published studies of luteal-phase administration of SSRIs for PMS/PMDD. A recent study specifically monitored discontinuation symptoms with luteal-phase administration with sertraline, but none were identified during the 3-month course of intermittent treatment.<sup>72</sup> In a secondary analysis of symptoms reported during the first 3 days after stopping luteal-phase doses of sertraline, no discontinuation symptoms were identified.<sup>90</sup> Possible reasons for the absence of discontinuation symptoms in patients with PMS/PMDD who are treated with SSRIs are the lower doses that typify luteal-phase treatment of PMS/PMDD; the short interval of each drug treatment (2 weeks); insufficient monitoring of discontinuation effects, which could be confused with re-emergence of premenstrual symptoms; and the short course of therapy that has been studied in PMS/PMDD (about 3 months), which may be too brief to determine the long-term effects of medication and discontinuation.

There is no evidence in the PMS/PMDD literature that the likelihood of discontinuation symptoms varies among the SSRIs. This may, in part, be a result of the absence of sufficient data that address this question in PMS/PMDD studies, but it is also possible that the likelihood of discontinuation symptoms is lower in PMS/PMDD treatment for the reasons noted above. Although claims are made that discontinuation symptoms may be less frequent or severe with fluoxetine because of the long half-life of its metabolite norfluoxetine, this assertion is not supported in studies of its use in other depressive disorders, which identified discontinuation symptoms after a longer time interval than was consistent with its longer half-life.<sup>91</sup> Furthermore, other factors in addition to the half-life of the medication may effect discontinuation reactions, for example, the metabolism of the agent or other elements such as anticholinergicity (e.g., paroxetine has shown a greater propensity to produce discontinuation symptoms than fluvoxamine, an SSRI with a similarly short half-life).<sup>91</sup> Nonetheless, discontinuation reactions are an important clinical issue, particularly because they may be confused with the re-emergence of the treated symptoms and the reinstatement or expansion of drug therapy. It is clinically important to carefully evaluate complaints of follicular phase symptoms after stopping medication.

On the basis of limited evidence, improvement is maintained with the long-term use of SSRIs and PMS/PMDD symptoms

**Table 2-7**

return swiftly when medication is discontinued.<sup>92–94</sup> The appropriate duration of treatment for patients with PMS/PMDD that has responded to medication and the cost/benefit ratio of long-term treatment are important clinical issues that warrant further study.

#### Pregnancy and Breastfeeding

By definition, women being treated for PMS/PMDD are of reproductive age and the possibility of pregnancy is a consideration. Data obtained from pharmaceutical registries and SSRI studies have shown no increased incidence of fetal teratogenic risk during any trimester<sup>95</sup> and no effect on global development in infants and preschool-aged children.<sup>96</sup> Infant exposure to SSRIs through breastfeeding was low in most studied cases, with no evidence of long-term complications in exposed infants.<sup>97</sup> However, the small numbers studied limit definitive conclusions about infant exposure through breastfeeding.

#### Drug-Drug Interactions

Drug-drug interactions (particularly with drugs metabolized by the same microsomal system in the liver) remain as potentially serious during intermittent therapy as when used daily. Table 2-7 provides a list of drugs that interact with specific SSRIs according to the pathway in which they are metabolized.<sup>98,99</sup>

#### General Guidelines for Treating PMS/PMDD with SSRIs

The effective dosage range for treatment of PMS/PMDD with SSRIs appears to be somewhat lower than that used in other psychiatric disorders such as major depression or obsessive-compulsive disorder. Many clinicians initiate fluoxetine treatment at 10 mg and sertraline at 25 mg. For sertraline, there is evidence from a large crossover study<sup>100</sup> that the 25 mg dose is as effective in treating the PMS/PMDD spectrum as the 50 mg dose, using either dosing strategy. A distinctive feature of PMS/PMDD treatment with SSRIs is the rapid response, which occurs within 2 to 3 days in the majority of patients.<sup>69,70,71,73</sup> It is this rapid response that makes intermittent premenstrual dosing an effective treatment strategy.

The decision about which dosing strategy to choose for a patient with PMS/PMDD must be individualized. Table 2-8 lists commonly used dosage regimens. Certainly if PMS/PMDD is complicated by another comorbid depressive or anxiety disorder, then continuous dosing is indicated. Similarly, if the duration of symptoms is highly variable, then continuous dosing may also be indicated. In most patients presenting with only PMS/PMDD, intermittent premenstrual dosing is highly effective, very well tolerated, and likely to be the treatment of choice.

Data still are insufficient to guide physicians about the appropriate duration of treatment in women with PMS/PMDD who have successfully responded to a course of SSRIs. Preliminary studies of sertraline and fluoxetine<sup>93,101</sup> suggest that treatment prevention studies have not been reported for either continuous or premenstrual dosing. It seems reasonable to recommend occasional one- or two-cycle treatment “holidays” to permit reassessment of the ongoing need for treatment. Premenstrual dosing lends itself particularly well to this empirical approach.

#### Other Serotonergic Antidepressants

##### Venlafaxine

Venlafaxine increases the central activity of both serotonin and noradrenaline (norepinephrine). Venlafaxine (50 to 200 mg/day) was significantly more effective than placebo for mood, function,

**Table 2-8**  
**Dosage Regimens for Commonly Used Agents in Premenstrual Syndrome/Premenstrual Dysphoric Disorder**

Medication	Dosage	Dosing Strategy
Fluoxetine (Sarafem)	20 mg once daily 90 mg enteric-coated on days 14 and 7	Continuous, luteal Luteal (days 14 and 7 only)
Sertraline (Zoloft)	50–150 mg once daily	Continuous, luteal
Paroxetine (Paxil)	20–30 mg once daily	Continuous, luteal
Citalopram (Celexa)	10–20 mg once daily	Continuous
Venlafaxine (Effexor)	37.5–150 mg twice daily	Continuous

pain, and physical symptoms in a 4-month randomized trial in 164 women with PMS/PMDD.<sup>84</sup> Improvement was relatively swift, with approximately 80% symptom reduction in the first treatment cycle. Adverse events—primarily nausea, insomnia, and dizziness—were mild and transient. There are no published studies of luteal-phase administration of venlafaxine. It would be important to know whether similar efficacy is maintained with intermittent administration of this medication, which is now available as an extended-release formulation.

#### Buspirone

Buspirone is a partial 5-hydroxytryptamine receptor 1A (5-HT1A) agonist. While it can be administered in the symptomatic luteal phase, its effect appears to be modest. Improvement of the mood symptoms of PMS/PMDD is inconsistent, although evidence is limited to several preliminary studies. Buspirone administration (10 to 30 mg/day) in the luteal phase was compared with nefazodone and placebo in a 2-month randomized, double-blind, placebo-controlled trial with 63 PMS/PMDD subjects.<sup>87</sup> Response to buspirone was significantly greater than to placebo for patients' self-rated global improvement but did not reach significance in any of the mood symptom scores. There were no differences in frequency of adverse effects between the buspirone, nefazodone, and placebo-treated groups.

In another randomized, double-blind, 3-month study of 34 patients with PMS/PMDD, buspirone (25 mg/day) administered during the luteal phase<sup>102</sup> produced a significantly greater decrease in total PMS symptoms than did placebo. However, in item analysis only physical symptoms of aches, fatigue, cramps, and impaired social interaction significantly improved, whereas changes in mood symptoms did not reach statistical significance. Because of its modest effects and its requirement for multiple daily doses, buspirone should be limited to second-line treatment.

#### Clomipramine

Clomipramine is a tricyclic antidepressant (TCA) that is a potent but a relatively nonselective inhibitor of serotonin reuptake. Clomipramine (50 to 75 mg/day) was significantly more effective than placebo when administered during the luteal phase in a

3-month randomized study of 29 women with PMS/PMDD.<sup>103</sup> Adverse events reported by more than 10% of the subjects and more frequently with clomipramine than placebo included dry mouth, fatigue, vertigo, nausea, headache, and constipation. This was the first study to demonstrate that the clinical effect of serotonergic antidepressants occurred more rapidly when used for premenstrual syndrome than for other depressive disorders.

#### Ovulation Suppression

##### Oral Contraceptives

Although oral contraceptives (OCs) are widely prescribed for the treatment of PMS/PMDD, efficacy studies have shown mixed results. In one randomized trial, a triphasic formulation reduced physical symptoms but not mood alterations.<sup>104</sup> In another study comparing triphasic and monophasic regimens, the monophasic formulation was less likely to cause mood alterations.<sup>105</sup>

The major trend in the formulation of OCs over the last 40 years has been a reduction in the doses of both the estrogen and the progestin components, and more recently, chemical alterations of the progestins to provide fewer androgenic compounds. Ethynodiol doses have decreased from 100 µg to 20 to 30 µg. The dose of the progestin component has also decreased. All but one currently prescribed OC still contains a progestin derived from 19-nortestosterone. Table 2-9 summarizes the pharmacologic profile of progesterone, 19-nortestosterone, and a new progestin derived from spironolactone called drospirenone. Drospirenone has antiandrogenic and antiminerlocorticoid activity.<sup>106</sup> One 6-month open-label study of drospirenone and ethynodiol (30 µg) in 326 women with PMS/PMDD showed significant decreases in negative affect, water retention, and appetite.<sup>107</sup>

Numerous health advantages are afforded by OC intake. The OCs provide effective, reversible contraception but also have other known benefits including prevention of bone loss and decreased risk for ovarian and endometrial cancer, anemia, abnormal uterine bleeding, pelvic inflammatory disease, as well as complications of unplanned pregnancy, such as ectopic

**Table 2-9**  
**Pharmacologic Profile of Progestins (in Animal Models)**

<b>Progestins</b>	<b>Pharmacologic Activity*</b>			
	<b>Progestogenic</b>	<b>Antiandrogenic</b>	<b>Antimineralocorticoid</b>	<b>Androgenic</b>
Progesterone	+	(+)	+	-

## Ambulatory Office Practice

pregnancy and molar gestation. The most bothersome physical side effects of OCs are bloating and breast tenderness, and these symptoms are at least in part attributable to water retention, probably related to their estrogenic component.

Current evidence suggests that OCs should be considered if symptoms are primarily physical but may not be effective if mood symptoms are more prevalent. More controlled studies are needed to evaluate the efficacy of antiandrogenic progestins, such as drospirenone. Studies are also needed to determine whether continuous OCs are more likely to ameliorate premenstrual symptoms.<sup>108</sup>

### Transdermal Estradiol

High-dose transdermal estradiol 200 µg provided via patch can prevent ovulation and reduce symptoms of PMS/PMDD.<sup>109</sup> However, this high-dose estrogen therapy with cyclic low-dose progestin supplementation for the last 7 days of the cycle has not been clearly demonstrated to eliminate the risk of endometrial hyperplasia associated with estrogen administration.

### Progesterone

Historically, natural progesterone has been one of the most commonly employed therapies in women with PMS/PMDD, but careful scientific scrutiny has not supported an overall benefit of this hormone when compared with placebo, whether administered as a vaginal suppository<sup>110</sup> or as oral micronized progesterone.<sup>111</sup> Evidence from a large, placebo-controlled study,<sup>111</sup> as well as a recent meta-analysis,<sup>112</sup> suggests that micronized progesterone has no efficacy in the treatment of PMDD.

### Danazol

The synthetic steroid danazol appears to reduce affective and physical symptoms of PMS/PMDD<sup>113</sup>; however, its practical use is limited by the need for concurrent administration of a reliable contraceptive method. At 200 mg/day dosage, ovulation and thus conception are still possible, and danazol can cause virilization of the fetus. Doses sufficient to inhibit ovulation (600 to 800 mg/day) have been associated with undesirable side effects, including weight gain, mood changes, and acne.<sup>12</sup>

### Gonadotropin-Releasing Hormone Agonists

Improvement in PMS/PMDD symptoms with gonadotropin-releasing hormone (GnRH) agonists has been reported in the majority of well-designed studies<sup>114,115</sup> but not in all of them.<sup>116</sup> Like oral contraceptives, GnRH agonists appear to be less effective in treating affective symptoms than physical symptoms in PMS/PMDD.<sup>114</sup> The hypoestrogenic side effects and cost of GnRH agonists limit their usefulness except in severe cases of PMS/PMDD unresponsive to other treatment. Oral contraceptives may provide a safer means of inhibiting ovulation and reducing physical symptoms in PMS/PMDD patients.

If GnRH agonists are to be used for more than a few months, bone loss becomes a concern. The most commonly used approach is add-back estrogen therapy (with progestin if indicated). Add-back therapy also may result in return of symptoms, although studies are limited and sometimes confusing. In a double-blind, placebo-controlled study, both estrogen add-back therapy alone and progesterone therapy alone were associated with significant

recurrence of symptoms.<sup>117</sup> Another small, rigorous study evaluated eight women with PMS. Administration of the GnRH agonist resulted in an improvement of approximately 75% in luteal-phase symptom scores. The addition of estrogen as well as progesterone was associated with worsening symptoms, but a similar worsening also was seen with placebo.<sup>118</sup> If hormone therapy results in a return of symptoms, alendronate should be considered for osteoporosis prevention.

### Bilateral Salpingo-Oophorectomy

The final treatment option for women with severe PMS/PMDD symptoms and no response to other therapies is permanent suppression of ovulation through bilateral salpingo-oophorectomy. Bilateral ovariectomy with hysterectomy was highly effective in permanently eliminating symptoms of PMS/PMDD in two studies.<sup>60,119</sup> However, surgery for PMS/PMDD is controversial because it is irreversible. It is associated with morbidity and mortality, and the resulting hypoestrogenemia must be addressed to prevent long-term complications. This approach should be reserved for those severely affected patients who meet strict diagnostic criteria and who do not respond to any potentially effective therapy other than GnRH agonists.<sup>120</sup> These limitations are critical, because a major cause of therapy failure with any of the described treatments is an incorrect diagnosis of PMS/PMDD. It is advisable to perform a diagnostic trial with an agonist for a minimum of 3 months to determine whether oophorectomy will be effective. An additional advantage to extended use of an agonist is the opportunity to assess the woman's tolerance for estrogen replacement therapy.

### Other Medications

#### Alprazolam

Alprazolam, a benzodiazepine, has been studied in PMS/PMDD with some<sup>111,121–123</sup> but not all reports<sup>124</sup> indicating greater improvement with alprazolam compared with placebo. Study dosages ranged from 0.25 mg twice daily to 0.5 mg three times daily, administered during the luteal phase. A benzodiazepine such as alprazolam, with its swift onset of action and short half-life, lends itself to the treatment of luteal-phase symptoms, but the problems of dependence and tolerance that occur with benzodiazepines require careful diagnosis and monitoring with ongoing use. One study found no withdrawal symptoms when alprazolam administration was strictly limited to the luteal phase in patients clearly diagnosed with PMS/PMDD.<sup>125</sup> Nevertheless, patients whose symptoms are not strictly limited to the premenstrual phase and patients who are at risk for addiction are not appropriate candidates for this class of medication. Benzodiazepines may also be sedating and worsen symptoms in patients who are depressed. Conversely, alprazolam may be useful if agitation and anxiety are the primary premenstrual symptoms. The modest efficacy of alprazolam shown in the studies of PMS/PMDD, coupled with the potential for physical dependence and withdrawal, makes this drug a second-line treatment for PMDD.

### Nonsteroidal Anti-Inflammatory Drugs

Few studies of nonsteroidal anti-inflammatory drugs (NSAIDs) were identified. On the whole, studies of mefenamic acid<sup>126–130</sup> and naproxen sodium<sup>131</sup> provide insufficient data to determine

effectiveness, but NSAIDs are considered to be potentially useful, practical, and of low risk.

#### Spironolactone

Because complaints of fluid retention are common in the luteal phase, diuretic therapy has been advocated. No evidence exists that thiazide diuretics are of benefit. Spironolactone, an aldosterone antagonist with antiandrogenic properties, is the only diuretic that has been shown to be of benefit in PMS/PMDD. Several randomized, double-blind, placebo-controlled trials have shown a significant reduction in somatic and affective complaints.<sup>132–136</sup> Usual dosage in most studies is 100 mg/day in the morning during the 14-day luteal phase. However, not all reports evaluating spironolactone for PMS/PMDD have shown benefit.

## TREATMENT GUIDELINES

The treatment guidelines presented in Table 2-10 emphasize the availability of multiple treatment options and the need for reassessment following initiation of therapy. Any first-line treatment or combination of first-line treatments is considered appropriate for the management of PMS/PMDD. First-line options include nonpharmacologic treatments (exercise, diet modification, sleep hygiene, stress reduction, and patient education), psychotropics (SSRIs and venlafaxine), and other pharmacologic therapies (calcium, NSAIDs, and transdermal estradiol combined with oral progestin).

Once treatment is initiated, reevaluation should include measurement of luteal-phase symptoms using a standardized instrument. Failure to achieve a 50% or greater reduction in symptoms and either a resolution of interference with daily activities or the conclusion by the patient and clinician that overall the symptoms are at least moderately improved should lead to a modification in the management strategy.

Second-line treatments should be considered only for individuals who have failed to respond to various combinations of first-line options, as they tend to be less efficacious or impractical or to have significant potential side effects. Second-line treatment options include nonpharmacologic treatments (cognitive-behavioral therapy), psychotropics (fluvoxamine, buspirone, clomipramine, and alprazolam), other pharmacologic treatments (oral contraceptives, danazol, GnRH agonists, alprazolam, and spironolactone), and herbal products (chasteberry and black cohosh).

Evening primrose oil and progesterone are not recommended because there is no evidence to prove that they are effective. St. John's wort is not recommended primarily out of concern for potential drug interactions.

Bilateral ovariectomy with hysterectomy is highly effective in permanently eliminating symptoms of PMS/PMDD. However, because of the extreme nature of this treatment method, it is recommended only in the most recalcitrant of cases when future fertility is not an issue. It is possible that the sudden change in hormonal milieu associated with surgical menopause could also be a trigger for mood problems in vulnerable women.

## FURTHER RESEARCH

Because SSRIs are first-line therapy for severe premenstrual symptoms that require medical management, most research questions pertain to this class of agents. Whether SSRIs remain effective when used as long-term maintenance treatment is a major question that warrants further study. It is particularly important to determine whether the long-term use of intermittent administration differs from long-term continuous administration. The rate and extent of which symptoms return after stopping medication for one or more menstrual cycles is not clear.

Another unanswered question is whether SSRIs with longer half-lives (e.g., fluoxetine) provide ongoing, rather than

**Table 2-10**  
**Treatment Guidelines for Premenstrual Syndrome/Premenstrual Dysphoric Disorder**

Treatment	First Line	Second Line	Not Recommended
Nonpharmacologic	Exercise Diet modification Sleep hygiene Stress reduction Patient education	Cognitive-behavioral therapy (CBT)	
Dietary supplements	Calcium	Magnesium Vitamin E Vitamin B <sub>6</sub>	
Psychotropics	Fluoxetine Sertraline Paroxetine Citalopram Venlafaxine	Fluvoxamine Buspirone Clomipramine Alprazolam	
Other pharmacologics	Estrogen patch NSAIDs	Oral contraceptives Danazol GnRH agonists Spironolactone	Progesterone Ovariectomy
Herbal products		Chasteberry Black cohosh	St. John's wort Evening primrose

## Ambulatory Office Practice

intermittent, medication effects and whether such medications enable a swifter adjustment to adverse events than do short half-life medications when intermittently administered. Whether SSRIs with short half-lives (e.g., paroxetine) are more likely to manifest discontinuation symptoms, as has been observed in the treatment of major depressive disorder, remains in question although there is no evidence for this in currently available studies of paroxetine in the treatment of PMS/PMDD.

Another major gap in our knowledge of the treatment for PMS/PMDD is availability of data to guide the treatment of patients whose symptoms do not respond to SSRIs. Whether such patients will respond to anxiolytic or other classes of medication that have been studied for PMS/PMDD is not known. The treatment of PMS/PMDD with comorbid conditions also has not been studied and lacks guidelines. Predictors of response to SSRIs or other treatments for PMS/PMDD have not been identified.

Finally, the role of newer OCs with antiandrogenic properties, and continuous dosing of OCs, require further study. More research is necessary on nonpharmacologic treatments. The role of cognitive functioning in PMS/PMDD and the efficacy of cognitive therapy have been suggested, but data are sparse. Exercise provides promising preliminary data and warrants more investigation.

# Chapter 3

# Geriatric Gynecology

Rudi Ansbacher, MD, MS

## KEY POINTS

- The physiologic condition of the woman is more important than her chronologic age.
- Listening to what is said by the patient helps derive the maximum benefit for her.
- The periodic assessment guidelines in Table 3-1 are essential in evaluating women 65 years of age and older.

The word *geriatric* is derived from Greek words *geras* meaning old age and *iatrike* meaning surgery or medicine. Thus, it pertains to the aged or their characteristic afflictions. Gerontology is the study of normal aging, whereas geriatrics is the medical study of the physiology and pathology of old age. Geriatric gynecology includes preventive care for and diagnosis and treatment of illnesses and disabilities in older women. Interest in this medical field intensified after World War II. The first issue of the journal *Geriatrics* appeared in 1945.

Stenchever<sup>1</sup> coined the word *gynogeriatrics* in a 1997 editorial focusing on health maintenance by paying attention to screening for acute and chronic illnesses in women over the age of 65. No one to date has identified a specific age when this period of life begins. Many use the age of 65, since this is the eligible age for Medicare, Social Security payments often begin, and retirement may occur. However, the age of 65 is arbitrary because the genetic background of an individual is more important in determining the impact of disease processes with aging than is a specific age limit.

The Committee on Gynecologic Practice of the American College of Obstetricians and Gynecologists (ACOG) outlined what should be emphasized as part of the periodic assessment of women over 65 years of age,<sup>2</sup> as modified in Table 3-1. This is an excellent guide to what should be covered and accomplished during a patient's initial and follow-up visits. There is a mixture of primary and specialty care, which typifies how a gynecologist should practice the specialty in an office setting.

## DEMOGRAPHICS

At present, the expected life span for a woman is around 80 years, almost double what it was at the beginning of the 20th century. Whether the increase occurred owing to genetic predisposition or better nutrition and environmental conditions, or to a combination of these and other factors, is undetermined. The population of developed countries such as the United States is graying. The physician must become familiar with the aging process in order to provide good health care for those

rapidly gaining entrance to the geriatric population. By the year 2050 it is estimated that 25% of the U.S. population will be over age 65.

## PHYSIOLOGY OF AGING

A person's physiologic condition is more important than chronologic age because the former monitors how the body reacts to both internal and external stimuli. Most older persons maintain adequate though diminished reserves. As a person ages, there is a generalized functional decline with subsequent physiologic changes. These affect multiple organ systems and may result in a decreased response to inflammatory diseases, probably owing to lowered immune response, diminished neuroendocrine response to stimuli, and inability to maintain homeostasis.

Visual impairments are frequently encountered as a result of loss of visual acuity secondary to conditions such as cataract, diabetic retinopathy, glaucoma, macular degeneration, and retinal degeneration. Hearing impairment is due to diminished ability to discriminate frequency changes and to delays in the processing of auditory messages.

The cardiovascular system loses the elasticity of its blood vessels secondary to intimal thickening, and hypertrophy of smooth muscle cells occur, leading to decreased blood flow to the heart, gastrointestinal tract, kidneys, liver, and brain. There is an increase in the systolic component of the blood pressure, whereas the diastolic component remains the same or slightly decreases. Orthostatic hypotension is more common and can result in syncope and falls.

The respiratory system experiences a loss of lung elasticity resulting in a decrease in vital capacity and expiratory rates. The cough reflex is less vigorous, which may lead to a decrease in the evacuation of mucous secretions. As a result, older individuals are more susceptible to pulmonary infections such as pneumonia and influenza, thus the emphasis on annual influenza vaccination and the one-time administration of pneumococcal vaccine after age 65. According to the University of Michigan Immunization Clinic, the latter should be repeated after 5 years if the patient develops a chronic illness or debilitating disease.

The gastrointestinal tract loses motility. Dentition and mastication decrease, hepatic clearance is diminished, and the coordination required in swallowing is reduced. Therefore, there is less absorption of nutrients. Constipation may result, especially when activity is curtailed or in conjunction with poor nutritional habits. Fecal incontinence also can occur and causes much embarrassment.

The renal/urinary system is characterized by a decrease in kidney mass, loss of nephrons, and a decrease in creatinine clearance although creatinine levels remain in the normal range. The

Mixed  
Transient (temporary, due to infection or medication)

by holding hands, caressing, and kissing or the intimacy of intercourse.

The musculoskeletal system is characterized by a loss in muscle mass, osteoarthritis, osteopenia, and osteoporosis. Lean body mass decreases and total body fat increases.

Counseling should include discussions about appropriate exercise, adequate nutrition, and supplements such as calcium and vitamin D when indicated, the latter being especially necessary in areas with inadequate sunshine or for women in nursing homes unable to partake in outdoor activities.

Central nervous system changes are highlighted by a decrease in memory, cognition, and attention deficits. Anxiety, confusion, and depression are not uncommon and may lead to aggression, fearfulness, overcompliance, or withdrawal. Changes in affect and cognition, decreased involvement in the basic activities of everyday living, gait disorders or a tendency to fall, and a lessened desire to partake in activities that require the use of instruments occur as one ages.

The endocrine system is characterized by diminished thyroid function and a slight increase in fasting glucose levels. The former should be evaluated yearly.

Healing takes longer because of physiologic changes that decrease the body's response to injury. Aging skin is result of both intrinsic (time elapsed) and extrinsic (sun, smoking, deficient nutrition) factors, which lead to declining epidermal cell repair. The accompanying loss of elastin and collagen in the dermis leads to laxity of the overlying epidermis, wrinkling, and eventually to dermatitis and skin breakdown even with minor trauma.

The main causes of morbidity in women over 65 years of age are listed in Table 3-3.<sup>2</sup>

The leading causes of mortality in women over 65 years of age are given in Table 3-4.<sup>2</sup>

bladder capacity is diminished and urinary frequency is a common sequela. The intake of cranberry juice will reverse diminished urine acidity. Calcium absorption is decreased as is vitamin D hydroxylation. The various forms of incontinence are listed in Table 3-2 and discussed in urogynecology sections of this book.

The pelvic floor is prone to relaxation, which may result in uterine prolapse, cystocele, rectocele, and enterocele. The production of moisture by the mucosal lining of the vagina is enhanced by coital activity. Sexual function may decrease, but most women with a partner still enjoy the closeness provided

## COMMUNICATION

To establish rapport, the physician has to develop both verbal and nonverbal communication skills. The physician must become a good listener to derive the most benefit from talking with patients. To do so requires a quiet, neutral setting. It is preferable to be face to face, without anything in between. Sitting behind a desk implies a superior attitude or authority. The discourse should remain focused and the time spent uninterrupted in order to maximize attention. An unemotional, undemonstrative, neutral attitude enhances the stature of the listener, exhibits support, and creates the trust needed to proceed with medical interventions when indicated. Remember that a person cannot learn anything while talking!

Seventy-six percent of a diagnosis comes from a properly taken history (listen to what the patient tells you and watch her body language), 12% from an appropriately performed physical examination (physical diagnosis is an extremely important component in the evaluation of a patient), and 12% from laboratory or ancillary studies.<sup>3</sup>

## HISTORY

The physician must be diligent in assessing the patient's current and past medical and surgical history. The review of systems should be specific, with directed questions such as "do you have diabetes?" The importance of the family history cannot be overemphasized. As the author has often stated, "you have to pick the right parents," meaning that much of what happens to a person is genetically determined. This aspect will be better clarified when personal genomes have been determined.

The nutritional status of the individual must be determined, as well as what may be needed to round out a person's diet. Nutritional requirements are not met by those who partake of only one meal a day. The best source of nutrients still is food, although supplements may be needed.

Daily activities and exercise should be explored and the latter encouraged when indicated. Medications the person is taking should be documented, side effects discussed, and interactions with proposed additional drugs evaluated. Micromedex Healthcare Services on the Internet and The United States Pharmacopeial *Drug Information for the Health Care Professional* are good resources for such information. The physician should also ask

about the use of tobacco, alcohol, and over-the-counter or street drugs in order to help stop their intake.

The possibility of domestic and elderly violence or abuse should be evaluated. Abandonment, financial exploitation, and neglect are frequently encountered, especially in women who are living alone. Emotional, physical, and sexual abuse must be addressed during history taking.

Malnutrition, dehydration, hypothermia, hyperthermia, decubitus ulcers, general health deterioration, lack of hygiene, and misuse of medications are all problems that may be encountered.

## PHYSICAL EXAMINATION

The height, weight, and blood pressure should be recorded yearly. The first indication of loss of bone mass, osteopenia, and eventually osteoporosis is decreased height. Have a height scale chart attached to a wall in your office or clinic so that actual height can be determined. The height measurements attached to weight scales are inaccurate. A thorough physical examination should be performed and recorded and is essential to the primary care evaluation of the patient.

## LABORATORY TESTING

The guidelines listed in Table 3-1 should be followed, with a Papanicolaou (Pap) smear and mammography performed on a yearly basis, although some suggest that this may not be necessary. In late 2003, a 65-year-old in a monogamous relationship for 25 years, with 15 consecutive years of negative Pap smears, had a report of a low-grade intraepithelial lesion (LGSIL) and subsequent human papillomavirus (HPV) testing positive for types 16, 18, and others (high risk). Because the sixth is the second most common decade in which to find abnormal Pap smears and cervical lesions, since 25% of cervical cancer occurs after age 65,<sup>4</sup> and because of the preceding case, the author still performs yearly Pap smears until age 75.

A cervical Pap smear may be reported as abnormal or with too few cells to evaluate if there is estrogen deficiency. Type-specific HPV testing enables the clinician to properly triage patients with abnormal Pap smears for further evaluation.

A woman should still perform breast self-examination if culturally acceptable. The advice to not do so is based on the lack of finding a benefit in a randomized controlled trial performed in China. Whether this finding is applicable to white and African American women in the United States, where there is a higher incidence of breast cancer than in Asia, is unclear. Mammography may be performed 6 months after the woman's office visit and breast examination, thereby giving her two breast evaluations per year, 6 months apart.

## IMMUNIZATIONS

In addition to one-time immunization with the pneumococcal vaccine, the yearly need for the influenza vaccine, and the tetanus-diphtheria booster every 10 years, patients who frequently travel are encouraged to receive hepatitis A (two doses) and hepatitis B (three doses). The hepatitis A infections that occurred in November 2003 in more than 500 people

eating tainted green onions from Mexico emphasizes the need for protection secondary to consumption of imported foods.

## FREQUENTLY ENCOUNTERED CONDITIONS

### Estrogen Deficiency

Hot flashes (hot flushes) are one of the symptoms of estrogen deficiency. The etiology of hot flashes is undetermined. Many women who were placed on hormonal therapy to relieve this symptom and discontinued it as a result of reports from the Women's Health Initiative had recurrences and needed to be re-placed on estrogen therapy. The oldest woman reporting such problems in the author's practice was 73. The use of alternative and complementary medicines such as herbal products, phytoestrogens, and soy, to date in the majority of randomized controlled trials, have not been more effective than placebos in relieving hot flashes, and no long-term data support their use to prevent osteoporosis.<sup>5</sup>

After menopause, estrogen deficiency can be a frequent cause of discomfort with intercourse. The epidermis of the vulva thins, making the labial folds less prominent. Elastic fibers decrease, and hair thins. There is a loss of elasticity in the rugal folds of the vagina, which can appear shiny or slightly reddened. The vaginal pH rises from below 4.5 to above 6.5, and the rate of production and volume of vaginal fluid is reduced. Döderlein bacilli are diminished. The genital tissues become atrophic, and fissures or ulcerations can occur. Symptoms of genital atrophy include the feeling of burning, dryness, irritation, soreness, and tightness. Dyspareunia, especially on insertion of the penis or with deep thrusting, and postcoital spotting can occur.

Local therapy with estrogen creams (e.g., Premarin or Estrace vaginal creams) or estrogen vaginal rings (Estring), releasing estrogen in a measured amount daily, are effective in restoring tissues to a premenopausal state. Advise the patient to use estrogen cream after intercourse to decrease absorption of estrogen by the skin or genitalia of her partner. Vaginal lubricants such as Astroglide, Gyne-Moistrin, K-Y Jelly, Lubrin, Moist Again, Replens, Surgilube, Today Personal Lubricant, and Vagisil counteract vaginal dryness and thereby reduce the incidence of dyspareunia. Some women prefer to use virgin olive oil.

Androgen supplementation for women as they age is still controversial, mainly because of lack of data derived in a scientific fashion to prove its efficacy in enhancing sexual responsiveness. It has long been thought that androgen supplementation in a woman enhances her feelings of well being. The need for libido-enhancing medications for women is important because such items are supplied to their male partners.

The use of DHEA, DHEAS, and melatonin have not been proved to be beneficial.

Selective estrogen receptor modulators (SERMs) are being developed and most likely will replace many items in current use for hormone therapy in postmenopausal women.

The future preferred avenue for hormonal therapy will be through the vagina. The use of the tampon has desensitized women to the use of medications intravaginally.

### Vaginitis

Women with symptomatic vaginal discharge are frequently seen by their health care providers. Atrophic vaginitis is characterized

by a watery discharge, as opposed to the characteristic malodorous white-to-yellow discharge of bacterial vaginosis, the white cottage cheese-like discharge of candidal infections, and the yellow-to-green frothy discharge of trichomoniasis. The last is rarely seen in postmenopausal women. Candidal infections should alert the health care provider to the patient's use of antibiotic or immunosuppressive agents, or the presence of diabetes or human immunodeficiency virus (HIV).

The vaginal pH should be checked in patients complaining of vaginal discharge. The proper area to obtain the pH is the upper lateral third of the vagina. Microscopic examination of the secretions should be performed with both saline and potassium hydroxide. This helps distinguish among the various forms of vaginitides encountered.

Atrophic vaginitis results from the lack of estrogen or is secondary to the intake of antiestrogenic medications. Symptoms may include vaginal discomfort and dyspareunia. The epithelium is thin and friable and may bleed after minimal trauma (e.g., intercourse or vaginal or speculum examination). Small epithelial tears, erosions, or ulcers may be noted. Concomitant capillary fragility results in punctuate hemorrhages or hemosiderin deposits. Cell maturation from parabasal to superficial cells does not occur. On microscopic examination, numerous white blood cells are noted in the thin watery discharge, making Pap smear evaluation difficult to interpret. Vaginal estrogen cream will thicken the epithelium, and the maturation of parabasal to intermediate and subsequently to superficial squamous cells will recur. Occasionally a woman on adequate exogenous estrogen therapy, given either orally or transdermally, will still have atrophic vaginal epithelium.

Proper perineal hygiene should be emphasized, including wiping from front to back to exclude rectal organisms from the vulva and vagina, wearing 100% cotton underwear, and discontinuing the use of abrasive soaps or laundry detergents, scented vaginal products, and occlusive sleepwear, which keeps the vulvar area moist at night.

### Vulvar Conditions

Lichen sclerosus is the next most frequently encountered vulvar condition after atrophy and is typified by whitening of the epidermis. Microscopically, a thin keratin layer, loss of the rete pegs, and thinning of the dermal layer are noted, although hyperkeratosis may be present secondary to scratching. Various treatment regimens are utilized for vulvar lichen sclerosus.

Generally, a class 1 topical corticosteroid ointment such as clobetasol propionate 0.05% twice a day for 1 month, then once a day for 2 months, is prescribed. This may be followed by the daily application of a less potent corticosteroid such as 0.1% triamcinolone acetonide ointment (a class 4 topical corticosteroid) with a gradual reduction in strength and frequency. Some health care providers prefer to prescribe a class 1 corticosteroid on an as-needed basis after the first 3 months of use.

There should be increased surveillance for vulvar carcinoma (Fig. 3-1). Any lesion that appears thickened, with ulcerations or increased punctuation and vessel ingrowth, irregular borders, and increased pigmentation should be sampled by biopsy to rule out vulvar intraepithelial neoplasia, invasive squamous cell carcinoma, melanoma, and Paget's disease.

Sixty-five percent of vulvar cancers occur in the elderly.<sup>6</sup> Brown spots (lentigines) must not be confused with melanomas,

**Figure 3-1 Small carcinoma of the left vulva that is less than 2 cm in size.** (From DiSaia PJ, Creasman WT: Clinical Gynecologic Oncology, 6th ed. St. Louis, Mosby, 2002, color plate 8-1.)

and if the distinction is unclear, a biopsy specimen with adequate margins should be studied. Other suspicious skin lesions should be excised under local analgesia.

A woman may become more susceptible to recurrence of herpes virus and HPV infections or to HIV because of the decrease in responsiveness of her immune system.

### Urinary Tract Conditions

A urinary tract infection is due to bacterial invasion of the urothelium. It presents with the classic symptoms of frequency, urgency, and dysuria, associated with microscopic evidence of pyuria and bacteruria. A clean-catch urine culture aids in determining the antimicrobial agent with the best sensitivity to eradicate the offending organism. Elderly women are more susceptible to urinary tract infections; if left untreated, they may be a source of bacteremia. For those with recurrent cystitis, emphasis should be placed on proper perineal hygiene, as previously discussed.

Fever and flank pain are suggestive of a kidney infection (i.e., pyelonephritis). Hematuria is associated with some urinary tract infections but is more likely present with kidney or ureteral stones.

Urethritis is rare. A history of dribbling may signal a urethral diverticulum. A caruncle is an eversion of the urethral mucosa at the orifice of the urethra. It is a frequent finding in elderly women and requires no therapy.

### Other Conditions

Urinary and rectal incontinence are frequently encountered, and to a lesser extent cystocele, rectocele, and enterocele. The reader is referred to the chapters on urogynecology for discussions of pelvic floor support, alterations in urinary bladder and rectal functions, and appropriate therapies. However, surgery can be obviated in some estrogen-deficient patients by the use of vaginal estrogen plus Kegel exercises. Women who are not candidates for surgery, usually because of the anesthetic risk in associated chronic medical conditions, can be fitted with an appropriate pessary. For further information on indications for use, types available, and complications of pessaries, please refer to the article by Bash.<sup>7</sup>

The woman's views concerning sexual matters should be explored. Reticence to do so usually implies that the medical caregiver is uncomfortable discussing sex despite the importance of this subject to many women as they age. Moreover, male libido-enhancing agents have stimulated greater demands on the older woman by her male partner. There is an urgent need to develop a corresponding female libido-enhancing agent.

## CONCOMITANT CONDITIONS

Osteoporosis is covered in Chapter 1.

Cancer is worrisome to many women in their waning years. Therefore, appropriate screening (see Table 3-1) should be undertaken for the more common cancers (breast, colon, and genital tract, which includes the cervix, endometrium, ovaries, vagina, and vulva).

Cardiovascular changes occur with aging, and the signs of impending myocardial infarction in a woman are more subtle than those in men. Therefore, evaluation of cardiac status by an internist is often indicated. Death due to heart disease leads all other causes of death in women by tenfold.

Sinusitis and upper respiratory conditions are not infrequent complaints, especially during the winter months, and should be treated accordingly.

Lung cancer in present or past smokers must be sought for those with a chronic cough.

Gastrointestinal complaints can be evaluated. Indigestion and abdominal discomfort are common, and these symptoms must be evaluated to rule out a cardiac condition or pneumonia.

Gait disturbances, incontinence of urine, malnutrition, osteoporosis, and sleep disturbances often generate an office visit. Since seniors are more sensitive to medications for pain and sleep, the minimal effective dose to obtain the desired result should be prescribed.

Persistent adenopathy, fever, night sweats, and weight loss should alert the physician to the possibility of lymphoma or leukemia.

Changes in mentation, including delirium, dementia, and depression, must be recognized. Often, these conditions are secondary to malnutrition or substance abuse and are associated with gait disturbances.

## OFFICE PROCEDURES

The physical examination can be augmented by in-office procedures including, when indicated, colposcopy; endocervical curettage; cervical, endometrial, vaginal, and vulvar biopsy; and transvaginal ultrasound. Office transvaginal ultrasound is complementary to the pelvic and rectal examinations. Transvaginal ultrasounds allow visualization of endometrial stripes and masses felt, such as leiomyomata and ovarian enlargement. Rarely does an endometrial stripe of 5 mm or less indicate intrauterine disease. Office sonohysterograms help determine uterine intracavitory polyps and leiomyomata. It is important to remember that tamoxifen therapy can induce hyperplasia of the endometrium and endometrial polyps.<sup>8</sup>

Any woman exhibiting postmenopausal bleeding must undergo appropriate evaluation including endometrial sampling. Forty-five percent of endometrial cancers occur in the elderly.<sup>7</sup>

Abdominal discomfort may occur secondary to hematometra or hydrometra, secondary to cervical stenosis, and although rare, tubal carcinoma must also be ruled out if there is fluid discharge. If needed, paracervical block and subsequent dilation of the cervical canal can be performed to enhance outpatient endometrial biopsy, and the use of a nonsteroidal analgesic 1 hour prior to the procedure helps diminish the cramping associated with the procedure.

Transvaginal ultrasound is helpful in the evaluation of adnexal masses. Forty-three percent of epithelial ovarian carcinomas occur in the elderly.<sup>7</sup> The majority of unilocular ovarian cysts having a diameter of less than 5 cm in postmenopausal women are benign. Expectant management can be advised if there is no increase in the ovarian cyst diameter and the serum CA 125 concentration remains normal.<sup>9</sup> Persistent adnexal masses greater than 5 cm should be evaluated surgically.

Nipple discharge should be sampled for cytologic screening. Breast aspiration can be performed in the office after proper training, or women requiring this procedure can be referred to a breast care specialist.

## ADDITIONAL PREVENTIVE CARE

Senior citizens are more sensitive to medications, especially those for pain and sleep. The minimal effective dose to obtain the desired result should be prescribed.

Adverse drug reactions are not infrequent in those taking multiple medications, and the central nervous system and gastrointestinal tract manifestations are listed in Table 3-5.<sup>10</sup> The physician should review all the medications that a woman is taking and ensure that she knows the proper dosage for each. Drug interactions can be identified, and she can be informed of possible side effects.

The functional status should be ascertained (i.e., activities of daily living). These include the ability to bathe, dress, prepare

Table 3-5 Adverse Drug Events			
Central Nervous System		Gastrointestinal Tract	
Symptom	Possible Cause	Symptom	Possible Cause
Confusion	Narcotics	Anorexia	Antidepressants
Drowsiness	Antidepressants	Constipation	Narcotics
Restlessness	Theophylline	Diarrhea	Antibiotics
Nausea	Various medications

meals, eat, take medicine, ambulate, urinate, and defecate. A review of systems, physical assessment, support systems, and vaccination history should all be evaluated. Pertinent laboratory and radiologic imaging studies are ordered as needed.

Advanced directives, available systems of care, living wills, and end-of-life care needs should be discussed well in advance of the development of adverse conditions and are explained by Finnerty and colleagues for the primary care obstetrician/gynecologist.<sup>11</sup>

All women over the age of 65 should have access to comprehensive and, at times, multidisciplinary geriatric care. Therefore, the physician needs to be aware of the social and community resources available for caring for the aging woman.

Clinical experience will help the physician make decisions. Every patient is different, and each may respond differently to a particular therapy.

Know your limitations. Make referrals to those who have more experience with medical conditions that you are uncomfortable evaluating and treating. This is particularly important for gynecologists as the attempt is under way to define and integrate primary care and specialist activities.

## KEY POINTS

- Chronic pelvic pain is a common disorder in women, with an estimated prevalence of 4%.
- Disorders of the gastrointestinal, urologic, and musculoskeletal systems are at least as common as reproductive system disorders in women with chronic pelvic pain.
- Chronic pain differs from acute pain in that it serves no known biologic function and frequently is a diagnosis, not a symptom.
- Chronic pelvic pain may be treated in a disease-specific manner or in a pain-specific manner; in many women it is more effective to treat both specific diseases (e.g., endometriosis) and pain.
- A thorough history and physical examination are crucial in the evaluation and treatment of women with chronic pelvic pain.

## EPIDEMIOLOGY

Chronic pelvic pain is a far more common affliction of women than is generally recognized. One study from the United Kingdom found a prevalence of 3.8% in women age 15 to 73. This was higher than the prevalence of migraine (2.1%) and was similar to that of asthma (3.7%) and back pain (4.1%).<sup>1</sup> Similarly a study in Seveso, Italy, found that 4% of all women had moderate to severe, noncyclic pelvic pain.<sup>2</sup> A U.S. study using telephone polling suggested a higher prevalence. It found that 15% of women reported pelvic pain, with a mean average pain score of 5 (on a 0 to 10 scale), and 4% had pain severe enough to cause them to miss work.<sup>3</sup> This study estimated that 9.2 million U.S. women suffer from chronic pelvic pain.

Chronic pelvic pain is the indication for 12% of all hysterectomies and more than 40% of gynecologic diagnostic laparoscopies. It is estimated that direct and indirect costs of chronic pelvic pain in the United States are over \$2 billion per year.<sup>3</sup> At an individual level, chronic pelvic pain frequently leads to years of disability and suffering, with loss of employment, marital discord, and divorce, as well as numerous untoward and unsuccessful medical interventions. Clearly, pelvic pain is an important issue in the health care of women.

*Chronic pelvic pain* may be defined as nonmenstrual pain of 6 or more months' duration that localizes to the anatomic pelvis, anterior abdominal wall below the umbilicus, or the lumbosacral back and causes functional disability or requires medical or surgical treatment. This definition excludes vulvar pain and the cyclical pain of dysmenorrhea. These exclusions are somewhat

arbitrary. In fact, women with chronic pelvic pain often have vulvar pain or dysmenorrhea as part of their symptom complex.

## RISK FACTORS

### Age

Women of all ages may experience chronic pelvic pain, but it tends to be more common in women of reproductive age. Otherwise, patient age does not appear to be a specific risk factor for chronic pelvic pain.

### Physical and Sexual Abuse

There is a significant association of physical and sexual abuse with various chronic pain disorders, including chronic pelvic pain. Of women with chronic pelvic pain, 40% to 60% have a history of abuse. Whether physical or sexual abuse specifically causes chronic pelvic pain is not clear.

### Pelvic Inflammatory Disease

It is estimated that 18% to 35% of all women with acute pelvic inflammatory disease (PID) develop chronic pelvic pain. The actual mechanisms by which chronic pelvic pain results from PID are not known, nor is it clear why some, but not all, women with reproductive organ damage secondary to acute PID develop chronic pelvic pain. Whether acute PID is treated with outpatient or inpatient regimens does not appear to significantly alter the odds of developing subsequent chronic pelvic pain (34% with outpatient therapy vs. 30% with inpatient therapy).<sup>4</sup>

### Endometriosis

Although endometriosis may be a direct cause of dysmenorrhea and chronic pelvic pain, it may also indirectly place women at increased risk of chronic pelvic pain. For example, human and animal experimental data show that women with dysmenorrhea or endometriosis have increased episodes and severity of pain related to urinary calculi than women without dysmenorrhea or endometriosis. Similar results have been experimentally demonstrated for vaginal pain, as well. Such viscerovisceral interactions may have a significant role in chronic pelvic pain in women and may explain why some women with a past history of endometriosis have persistent pelvic pain after their endometriosis is gone.

### Obstetrical History

Pregnancy and childbirth may lead to chronic pelvic pain, possibly due to musculoskeletal trauma, particularly to the pelvis and back. Historical risk factors associated with pregnancy and pain include lumbar lordosis, delivery of a large infant, muscle weakness and poor physical conditioning, a difficult delivery,

vacuum or forceps delivery, and use of gynecologic stirrups for delivery. Conversely, women with a history of no pregnancies may have disorders that cause infertility and chronic pelvic pain, such as endometriosis, chronic PID, or pelvic adhesive disease.

### Past Surgery

A history of abdominopelvic surgery is associated with chronic pelvic pain. In some cases the relationship is relatively clear, such as unrecognized spillage of gallstones at the time of cholecystectomy, or osteitis pubis or osteomyelitis after a Marshall-Marchetti-Krantz procedure. Prior cervical surgery for dysplasia may cause cervical stenosis, and there is a reported high association of cervical stenosis and endometriosis. Additionally, in women without preoperative pelvic pain, 3% to 9% develop pelvic pain or back pain in the 2 years after hysterectomy.<sup>5,6</sup> A recent case-control study suggests that cesarean section may also be a risk factor for chronic pelvic pain (odds ratio [OR] = 3.7).<sup>7</sup>

### PATHOGENESIS

Pain is “an unpleasant sensory and emotional experience primarily associated with tissue damage or described in terms of such damage, or both.”<sup>8</sup> Pain is defined in this way to make it clear that pain is a personal subjective experience, not an objective physiological event. No objective tests allow measurement, characterization, or confirmation of the patient’s pain. Many patients report pain in the absence of tissue damage or any likely pathophysiological cause. If patients regard their experience as pain and report it in the same ways as pain caused by tissue damage, it should be accepted as pain. This definition of pain avoids tying pain to the stimulus.

Pain may be of central or peripheral origin (Table 4-1). Central pain may be due to psychogenic or neurogenic mechanisms. *Neurogenic* refers to pain caused by a primary lesion or lesions, or intrinsic dysfunction, in the central nervous system. Peripheral pain may be neurogenic or nociceptive. *Nociceptive pain* is caused by stimulation of nociceptors, neurons or neuroreceptors that

**Table 4-2**

\*Do not appear to cause pain in viscera, only in somatic tissues.

are sensitive to a noxious stimulus (Table 4-2). Both visceral and somatic structures have nerves that function as nociceptors. Neuropathic or neurogenic pain is caused by a primary lesion or dysfunction in the peripheral nervous system, meaning the nerve or nerves themselves are the pain generators. Such lesions or dysfunctions may be due to injury, disease, or localized insult or injury due to infection or surgery, for example.

In women with chronic pelvic pain, pain is thought usually to be of peripheral, not central, origin. Clinically, chronic pelvic pain is not commonly diagnosed as being primarily due to psychological or central neurologic disorders. Many visceral and somatic disorders are thought to cause or precipitate chronic pelvic pain (Table 4-3), but the mechanisms that cause these diseases to result in chronic pain are not well understood. Pain may become chronic because there is no known cure for the etiologic disease; for example, interstitial cystitis or irritable bowel syndrome (IBS). In other cases, it may be that the development of neurogenic pain is responsible or that pain becomes “centralized” and is maintained by central nervous system dysfunction.

Potential visceral sources of chronic pelvic pain include disorders of the reproductive, urinary, and gastrointestinal tracts. Potential somatic sources include the pelvic bones, ligaments, muscles, and fascia. Although it is helpful to the gynecologist to classify potential etiologies into gynecologic and nongynecologic causes, clearly knowledge and familiarity with all visceral and somatic diagnoses are crucial to the clinician evaluating and treating a woman with chronic pelvic pain.

Realistically, not many of the diseases thought to cause chronic pelvic pain fulfill traditional epidemiologic criteria of causality. Sufficient evidence strongly suggests that several of the most common disorders in women with chronic pelvic pain are causal, such as endometriosis, interstitial cystitis, and IBS (see Table 4-3). For many of the diseases often listed as causes of chronic pelvic pain, only limited evidence or expert opinion supports an etiologic relationship.

## CLINICAL FEATURES

More than 80% of women with chronic pelvic pain have had pain for longer than 1 year when they seek medical care, and about one third have had pain for longer than 5 years.<sup>9</sup> About one half of women with chronic pelvic pain have either urinary or gastrointestinal symptoms, or both, in addition to their pelvic pain. Reproductive tract symptoms are also common. For example, dysmenorrhea is present in more than 80% of women with chronic pelvic pain (in contrast to about 50% in the general population).

Dyspareunia is also more common in women with chronic pelvic pain, being present in at least 40% (in comparison to 10% to 15% in the general population). Most women with dyspareunia and chronic pelvic pain report the pain is deep and occurs both during and after intercourse. Dyspareunia is more severe and disabling in women with IBS and urinary symptoms, when compared to women with chronic pelvic pain and no gastrointestinal or urinary symptoms.

Women with nociceptive, somatic pain usually describe pain that is well localized to the area of disease. This is not always the case, however. For example, sometimes with levator ani pain

the symptoms are described as deep, aching, heavy pain and the patient cannot accurately localize the pain to the pelvic floor muscles. With nociceptive, visceral pain there is almost always poor localization and usually a description of deep, dull, and cramping pain.

## DIAGNOSIS

Making an accurate diagnosis in the woman with chronic pelvic pain can be difficult. The number of potential diagnoses, the variety of anatomic sources of pain, the likelihood that the patient may have more than one diagnosis, and the potential that pain itself may need to be considered a diagnosis are only a few of the issues that make diagnostic evaluation challenging.

The history and physical examination are powerful diagnostic and therapeutic tools in chronic pelvic pain. As diagnostic tools, a thorough history and examination may lead to accurate diagnosis, minimizing the need for expensive laboratory or imaging testing or risky operative interventions. As therapeutic tools, a compassionately taken history, during which the patient talks and the physician listens, and a sensitively performed examination establish rapport and trust that the physician is caring and competent and allow the patient to leave the physician's office feeling better. Because the examination is often painful for the woman with chronic pelvic pain, it is important that the physician remember that even a "routine" pelvic examination is emotionally stressful for many patients with chronic pelvic pain.

The diversity of potential etiologic or associated diagnoses demands a multidisciplinary approach to diagnostic evaluation. Referrals to and consultations with other specialists may be needed. The history of the patient's pain must be thoroughly obtained, as must the review of systems, with particular attention to the gastrointestinal, reproductive, urologic, and musculoskeletal systems. Because of the complexity of the history in most patients, intake questionnaires are extremely helpful in obtaining details of the history (see, for example, [www.pelvicpain.org](http://www.pelvicpain.org)). However, they should not replace allowing the patient to tell her story.

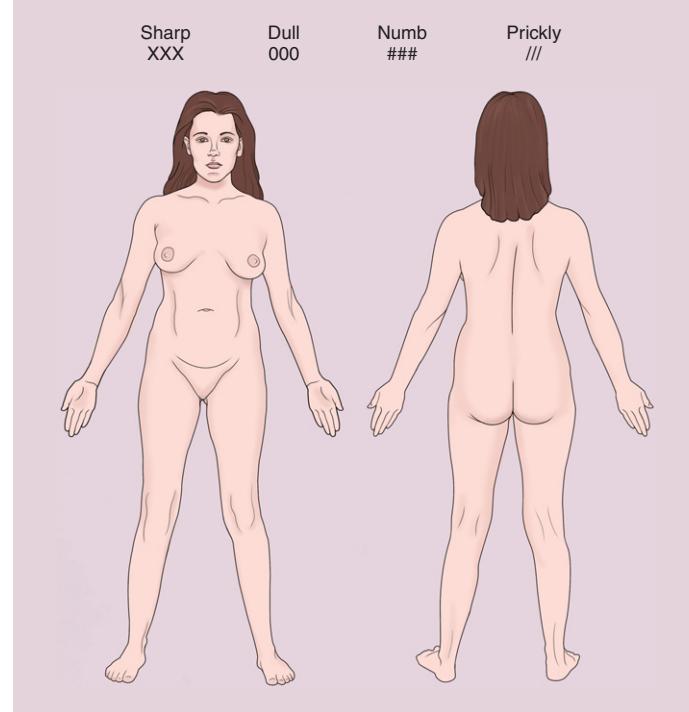

Establishing the location of the patient's pain can be crucial to accurate diagnosis. An ideal way to do this is to have the patient mark the location(s) of her pain on a pain map (Fig. 4-1). Pain maps frequently reveal that the patient has other areas of pain. For example, up to 60% of women with chronic pelvic pain also have headaches, and up to 90% have backaches. A pain map may show both ventral and dorsal pain, suggesting intrapelvic pathology, whereas one showing only dorsal lower back pain suggests an orthopedic or musculoskeletal origin. A pain map may show a dermatomal distribution of pain, suggesting a central neurologic source, or it may show a unilateral cutaneous distribution along the anterior lower abdominal wall into the labia or upper inner aspect of the thigh, suggesting neuropathic pain of the iliohypogastric or ilioinguinal nerves. A pain map may show a very diffuse distribution, consistent with visceral pain. Visceral pain is not as well localized as somatic or dermatomal pain, so patients with chronic pain and visceral pathology may have trouble localizing their pain. Furthermore, because the cervix, uterus, and adnexae have the same metameric innervation as the bladder, distal ureter, lower ileum, colon, and rectosigmoid, it is often difficult to determine if visceral

abdominopelvic pain is of gynecologic, urologic, or intestinal origin.

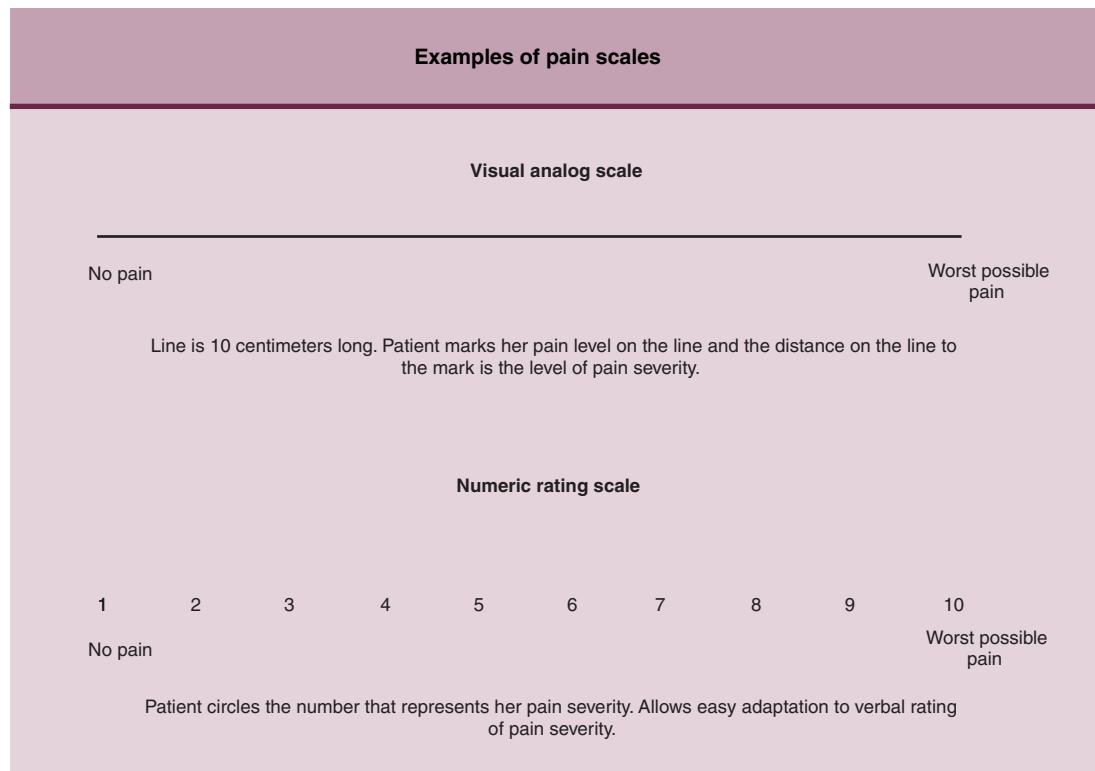

The patient should also be questioned about radiation of pain. It is not uncommon for the lateral pain of adnexal origin to radiate down the anterior or anteromedial thigh. Pain of uterine or cervical origin, including dysmenorrhea, may also radiate down the anteromedial thigh. Radiation down the posterior thigh is often associated with musculoskeletal problems. Sciatica associated with lumbosacral disease is a classic example of this.

Asking about the severity of pain is less useful diagnostically in chronic pain than it is in acute pain. It is still important, because it is one of the major measures of response to any treatment. In clinical practice, a simple rating system of "no pain, mild pain, moderate pain, severe pain" is often used, but this is not very sensitive to changes in pain severity and may not be very useful in following patients' responses during treatment. For endometriosis-associated pain the American Fertility Society (now the Society for Reproductive Medicine, Birmingham, Ala.) has suggested rating pain as "mild," "discomforting," "distressing," "horrible," and "excruciating" (this is the same rating as that of the McGill Pain Questionnaire). Numerical scales may be more useful and reliable. The best-studied numerical scale is the visual analog scale, which uses a 10-cm line with descriptive labels of pain severity at the ends. The patient marks the line at the point that best represents the severity of her pain (Fig. 4-2). The distance in centimeters from the beginning of the line to the patient's mark is a measure of her pain severity. A numerical

**Example of a diagram that a patient may use to "map" her pain**

**Figure 4-1 Example of a diagram that a patient may use to "map" her pain.**

**Figure 4-2 Examples of pain scales.**

rating scale is a commonly used adaptation of the visual analog scale. This allows the patient to directly give a numerical rating to her pain and facilitates conversion to a verbal numerical rating system. Whatever pain severity scale is used, it is important to be consistent.

Exploring the nature of the onset of pain may aid in diagnosis. For example, an immediately antecedent trauma, such as a fall, surgery, or motor vehicle accident, suggests a musculoskeletal cause. Pain that started with a pregnancy or immediately post-partum may suggest peripartum pelvic pain syndrome. Pain that started at or soon after menarche as dysmenorrhea, progressed to premenstrual pain, and then became constant suggests endometriosis. If pain started soon after a physical or sexual assault, it may have significant musculoskeletal or psychological components.

Finding out if there is any temporal pattern to the pain may be helpful. Cyclicity related to menses suggests gynecologic pain, but is not pathognomonic of gynecologic disease. The same pattern may occur with pain of intestinal, urologic, or musculoskeletal origin also. For example, symptoms of IBS or interstitial cystitis frequently increase premenstrually. A history of pain or increased pain with coitus is frequently present and may be due to a variety of disorders, including psychological disease, marital problems, endometriosis, vulvodynia, interstitial cystitis, and IBS. If intercourse is painful, it is important to find out if pain is with entry at the outermost part of the vagina or if it is with deeper penetration high in the vagina or pelvis, or both. Diseases associated with chronic pelvic pain do not generally cause entry dyspareunia, except as vaginismus secondary to deep dyspareunia.

The quality or nature of pain should be sought, because such descriptors may have diagnostic value. The McGill Pain

Questionnaire short form (Table 4-4) is helpful in assessing the quality of pain. For example, neuropathic pain is often described as burning or sharp and piercing, with an electric shock-like quality. Muscular pain may be aching in quality, with sharp, lancinating pain with changes in position. Similar qualities of aching with occasional intermittent sharp and radiating pains may also be described with visceral pain.

## Ambulatory Office Practice

Finding out about any prior treatments for chronic pelvic pain and the response to those treatments is a crucial part of the history. It may be important to know about any prior surgery, not just surgical treatment for pain, because pain may be a risk factor for or cause of chronic pelvic pain.

Ideally a thorough psychosocial history should be obtained on every patient with chronic pelvic pain. An extensive evaluation by a psychologist or similarly educated professional cannot always be done—nor is it always necessary. However, a basic psychosocial history is always important, especially asking about depression. Depression is one of several predictors of pain severity in women with chronic pelvic pain, and it is also a significant indicator of responsiveness to treatment. Using a screening tool such as the Zung or Beck depression inventories or HANDS questionnaire is helpful. Asking about abuse is another important part of the psychosocial history. There is a significant association between physical and sexual abuse and the development of chronic pelvic pain.

The physical examination should seek to find the exact anatomic locations of any areas of tenderness and, as much as possible, correlate these with areas of pain. This type of “pain mapping” examination requires a systematic and methodical attempt to duplicate the patient’s pain by palpation, positioning, or bodily movement. At any tender areas or painful positions, the patient should be asked whether the pain produced is the same as her chronic pain. The examination should evaluate the musculoskeletal, gastrointestinal, urinary, and neurological systems, not just the reproductive tract. It facilitates the examination to divide it into standing, sitting, supine, and lithotomy components. Tables 4-5 to 4-8 summarize some of the evaluations that may be helpful, as well as some of the potential diagnoses that may be suggested.

One of the aspects of the pain mapping examination that differs from the traditional examination is the use of single-digit palpation of the back, abdomen, and pelvis. The single-digit examination is particularly useful when looking for myofascial or trigger point pain. The abdominal wall tenderness test (Carnett’s test) is also a useful technique in pain mapping and may be used to distinguish abdominal wall tenderness from visceral tenderness. In this test, while the area of abdominal tenderness is palpated, the patient voluntarily tenses the abdominal muscles, which is readily accomplished by having her raise her head or legs. If the pain is increased, it suggests that the pain is of abdominal wall origin. If the pain is decreased or unchanged, it suggests that the pain is most likely of visceral origin.

A single-digit examination, using only one hand, is also how the pelvic examination should be initiated. The introital bulbocavernosus and transverse perineal muscles, then the levator ani muscles, should be palpated for tone, spasm, and tenderness. In patients with pelvic floor pain this may cause pain consistent with at least part of the patient’s clinical pain symptoms. Pelvic floor pain may also result from trigger points of one or more of the muscles of the pelvis. The piriformis, coccygeal, and internal obturator muscles should be thoroughly evaluated using single-digit examination. The piriformis muscles can be difficult to evaluate transvaginally, however. Rectal examination may allow an easier evaluation than vaginal examination. Transvaginally or transrectally the examining finger is pressed posterolaterally just superior to the ischial spine. In the lithotomy position, if the

**Table 4-5**

Standing Examination	Possible Problems
Gait	Short leg syndrome; herniated disk; general musculoskeletal problems
Posture with and without forward	Typical pelvic pain posture; scoliosis; one-leg standing
Standing on one leg with and without hip flexion	Laxity of the pubic symphysis; laxity of pelvic girdle; weakness of the hip and pelvis
Iliac crest symmetry	Short leg syndrome; one-leg standing
Groin evaluation with and without Valsalva maneuver	Inguinal hernia; femoral hernia
Pubic symphysis evaluation, including trigger points	Peripartum pelvic pain syndrome; trigger points; osteitis pubis; osteomyelitis pubis
Hip and sacroiliac evaluation, including trigger points	Arthritis of hip; trigger points
Buttocks (gluteus and piriformis) evaluation, including trigger points	Piriformis syndrome; pelvic floor pain syndrome; gluteal trigger points
Fibromyalgia tender point evaluation	Fibromyalgia

patient is asked to abduct the thigh against resistance as the piriform muscle is palpated, the muscle may be more easily palpated, and there is exquisite tenderness of the muscle if there is spasm or tension myalgia involving the piriform muscle (piriformis syndrome).

The anterior vaginal, urethral, and trigonal areas should be palpated to elicit any areas of tenderness, induration, discharge, or thickening suggestive of chronic urethritis, chronic urethral syndrome, urethral diverticulum, vaginal wall cyst, trigonitis, or interstitial cystitis. With deeper palpation the cervix, paracervical areas, and vaginal fornices should be palpated with the single digit for tenderness or trigger points suggestive of problems such as repeated cervical trauma (usually from intercourse), pelvic infection, endometriosis, ureteral pain, or trigger points.

**Table 4-6**  
**Components of the Sitting Physical Examination of the Woman with Chronic Pelvic Pain**

Sitting Examination	Possible Problems Diagnosed
Posture	Levator ani spasm; pelvic floor pain syndrome
Palpation of the upper and lower back	Trigger points; myalgia; arthritis
Palpation of sacrum	Trigger points; sacroiliitis
Palpation of gluteal and piriform muscles	Trigger points; myalgia
Palpation of the posterior superior iliac crests	Peripartum pelvic pain syndrome
Basic sensory testing to sharpness, dullness, and light touch	Herniated disk
Muscle strength testing and deep tendon	Herniated disk

**Table 4-7**  
**Components of the Supine Physical Examination of the Woman with Chronic Pelvic Pain**

Supine Examination	Possible Problems Diagnosed
Active leg flexion, knee to chest	Low back dysfunction; low back pain; abdominal muscle weakness; deconditioning
Obturator and psoas sign testing	Shortening, dysfunction, or spasm of the obturator or iliopsoas muscles or fascia
Head raise and leg raise	Herniated disk; abdominal muscle weakness; deconditioning
Light abdominal palpation	Referred visceral pain; nerve entrapment; neuropathy
Gentle pinching	Referred visceral pain; nerve entrapment; neuropathy
Head's maneuver	Referred visceral pain; nerve entrapment; neuropathy
Dermographism evaluation	Referred visceral pain; nerve entrapment; neuropathy
Single-digit palpation	Trigger points; myofascial pain; hernias; nerve entrapments
Abdominal wall tenderness test	Abdominal wall pain; visceral pain
Groin and abdominal evaluation with and without Valsalva maneuver	Inguinal hernia; Spigelian hernia; epigastric hernia; diastasis recti
Incisional evaluation with and without Valsalva maneuver	Incisional hernia
Pubic symphysis evaluation	Trigger points; osteitis pubis; osteomyelitis pubis
Traditional abdominal examination for distention, masses, ascites, bowel sounds, shifting dullness, vascular bruits, deep tenderness, guarding, or rigidity	Acute disease

The uterus usually can be adequately evaluated for tenderness by direct palpation with a single digit. Significant uterine tenderness may be consistent with diseases such as adenomyosis, pelvic congestion syndrome, pelvic infection sequelae, endometriosis, or premenstrual syndrome. A uterus that is immobile and fixed in position, especially a retroflexed one, may suggest endometriosis or adhesions. The coccyx should also be palpated with the single digit, and an attempt should be made to move it 30 degrees or less. This may be easier to evaluate during the rectovaginal examination. Normally the coccyx moves 30 degrees without eliciting pain, but in patients with coccydynia this movement elicits pain. The ureteral and the adnexal areas should be palpated next, still using a single digit without the use of the abdominal hand. All of the preceding evaluations are “monomanual-monodigital”—that is, only one finger of one hand is used. No abdominal palpation with the other hand is involved.

Examination with a moistened cotton-tipped swab may be more useful than the single-digit examination to evaluate the vulva and the vulvar vestibule for tenderness. This is particularly useful in patients with localized vulvodynia (vulvar vestibulitis), who have exquisite tenderness in localized areas at the minor vestibular glands just external to the hymen, with normal sensation in adjacent vulvar areas. Sometimes palpation with a

cotton-tipped swab also can elicit allodynia in a neural distribution in women with pudendal neuralgia. A cotton-tipped swab can be used to evaluate the cervical os and the paracervical and cervical tissues for tenderness. In posthysterectomy patients the full vaginal cuff should be similarly palpated for tenderness with a cotton-tipped swab.

The traditional visual, speculum, and bimanual examinations are still needed for a thorough evaluation, but they should usually follow the single-digit examination. The pain or tenderness

**Table 4-8**  
**Components of the Lithotomy Physical Examination of the Woman with Chronic Pelvic Pain**

Lithotomy Examination	Possible Problems Diagnosed
Visual inspection of the external genitalia	Inflammatory and infectious disease; vulvar abscess; trauma; fistula; ulcerative disease; pigmented lesions (neoplasias); condylomata; atrophic changes; fissure
Basic sensory testing to sharpness, dullness, and light touch	Nerve entrapment; neuropathy; spinal cord lesion
Cotton-tipped swab evaluation of the vestibule	Vulvar vestibulitis
Single-digit palpation of vulva and pubic arch	Trigger points
Colposcopic evaluation of the vulva and vestibule	Neoplasia
Sims retractor or single-blade speculum examination of vagina and pelvic muscles	Enterocoele; cystocele; rectocele; uterine descensus
Cotton-tipped swab evaluation of cervical os, paracervical and cervical tissues	Trigger points
Cotton-tipped swab evaluation of vaginal cuff	Trigger points; neuroma
Single-digit pelvic examination of introitus	Vulvar vestibulitis; vaginismus; trigger points
Single-digit pelvic examination of levator ani	Pelvic floor pain syndrome, trigger points
Single-digit pelvic examination of coccygeus	Pelvic floor pain syndrome; trigger points
Single-digit pelvic examination of piriformis with and without abduction	Piriformis syndrome
Single-digit pelvic examination of anterior vaginal urethral and trigonal evaluation	Chronic urethral syndrome; urethritis; cystitis; interstitial cystitis; trigonitis; urethral diverticulum; vaginal wall cyst
Single-digit pelvic examination of cervix, paracervical areas, and vaginal fornices	Trigger points; endometriosis; cervicitis; repeated cervical trauma; pelvic infection; ureteral pain
Single-digit pelvic examination of uterus	Adenomyosis; pelvic congestion syndrome; pelvic infection; premenstrual syndrome; adhesions
Single-digit pelvic examination of coccyx	Coccydynia
Single-digit pelvic examination of adnexa	Pelvic congestion syndrome; endometriosis
Bimanual pelvic examination	See text
Rectovaginal examination	See text

Table 4-9 Diagnostic Tests Useful in the Evaluation of Women with Chronic Pelvic Pain	
Symptom, Finding, or Suspected Diagnosis	Potentially Useful Tests
Adenomyosis	Ultrasonography; hysterosalpingography, MRI
Chronic urethral syndrome	Urodynamic testing
Compression or entrapment neuropathy	Nerve conducting velocities; needle electromyographic studies
Constipation	Anorectal balloon manometry; colonic transit time
Diarrhea	Stool specimens for ova and parasites; stool polymorphonuclear leukocytes and red blood cells; stool cultures; stool for <i>C. difficile</i> toxin; stool guaiac testing; barium enema radiography; colonoscopy; upper gastrointestinal series with follow-through; CT
Diverticular disease	Barium enema radiograph
Dyspareunia	Urethral and cervical gonorrhea and chlamydia cultures; chlamydial PCR testing; vaginal cultures; urine cultures; vaginal wet preparations; vaginal pH
Endometriosis	Ca-125; ultrasonography; barium enema radiography; hysterosalpingography; CT; MRI
Hernias	Abdominal wall ultrasonography; CT; herniography
Interstitial cystitis	Cystourethroscopy; KCl bladder challenge test; urine culture; urine cytologies; urodynamic testing; bladder biopsy
Ovarian remnant syndrome	Follicle-stimulating hormone; estradiol; gonadotropin releasing hormone agonist stimulation test; ultrasonography ± clomiphene stimulation; barium enema radiography; CT
Ovarian retention syndrome	Ultrasonography; CT
Pelvic congestion syndrome	Pelvic venography; ultrasonography ± Doppler
Pelvic tuberculosis	Chest x-ray; PPD skin test
Porphyria	Urine porphobilinogen
Urethral diverticulum	Vaginal sonography; voiding cystourethrography; double balloon cystourethrography; MRI

CT, computed tomography; KCl, potassium chloride; MRI, magnetic resonance imaging; PCR, polymerase chain reaction; PPD, purified protein derivative.

elicited with the bimanual examination is less specific, because it involves stimulation of all layers of the abdominal wall, the parietal peritoneum, and the palpated organ or organs. Including the rectovaginal examination is important in most women with chronic pelvic pain, looking particularly for nodularity and tenderness, suggesting endometriosis.

A thorough history and examination often are diagnostic. Further diagnostic testing may or may not be deemed necessary. Table 4-9 lists some of the diagnostic tests that may be helpful in the evaluation of women with chronic pelvic pain.

Laparoscopy is a particularly important diagnostic test in the evaluation of pelvic pain—more than 40% of gynecologic

diagnostic laparoscopies are done for chronic pelvic pain. It is important to remember that a negative laparoscopy is not synonymous with no diagnosis or no disease and does not mean that a woman has no physical basis for her pain. Discriminative use of laparoscopy, carefully based on the patient's history, physical examination, laboratory, and imaging findings might decrease the rate of negative laparoscopies from 39% to 4%.

Diagnostic laparoscopy under local anesthesia, termed *conscious laparoscopic pain mapping* or *patient-assisted laparoscopy*, has been suggested as a way to improve the diagnostic capability of laparoscopy.<sup>10,11</sup> The stimulus used with conscious laparoscopic pain mapping is a gentle probing or tractioning of tissues, lesions, and organs with a blunt probe or forceps passed through a secondary trocar site. Diagnosis of an etiologic lesion or organ is based on the severity of pain elicited and on replication of the pain that is the patient's presenting symptom. Chronic pelvic pain, however, is a multifaceted and complicated problem, and it is not established that the findings with mechanically elicited pain at conscious pain mapping directly translate into cause and cure. Published data from an observational controlled study failed to show any improvement in outcome.<sup>10</sup>

### Irritable Bowel Syndrome

Irritable bowel syndrome appears to be the most common diagnosis in women with chronic pelvic pain,<sup>12</sup> with symptoms suggestive of IBS in 50% to 80%. The diagnosis is based on the history (Table 4-10); usually extensive laboratory and radiologic tests are not necessary. In the patient with suspected IBS a complete blood cell count with differential, chemistry profile, and sedimentation rate are suggested. The complete blood cell count helps rule out anemia and inflammation or infection. The sedimentation rate similarly helps rule out an inflammatory process. The white blood cell differential is useful in evaluating parasitic infection (which often causes eosinophilia), tuberculosis (which causes monocytosis), and inflammation (which may cause toxic granulation). With IBS the chemistry profile should be normal, whereas in inflammatory bowel disease electrolyte abnormalities are more likely. To rule out infection with *Giardia*, amoeba, and other parasites, three stool specimens should be sent for ova and parasite testing.

Table 4-10  
Rome II Criteria for the Diagnosis of Irritable Bowel Syndrome

At least 12 weeks, which need not be consecutive, in the preceding 12 months of abdominal discomfort or pain that has two or three features:

1. relieved with defecation, and/or
2. onset associated with a change in frequency of stool, and/or
3. onset associated with a change in form (appearance) of stool

Supportive symptoms of irritable bowel syndrome:

- <3 bowel movements/week
- >3 bowel movements/day
- Hard or lumpy stools
- Loose or watery stools
- Straining during a bowel movement
- Urgency
- Feeling of incomplete bowel movements
- Passing mucus
- Abdominal fullness, bloating, or swelling

Stool also should be checked for occult blood; results should be negative in IBS patients. Similarly, methylene blue stain of stool to look for white blood cells should be negative with IBS, because the presence of large numbers of white blood cells is diagnostic of inflammation. A Sudan stain for fat can be performed to exclude severe steatorrhea, if suspected. Stools should be checked for *Clostridium difficile* toxin if there has been antibiotic exposure within the past 6 weeks.

The possibility of lactose intolerance can be formally tested with a hydrogen breath test if there is any question. The breath test is much more sensitive than the blood test.

Some of the findings that mandate more extensive diagnostic testing to rule out more serious pathology are blood in stool, weight loss, ascites, watery bowel movements more than three times per day, an abdominal mass, or fever.

### Interstitial Cystitis

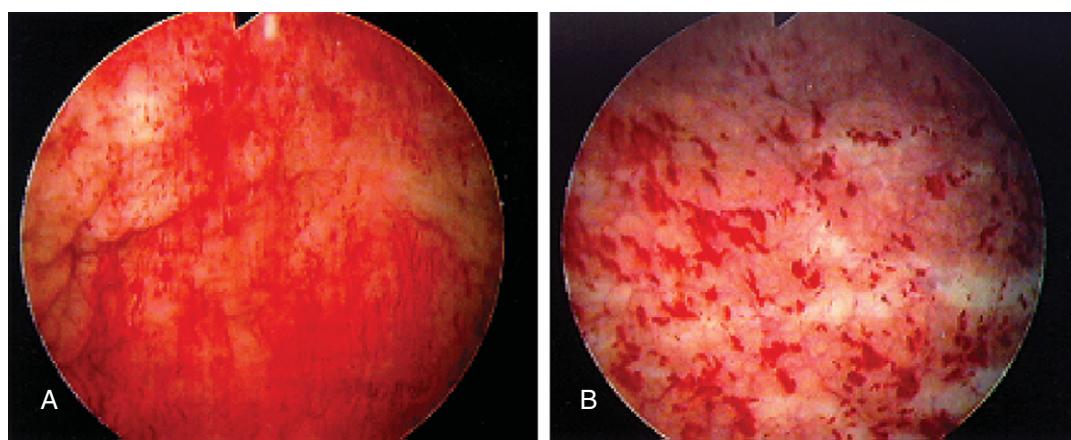

Interstitial cystitis is a chronic inflammatory condition of the bladder of unknown etiology. The criteria to diagnose interstitial cystitis are controversial, but most often it is defined clinically by the following triad: urinary urgency and frequency, pelvic pain, and mucosal hemorrhages with cystoscopic hydrodistention. Hunner's ulcer at the time of cystoscopy is considered pathognomonic but is not a common finding. Voiding frequency with interstitial cystitis is usually every 2 hours or less during the day and two or more times at night. Incontinence is not a common symptom. Evaluation should show the absence of objective evidence of another urinary tract disease that could cause the symptoms. Bladder tumors, especially carcinoma in situ, may cause symptoms similar to those of interstitial cystitis.

Cystoscopy with hydrodistention causes mucosal hemorrhages, called *glomerulations*, in patients with interstitial cystitis, although there are false-positive cystoscopies. In addition to glomerulations (Fig. 4-3), linear cracking and Hunner's ulcer may also be noted. Because significant bladder distention is needed to perform this test and this is very painful in women with interstitial cystitis, general or spinal anesthesia is usually necessary.

Cystoscopy for the diagnosis of interstitial cystitis is performed as follows: The bladder is passively distended to a pressure of 60 to 80 cmH<sub>2</sub>O. This may require compression of

the urethra by upward digital compression of the anterior vaginal wall against the urethroscope to prevent leakage. Although the risk is low, it is possible to rupture the bladder in interstitial cystitis patients during this distention. Findings during this first filling are usually normal, although occasionally increased trabeculation or Hunner's ulcer may be noted. As soon as maximal capacity is reached, the volume is noted. Distention is maintained for 3 to 5 minutes and then the irrigant is drained. If videocystoscopy is performed and the bladder is visualized during this emptying phase, diffuse bleeding from the mucosa is noted that causes the terminal portion of drained irrigant to be blood-tinged (see Fig. 4-3). The bladder is refilled and examination reveals splotchy, submucosal hemorrhages (glomerulations) throughout the bladder of the patient with interstitial cystitis. Bladder biopsies are useful but not essential unless other abnormalities are seen. In such cases biopsies must be done to rule out carcinoma in situ or cancer. Up to 1% of women diagnosed with interstitial cystitis may actually have carcinoma in situ. It is important that any infection has been cleared for several weeks before cystoscopy, not only because of infection concerns, but also because current or recent infection may cause cystoscopic findings similar to those of interstitial cystitis. Postprocedure pain may be decreased by instillation of a dilute solution of local anesthetic after completing cystoscopy (for example, 30 mL of 0.25% bupivacaine).

The potassium sensitivity test has been proposed as an office screening test for interstitial cystitis. This test evaluates pain and urgency after intravesical instillation of 40 mL of potassium chloride (0.4 mEq/mL) compared to symptoms with 40 mL of water. It is reportedly positive in 70% to 90% of patients with interstitial cystitis. As many as 85% of women evaluated by gynecologists for chronic pelvic pain may have positive intravesical potassium sensitivity tests.<sup>13</sup> It is probably appropriate to diagnose interstitial cystitis in women with characteristic symptoms and a positive potassium sensitivity test. Pain caused by a positive potassium sensitivity test should be alleviated by intravesical instillation of 20 to 30 mL of 1% lidocaine or 0.5% bupivacaine. Figure 4-4 shows a questionnaire that may expedite the identification of patients likely to have interstitial cystitis.

**Figure 4-3 Glomerulations with cystoscopic hydrodistention in a patient with interstitial cystitis.** A, Mucosal hemorrhages during emptying phase after hydrodistention. B, Glomerulations after refilling the bladder.

PELVIC PAIN and URGENCY/FREQUENCY PATIENT SYMPTOM SCALE					
Please circle the answer that best describes how you feel for each question.					
	0	1	2	3	4
1	How many times do you go to the bathroom during the day?				
2	a. How many times do you go to the bathroom at night? b. If you get up at night to go to the bathroom does it bother you?				
3	Are you currently sexually active? YES _____ NO _____				
4	a. IF YOU ARE SEXUALLY ACTIVE, do you now or have you ever had pain or symptoms during or after sexual intercourse?  b. If you have pain, does it make you avoid sexual intercourse?				
5	Do you have pain associated with your bladder or in your pelvis (vagina, lower abdomen, urethra, perineum, testes, or scrotum)?				
6	Do you have urgency after going to the bathroom?				
7	a. If you have pain, is it usually b. Does your pain bother you?				
8	a. If you have urgency, is it usually b. Does your urgency bother you?				
SYMPTOM SCORE = (1, 2a, 4a, 5, 6, 7a, 8a)					
BOTHER SCORE = (2b, 4b, 7b, 8b)					
TOTAL SCORE (Symptom Score + Bother Score) =					

**Figure 4-4** The PUF questionnaire: a screening questionnaire that may be useful in identifying patients with interstitial cystitis.

## **Endometriosis**

Endometriosis is the presence of ectopic endometrial glands and stroma (i.e., endometrium located outside of the endometrial cavity). Classically the woman with endometriosis presents with one or more of the following triad: an adnexal mass (endometrioma), infertility, or pelvic pain. Estimates are that

5% to 40% of women with endometriosis have chronic pelvic pain. Endometriosis-associated pain almost always starts as menstrual pain, then progresses to include more and more of the luteal phase, and in many women progresses to constant pain with premenstrual and menstrual exacerbation. Most women with endometriosis-associated pelvic pain have severe dysmenorrhea

as a component of their pain symptoms. Dyspareunia is present in at least 40%. The clinical diagnosis of endometriosis based on the history and physical examination is accurate in about 85% of women with chronic pelvic pain, but for absolute confirmation of the diagnosis there must be histological confirmation of ectopic endometrium. A solely visual diagnosis at the time of laparoscopy has a significant false-positive rate.

### Pelvic Inflammatory Disease

From 15% to 30% of all women with acute PID subsequently develop chronic pelvic pain. PID is most common among teenagers and women younger than age 25, which is about a decade younger than the mean age of women with chronic pelvic pain. Chronic pelvic pain secondary to prior PID is usually related to coitus and physical activity and is acyclic, although sometimes there may be premenstrual or menstrual exacerbation. The diagnosis is based on past history of PID and on operative findings consistent with prior PID, such as adnexal adhesions, tubo-ovarian complexes, tubal agglutination and phimosis, and hydrosalpinges. Little is known about the actual mechanisms by which chronic pelvic pain results from PID. Some evidence suggests it is related to the severity of adnexal adhesions and damage.

Antibiotic treatment is often empirically tried in women with suspected chronic pelvic inflammatory disease or sub-clinical, chronic pelvic infection. There is scant evidence that any pathogenic microorganisms persist in the uterus or tubes after PID, and there is no published evidence of efficacy of empiric antibiotic treatment of chronic pelvic pain when there is no suggestion of active, acute infection.

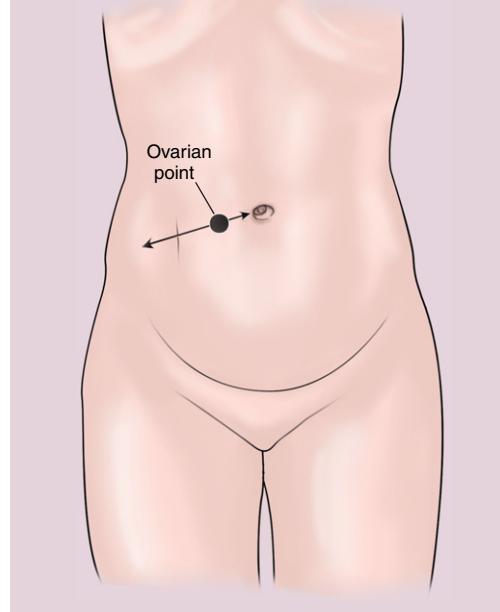

Although not a common diagnosis in the United States, tuberculous PID must be remembered as a potential diagnosis in patients with chronic pelvic pain, especially as the incidence of tuberculosis has increased in association with human immunodeficiency virus infection/acquired immunodeficiency syndrome. As many as 25% of women with pulmonary tuberculosis have pelvic tuberculosis, and about 25% of women with pelvic tuberculosis will have chronic pelvic pain.

### Pelvic Congestion Syndrome

Although not a common cause of chronic pelvic pain, pelvic congestion syndrome may be more common than generally recognized. Pain associated with pelvic congestion is typically worst premenstrually and although menstrual pain may be present, menses are not usually the time of most severe pain. Pain is usually dull and aching, similar in quality to the leg pain produced by leg varicosities. It is usually not constant and may be brought on by simple acts such as walking or changing posture. Occasional acute, severe exacerbations of sharp pain may occur. Backache is common, characteristically sacral in position, and made worse by standing. Deep dyspareunia is present in three fourths of women with pelvic congestion syndrome. Postcoital aching pain, lasting in some cases up to 24 hours, is present in 65% of cases.

Abdominal palpation at the ovarian point, which lies at the junction of the upper and middle thirds of a line drawn from the anterior superior iliac spine to the pubic symphysis (Fig. 4-5) reproduces the pelvic pain in 80% of women with pelvic congestion syndrome. Diffuse pelvic tenderness, particularly at the adnexae, is characteristic at bimanual pelvic examination.

The ovarian point, which produces pain in 80% of women with pelvic congestion syndrome

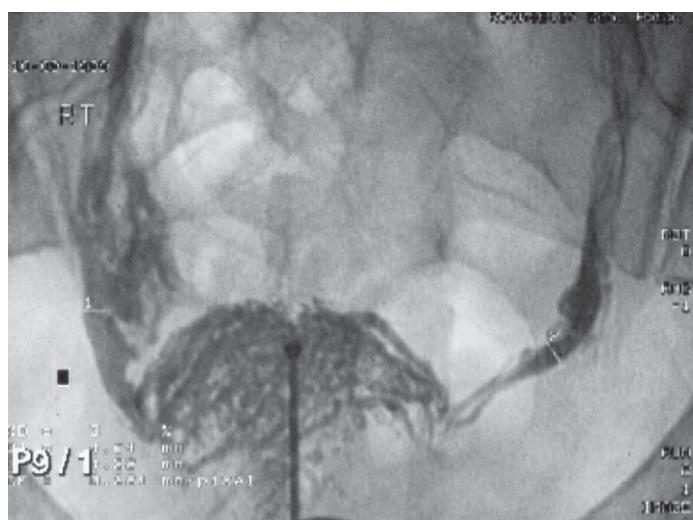

**Figure 4-5** The ovarian point, which reproduces pain in 80% of women with pelvic congestion syndrome.

The diagnosis is confirmed by pelvic venography showing venous stasis, dilation, and plexus formation of the ovarian or uterine vessels. Venography can be performed by transuterine injection of the myometrium (Fig. 4-6) or by retrograde injection of the ovarian veins.

### Adhesions

Adhesions are aberrant fibrous tissues that abnormally attach anatomic structures to one another. Immediately following a peritoneal wound, a cascade of events is unleashed that ultimately determines whether or not adhesions develop. In women

**Figure 4-6** Example of a positive transuterine pelvic venogram.

the major causes of adhesions are surgery, PID, appendicitis, endometriosis, inflammatory bowel disease, and neoplasia. Postmortem studies reveal that 67% of all patients develop adhesions postoperatively.

It is generally accepted that adhesions can cause intestinal obstruction and infertility, but their role as a cause of chronic pelvic pain is not clear. There is an association between adhesions and chronic pelvic pain, because intra-abdominal and pelvic adhesions are found more often in women with chronic pelvic pain than in women without pain, but this association does not prove causation. Laparoscopic conscious pain mapping has demonstrated that at least one third of patients with adhesions have focal, dramatic tenderness of some of their adhesions.<sup>10</sup> This suggests that adhesions cause pain in some, but not all, women with pelvic adhesions.

Pelvic pain due to adhesions is usually consistent in its location and may be exacerbated by sudden movements, intercourse, or certain physical activities. A history of PID, endometriosis, perforated appendix, prior abdominopelvic surgery, or inflammatory bowel disease makes adhesive disease a more likely diagnosis. A history of at least one of these is present in only 50% of women with adhesions, however.

Although nonsurgical methods such as computed tomography, magnetic resonance imaging, or ultrasound may suggest the presence of adhesions, presently the only definitive way to diagnose them is by surgical visualization. Laparoscopy, not laparotomy, is the gold standard for diagnosing pelvic adhesive disease.

### Chronic Pain Syndrome

Some chronic pain sufferers seem to maintain a good level of physical and psychological function despite significant pain, whereas others develop a set of emotional and behavioral characteristics that is called *chronic pelvic pain syndrome* (Table 4-11). The recognition of chronic pelvic pain syndrome can be critical to the successful treatment of chronic pelvic pain. In general, surgical and medical treatment are less successful in women with chronic pain syndrome compared to those without chronic pain syndrome.<sup>14</sup>

### Depression

The etiologic relationship between depression and chronic pain is complex and confusing. Regardless, depression is one of the

major findings that leads to a diagnosis of chronic pain syndrome and it is a major predictor of pain severity and response to treatment. It is important to seek evidence of depression in women with chronic pelvic pain.

## TREATMENT

Two primary approaches to the treatment of chronic pelvic pain are used:

1. Treatment of pain (pain-specific treatment)
2. Treatment of specific diseases responsible for chronic pelvic pain (disease-specific treatment)

Randomized clinical trials have been conducted to evaluate treatment of several of the common diagnoses associated with chronic pelvic pain, such as endometriosis, IBS, and interstitial cystitis. Pain-specific treatment of chronic pelvic pain is not as well studied.

### Disease-Specific Treatment

#### *Endometriosis*

Endometriosis may be treated surgically, medically, or with combined surgical and medical therapy. Laparoscopic surgical treatment by destruction of endometriotic lesions and lysis of adhesions relieves pain in a substantial percentage of patients. One published randomized, clinical trial of laparoscopic treatment showed that at 6 months, 63% of patients had significant relief of pain (the placebo effect was 23%).<sup>15</sup> This study showed a number needed to treat of 2.5, meaning that to obtain pain relief at 6 months in two women it is necessary to surgically treat five women.

Neurolytic procedures, particularly uterosacral ligament transections and presacral neurectomy, are sometimes performed to treat endometriosis-associated pelvic pain. Controlled clinical trials suggest that presacral neurectomy (excision of the superior hypogastric plexus) gives a small improvement in pain relief over that obtained with excision of endometriosis alone, with a number needed to treat for presacral neurectomy of 4.8 (meaning five patients would need to have a presacral neurectomy performed, in addition to excision of endometriosis, to have one patient who is better because of the presacral neurectomy).<sup>16,17</sup> However, transection of the uterosacral ligaments showed no efficacy in the treatment of endometriosis-associated pelvic pain over that obtained with only surgical excision of lesions in randomized clinical trials.<sup>18,19</sup> Transection of the uterosacral ligaments may have efficacy for the treatment of primary, central dysmenorrhea in women without endometriosis, with a number needed to treat of 2.2.<sup>20</sup>

Although hysterectomy and bilateral salpingo-oophorectomy are thought to be curative for endometriosis, no clinical trials of hysterectomy or salpingo-oophorectomy for endometriosis-associated pelvic pain have been reported. It is probably important that all endometriosis be resected or destroyed at the time of hysterectomy and bilateral salpingo-oophorectomy to minimize the potential of recurrence.

The mainstay of medical treatment of endometriosis-associated pelvic pain is hormonal, usually with oral contraceptives, danazol, progestins, or gonadotropin-releasing hormone (GnRH) agonists. Danazol and GnRH agonists are approved by

**Table 4-11**  
**Criteria for Chronic Pelvic Pain Syndrome**

Chronic pelvic pain (usually pain of 6 or more months' duration)
Pain out of proportion to pathology
Altered physical activities at home or work (e.g., stopping running or playing tennis, stopping working)
At least one vegetative sign of depression, usually early-morning awakening not caused by pain
Significantly altered emotional roles within the family or identification of the patient's illness as the most significant problem the family faces. Examples of alterations of emotional roles are:
Family decision making
Supervision and discipline of children
Nurturing of children and partner

the Food and Drug Administration (FDA) for endometriosis treatment. The GnRH agonists available in the United States are nafarelin, goserelin, and leuprolide. They work at the hypothalamic-pituitary level to shut down luteinizing hormone and follicle-stimulating hormone production and release. This down-regulation leads to a dramatic decline in estradiol levels. GnRH agonists have been evaluated in several placebo-controlled, randomized clinical trials, as well as numerous trials comparing them to danazol. Placebo-controlled trials suggest that the number needed to treat for GnRH agonists for endometriosis-associated pelvic pain is 2.0 to 2.5.<sup>21,22</sup> Comparative trials suggest that danazol and GnRH agonists have similar efficacies, whereas oral contraceptives and progestins may be somewhat less effective. The only placebo-controlled trial of medroxyprogesterone acetate, a commonly prescribed progestin, used a high dose, 100 mg/day. Lower doses and other progestins are probably effective. Side effects observed with medical therapy include breakthrough bleeding, mood changes, depression, hot flushes, weight gain, and irritability. Danazol may also cause androgenic side effects. Loss of bone density is a concern with GnRH agonists.

To minimize loss of bone density, GnRH agonist treatment may be given for less than 6 months<sup>23</sup> or add-back treatment with estrogen and/or progestins may be used. Add-back regimens evaluated with clinical trials include conjugated equine estrogen (0.625 mg or 1.25 mg) plus norethindrone acetate (2.5 mg or 5 mg) or norethindrone acetate alone.<sup>24</sup> All of the add-back regimens significantly decreased the loss of bone density (they also decreased hot flashes), but they slightly increased the likelihood of breakthrough bleeding and pain symptoms.

Preliminary results with mifepristone, an antiprogestrone, suggest that it induces amenorrhea and improves endometriosis-associated pelvic pain when given at 50 to 100 mg daily. It may be possible to achieve similar results with lower doses, but this remains to be adequately studied.

### **Interstitial Cystitis**

Dimethylsulfoxide (DMSO) was the first FDA-approved drug indicated for interstitial cystitis. Intravesical treatments with DMSO are usually repeated four to eight times at 1- to 2-week intervals. In addition to subjective evidence of decreased symptoms, objective evidence of significantly increased bladder capacity (<100 mL increase) has also been demonstrated. The number needed to treat for DMSO therapy of interstitial cystitis-associated pelvic pain is estimated at 3.6.<sup>25</sup> Unfortunately, DMSO treatments result only in remission of disease, not cure. At least 30% to 60% of patients relapse within the first year after successful treatment. Other intravesical therapies for interstitial cystitis have been less extensively studied and none other than DMSO has FDA approval for treatment of interstitial cystitis.

The other FDA-approved treatment of interstitial cystitis is oral pentosan polysulfate sodium, a polyanionic analog of heparin. One randomized clinical trial showed decreased pelvic pain in 45% of treated patients, compared to 18% with placebo, giving a number needed to treat of 3.7.<sup>26</sup> The dosage of sodium pentosan polysulfate is 100 mg orally three times a day.

Intravesical capsaicin therapy, in a small, placebo-controlled, randomized clinical trial of 36 patients showed significant

improvements in frequency and nocturia, but no improvement in pain levels.<sup>27</sup> A small placebo-controlled trial of intravesical bacillus Calmette-Guerin showed a response rate of 60%, compared to 27% in the placebo group, with a mean decrease of pain in 81%.<sup>28</sup> Amitriptyline also has shown efficacy in a clinical trial, but anticholinergic side effects hinder its use.<sup>29</sup>

Oral cyclosporine, L-arginine, nifedipine, and hydroxyzine have been used to treat interstitial cystitis but have not been substantiated as effective in randomized clinical trials.

The primary surgical treatment of interstitial cystitis for more than 50 years has been hydrodistention of the bladder. This procedure can be performed at the time of diagnostic cystoscopy if general or spinal anesthesia is used—hydrodistention is too painful to be done without anesthesia. Observational studies suggest that about 50% of patients have a successful response to hydrodistention. Remission generally lasts for 6 to 10 months, with a gradual recurrence of symptoms in almost all patients. Retreatment with hydrodistention has a greatly diminished success rate.

Neurolytic surgery via laser destruction of the vesicoureteric plexus has been reported to show some degree of success, but only in uncontrolled studies with limited follow-up. Further confirmation is essential before this procedure is widely used. Nd:YAG laser treatment has also been used, but data are limited regarding its efficacy.

Approximately 5% of patients have unresponsive, intractable, incapacitating symptoms. Such patients usually have small-capacity bladders (<400 mL), void 18 to 20 times per day, and have severe, uncontrolled pain. Augmentation cystoplasty or cystectomy-urethrectomy-continent diversion have been the most successful and acceptable radical surgical treatments.

### **Irritable Bowel Syndrome**

Dietary interventions constitute the initial approach to IBS. Lactose, fructose, and sorbitol can contribute to symptoms and should be eliminated from the diet, at least on a trial basis. Caffeinated products, carbonated beverages, and gas-producing foods (such as broccoli, cabbage, Brussels sprouts, asparagus, cauliflower, and beans) may contribute to bloating and should be avoided if possible. Smoking and chewing gum lead to more swallowed air and may also increase gas and bloating. Excessive alcohol consumption may lead to increased rectal urgency. Fiber supplementation is often useful for both diarrhea and constipation symptoms.

Pharmacologic treatment is not specific to the disease but rather is directed to relief of symptoms. Patients may be divided into one of three major symptom categories, depending on which symptoms are dominant. The three symptom categories are abdominal pain, gas, and bloating; constipation predominant; and diarrhea predominant. Unfortunately many patients do not fall clearly into one of these three groups but have overlapping symptoms. The severity of the symptoms also influences the choice of pharmacologic treatment.

With predominantly abdominal pain, gas, and bloating symptoms, a trial of an antispasmodic is suggested if there is no evidence of small bowel obstruction. Commonly used antispasmodics are dicyclomine (Bentyl), hyoscyamine (Levsin), Donnatal, and Librax. None has been shown to be consistently efficacious. Because many patients have these symptoms

## Ambulatory Office Practice

postprandially, it is best to give these medications 30 minutes before meals. Beano (a D-galactosidase) or a simethicone preparation (Gas X, Phazyme) also can be tried.

If constipation is the predominant symptom, a trial of increased roughage and psyllium is prescribed. Many patients have increased gas with increased fiber, and about 15% cannot tolerate fiber therapy. It is recommended, therefore, that fiber be increased gradually and be taken with a meal (usually breakfast). Sometimes tap water enemas during the initiation of fiber supplements are helpful. If necessary, a stool softener or osmotic laxative also can be used temporarily. An insufficient dose of fiber is a frequent cause of failure. Chronic use of stimulant laxatives should be discouraged. There may be a role for prokinetic agents in constipation, but data from clinical trials have been inconsistent. Cisapride, one of the most studied agents, is no longer readily available, because its use has been restricted in the United States. Tegaserod is FDA-approved for constipation-predominant IBS, but its approval is for 12 weeks of treatment.

In diarrhea-predominant patients, over-the-counter loperamide is a commonly used agent. An advantage of loperamide over many other antidiarrheal agents is that it does not cross the blood-brain barrier. Ondansetron, a serotonin receptor antagonist that slows colonic transit time may be useful in the treatment of diarrhea-predominant IBS, but studies have shown inconsistent results. Ondansetron is not approved by the FDA for this indication.

Peppermint oil is the major constituent of several over-the-counter remedies for IBS. It is a safe and inexpensive treatment, but clinical trials have shown inconsistent efficacy.

Psychotherapy with cognitive/behavioral therapy (including stress management), dynamic psychotherapy, hypnosis, and relaxation therapy may be helpful and may improve clinical response over medical treatment only. Factors that predict a good response to psychotherapy include diarrhea and pain as the predominant symptoms, the association of overt psychiatric symptoms, intermittent pain exacerbated by stress, short duration of bowel complaints, and few sites of abdominal pain. Patients with constant abdominal pain do poorly with psychotherapy or hypnotherapy. A recent review of controlled trials of psychological treatments for IBS found that 8 out of 14 studies reported that psychological therapy was significantly superior to control treatment in reducing the primary symptoms of IBS.<sup>30</sup>

### **Adhesions**

The traditional treatment of abdominopelvic adhesions is surgical adhesiolysis. The only randomized trial of adhesiolysis for chronic pelvic pain failed to show any significant improvement after lysis of adhesions by laparotomy, compared to a control group that did not undergo adhesiolysis.<sup>31</sup> Only when a subgroup analysis of 15 women with severe, stage IV adhesions was done could any detectable improvement in pain be attributed to adhesiolysis. A randomized trial of laparoscopic adhesiolysis for abdominal pain (in men and women) also failed to show any significant difference between surgically treated versus non-treated patients.<sup>32</sup>

A problem with studies of surgical adhesiolysis is that there are no effective methods for preventing recurrence of adhesions. The current adhesion barriers, oxidized regenerated

cellulose (Interceed, Johnson & Johnson Medical, Arlington, Tex.), Gore-Tex surgical membrane (W.L. Gore, Flagstaff, Ariz.), and hyaluronic acid-methylcellulose (Seprafilm, Genzyme, Cambridge, Mass.), are only somewhat effective and at best prevent up to 50% of adhesion recurrence. Crystalloid fluids, such as Ringer's solution, are easy to use, but are not effective. Colloid fluid such as Dextran 70 can cause rapid fluid shifts and anaphylactic reactions.

Adhesions will likely remain a cause for some cases of chronic pelvic pain until a method to prevent adhesions is found.

### **Pain-Specific Treatment**

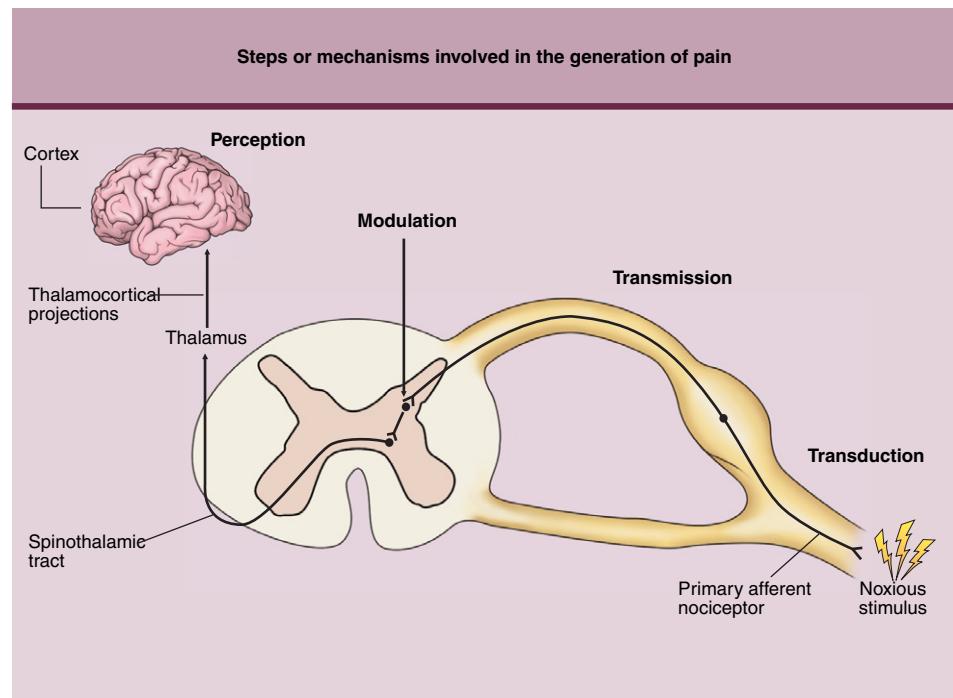

The fundamental steps involved in nociception provide a framework that helps explain the difference between pain-specific treatment and disease-specific treatment (Fig. 4-7). In general, disease-specific treatment attempts to remove the noxious stimulus and prevent transduction (the conversion of a noxious stimulus into a biochemical event that activates a nociceptor). Pain-specific treatment is directed not to the noxious stimulus but rather to the fundamental processes involved in nociception (i.e., transduction, transmission, modulation, or perception). Pain-specific treatment can be a crucial component of therapy because disease-specific treatment often gives inadequate pain relief. Pain-specific treatment may be pharmacological, psychological, physical, or neuroablative.

### **Pharmacologic Treatment**

The mosaic of neural elements and chemical mediators involved in pain perception make it possible to decrease pain with medications with different pharmacologic profiles and mechanisms. Oral analgesics are particularly important in the treatment of pain, yet optimization of analgesic medications is sometimes overlooked in the initial treatment of chronic pelvic pain. Optimization of analgesia is usually best accomplished with a scheduled regimen, not an as-needed regimen. However, a scheduled regimen also presents some hazards. For example, with nonsteroidal anti-inflammatory drugs (NSAIDs) it may lead to gastric irritation or renal damage and with opioids it may lead to constipation, sedation, habituation, addiction, or diminished analgesic potency.

### **Peripheral-Acting Analgesics**

Aspirin is a prototype peripheral-acting analgesic. It interferes with transduction by acting to inhibit prostaglandin synthesis, which decreases inflammation and the activation of nociceptors, and by blocking the action of bradykinin on pain receptors. The NSAIDs generally work via the same mechanisms, although potencies may vary significantly. The potential of side effects with NSAIDs is significant and their chronic use requires careful observation, especially for gastric or intestinal ulceration with gastrointestinal bleeding and less commonly for nephropathy. NSAIDs also inhibit platelet function and may lead to significant bleeding. They promote retention of salt and water and may cause edema in some patients. Certain individuals have intolerance to NSAIDs and display a "hypersensitivity reaction" to them that can manifest as vasomotor rhinitis, angioneurotic edema, urticaria, bronchial asthma, laryngeal edema, bronchoconstriction, or hypotension and shock. A history of hypersensitivity reaction to aspirin is an absolute contraindication to

**Figure 4-7 Steps or mechanisms involved in the generation of pain.**

the use of any NSAID. Such hypersensitivity reactions do not appear to occur with acetaminophen.

#### Opioid Analgesics

Although still controversial, the use of opioid analgesics to treat chronic pain is common in pain centers. Chronic dose opioid therapy provides improved quality of life and daily function in many patients who have failed other treatments.<sup>33</sup>

Some of the a priori bias of physicians against opioid treatment of chronic pelvic pain stems from a lack of understanding of the difference between tolerance, dependence, and addiction. Tolerance is the diminution of effectiveness over time from the same dose of drug. Physical dependence is the appearance of an abstinence syndrome if the drug is withdrawn. The initial symptoms of the abstinence syndrome are yawning, diaphoresis, lacrimation, coryza, and tachycardia, followed by peak symptoms at 72 hours of abdominal cramps, nausea, and vomiting. Withdrawal symptoms can be minimized by tapering opioids prior to discontinuation and by avoiding the use of antagonists. The term *addiction* should probably be replaced by the term *psychological dependence*. Psychological dependence represents a mental illness manifest by aberrant behaviors, consisting of drug craving, efforts to secure its supply, interference with physical health or psychological function, and recidivism after detoxification. Although tolerance and physical dependence are significant problems with opioid treatment, psychological dependence or addiction is the only complication that leads to unacceptable and illegal behavior by the patient. Greater than 90% of pain patients on chronic opioid maintenance never manifest addictive behavior.<sup>34</sup> Clinical experience suggests that a prior history of addiction to legal or illegal substances is a major risk factor and that patients with such histories are not good candidates for opioid treatment of chronic pelvic pain. The diagnosis and treat-

ment of addiction can be difficult; it is best diagnosed and managed by an expert on treatment of substance abuse.

After all traditional attempts at pain control have failed, opioid maintenance therapy for chronic pelvic pain should be considered.<sup>33</sup> Before opioid treatment is initiated there should be documentation that the patient has failed nonnarcotic treatment and has entered knowingly into a trial of opioid maintenance. A written or documented verbal contract or agreement should be made with the patient that includes at least the following particulars:

- The treating doctor is the sole provider of opioids
- The patient is seen by this physician before having her opioid prescription refilled
- Lost medications or prescriptions will not be refilled
- The patient agrees she will actively participate in strategies to develop alternative pain therapies.

Some physicians have advocated inclusion of random urine drug testing as a condition of opioid maintenance therapy.

Combining opioid treatment with central-acting and peripheral-acting medications may optimize efficacy with lower opioid doses, but use of commercially available formulations of opioids with acetaminophen, aspirin, or ibuprofen can lead to overdosage of the nonopioid drug. All medications are best given on a scheduled, not an as-needed, basis. Titration of the selected opioid should be done over several weeks with the goals of improvement in physical and social function and at least partial analgesia. Failure to achieve these goals at relatively low doses in the nontolerant patient should cause the clinician to question the feasibility of opioid maintenance therapy.

It is important to assess the extent of pain relief provided by the opioid medication and determine its role in restoring function and improving quality of life. When improved function and

reasonable analgesia are achieved, close and regular follow-up is essential in chronic pelvic pain patients on opioid maintenance therapy. Most patients should be seen and drugs prescribed monthly. If doses escalate during opioid maintenance, hospitalization is recommended to evaluate the medication requirements and, if possible, return medications to their baseline level. If inappropriate use occurs, such as using the medication to treat depression or anxiety, drug diversion, or hoarding, this should be pursued and managed firmly. Use of the medication for symptoms other than those for which it is prescribed (e.g., use for headaches in addition to pelvic pain) may lead to increased tolerance and dose escalation, and should be discouraged. If control cannot be maintained, treatment with opioids should be discontinued.

Table 4-12 summarizes most of the opioids available in the United States as oral formulations and gives doses that are equivalent to 10 mg of morphine administered intramuscularly. Side effects are common with opioid therapy. Opioids may cause drowsiness, difficulty in mentation, decreased physical activity, mood changes, respiratory depression, nausea, vomiting, dizziness, pruritus, constipation, increased biliary tract pressure, urine retention, miosis, depression, and (rarely) convulsions. Considering this long list of untoward effects, as well as the risks or tolerance and addiction, it is again worth stating that opioid treatment should be initiated only after other treatments have been insufficient, the patient has been carefully counseled, and assurance of close follow-up is possible.

#### Antidepressants

Antidepressants, particularly tricyclic antidepressants (TCAs), have been used to treat a number of chronic pain syndromes, including arthritis, diabetic neuropathy, headache, back pain,

and cancer pain. TCAs may result in improved pain levels at doses much lower than those typically used for the treatment of depression. Pain levels generally are decreased by 20% to 50% in chronic pain syndromes, although it is not clear that TCAs are effective in all pain syndromes. There are no randomized, clinical trials of TCAs for treatment of chronic pelvic pain. One open-label study suggested that nortriptyline at 100 mg/day was effective, but the dropout rate due to side effects was 50%.<sup>35</sup> Depression is common in women with chronic pelvic pain; when it is diagnosed, it should be treated with an appropriate antidepressant in most cases.

#### Combination Drug Therapy

Combination drug therapy uses medications with different sites or mechanisms of action to improve the treatment of pain. For example, combining a central-acting opioid analgesic and a peripheral-acting NSAID often gives better pain relief than either analgesic alone. Similarly, combining two medications that are central-acting but with different mechanisms, such as a TCA and an opioid analgesic, might result in better pain relief than monotherapy. Combination drug therapy may improve pain relief, but it also increases adverse effects and potential drug interactions.

#### Psychological Treatment

Ideally psychological evaluation and treatment would be part of the care of every patient with chronic pelvic pain. Patients with chronic pain develop psychological changes that maintain or increase the distress of their pain regardless of the degree of physical trauma or disease. Combining psychotherapy (usually cognitive/behavioral therapy) with traditional surgical or medical treatment results in better outcomes than those obtained with surgical or medical treatment alone.<sup>36–40</sup> Unfortunately, many women are unable to afford or reluctant to accept referral to a psychologist or psychiatrist for evaluation and treatment.

#### Other Treatments

Other treatments, especially alternative or complementary treatments, are used by women with chronic pelvic pain. Most patients use alternative treatments as adjuncts to conventional therapy, not as replacements. Thus the name *complementary medicine* may be better terminology. Most complementary treatments are not well-studied for chronic pain, let alone for chronic pelvic pain.

*Relaxation therapy* is a commonly used technique to aid in treatment of chronic pain and especially for acute exacerbation of pain. Music therapy is also used by many women. There appear to be no randomized clinical trials of efficacy.

*Transcutaneous electrical nerve stimulation* (TENS) has been extensively used by physical medicine and pain physicians and by physical therapists with seemingly good results. About three fourths of patients treated with TENS for chronic pain show improvement, although the degree of pain relief is not great. One might expect similar or better results with *acupuncture*, but not as much has been published.

*Bodywork* of a less traditional nature than physical therapy, such as *massage therapy*, *chiropractic manipulation*, and *reflexology*, is often used but there is no published research sufficient to reach a valid conclusion on such approaches as yet.

**Table 4-12**  
Some of the Opioids Available in the United States\*

Generic Name	Proprietary Name(s)	Mean Duration (hrs)	Equianalgesic Dose (mg)
Butorphanol	Stadol	3–6	2–3 (intranasal) (agonist-antagonist)
Codeine		4–6	200 (oral)
Fentanyl	Duragesic	72	25–100 µg/hr (transdermal)
Hydrocodone	Hycodan, Vicodin, Lortab, Lorcet, others	4–5	5–10 (oral)
Hydromorphone	Dilaudid	4–5	6–7.5 (oral)
Methadone	Dolophine	4–6	20 (oral)
Morphine	MSIR MS Contin	4–7	30–60 (oral)
Oxycodone	Percodan, Tylox, Percocet*, Oxycontin	4–6	5–10 (oral)
Pentazocine	Talwin	4–7	180 (oral)
Propoxyphene	Darvon, Darvocet*	4–6	180–240 (oral)

\*Equianalgesic doses to 10 mg of morphine administered intramuscularly are given.

*Magnetic therapy* and *magnetic field therapy* have shown results in animal studies that suggest they decrease pain levels. No significant clinical studies have been published. There is also insufficient clinical evidence to reach a conclusion about the efficacy of *hypnosis* in the treatment of chronic pain.

*Spiritual or religious treatments* such as intercessional prayer, healing, divine intercession, and meditation are important aspects of health care for many people, but have not been extensively studied with scientific techniques for pain treatment.

*General comfort measures* should always be included in the treatment of chronic pelvic pain. Examples are heat packs, hot baths or whirlpools, ice packs, back rubs, enhanced empathy and attentive listening by clinicians, and compassionate interactions between doctor and patient.

## PITFALLS AND CONTROVERSIES

There is still not a widely accepted definition of chronic pelvic pain. This hinders the applicability of published research, because it makes it difficult to know whether a particular investigation or treatment is applicable to one's specific patient. It is crucial that all research on chronic pelvic pain clearly define the population being studied.<sup>41</sup> It would be quite helpful if a consensus definition were available.

The role of laparoscopy in the evaluation of chronic pelvic pain is another area of controversy. Unfortunately many gynecologists, and thus their patients, consider laparoscopy the definitive diagnostic test in the evaluation of chronic pelvic pain. In reality, laparoscopy is important in diagnosing endometriosis and adhesions, but is not essential in the diagnosis of almost all other clinical conditions associated with chronic pelvic pain. A review of Table 4-3 will confirm that most of the other diagnoses can be made with less invasive laboratory and imaging tests. Yet it remains common for many women to undergo numerous laparoscopic evaluations in spite of prior negative or minimal prior laparoscopic findings. Although there is optimism that conscious laparoscopic pain mapping may improve the usefulness of laparoscopy, this is not sufficiently substantiated to recommend it in routine gynecologic practice.

The concept of pain as a diagnosis, not necessarily a symptom, and the use of therapies directed at pain rather than only at specific diagnoses, is another controversial subject. The current understanding of chronic pain would suggest that pain often represents a diagnosis, but this concept is not well studied or substantiated in chronic pelvic pain. As a corollary, the use of opioids in chronic pelvic pain is not well established.

Finally, a major pitfall for gynecologists is to assume that all or most chronic pelvic pain is due to the reproductive tract. Clearly, this is not the case, with gastrointestinal and urologic disorders both notably more frequent with chronic pelvic pain. Although a gynecologist may choose to only treat gynecologic disorders in women with chronic pelvic pain, it is essential that the gynecologist properly evaluate each patient for non-gynecologic diseases before assuming that gynecologic disorders, such as mild endometriosis, are the cause of the patient's pain. There are numerous examples of women with other disorders, such as interstitial cystitis, being treated repeatedly for insignificant or asymptomatic endometriosis, because a thorough evaluation was not done for nongynecologic diseases.

## KEY POINTS

- Female sexual dysfunction occurs in approximately 40% of the adult population and is especially prevalent among teens and women over 65 years of age.
- Women expect physicians to ask questions directed to their sexual health. Reluctance to discuss sexual matters often results from patient anxiety and embarrassment to bring up the topic; many women will discuss the topic only after direct clinician query.
- Using the PLISSIT model of sexual inquiry is an efficient way to address sexual concerns and problems in a busy practice.
- The use of hormonal therapy should be considered in appropriate postmenopausal women, especially surgically menopausal women, since urogenital atrophy and loss of sexual desire are common problems in this age group.
- Regardless of how advanced in age a woman is, sexual history taking should be a part of the annual examination and counseling and treatment should be offered if the woman reports distress from a sexual dysfunction.

## EPIDEMIOLOGY, RISK FACTORS, AND PATHOGENESIS

Sexuality is an intimate and integral portion of a woman's life, reflecting both her physical health and emotional well-being. A neglected medical topic for many years, the emergence of effective pharmacologic interventions, especially for male sexual dysfunction, has infused the field with renewed research and clinical interest. Sexual function, however is a difficult area to objectively analyze because it is influenced by emotional, biologic, and psychosocial factors, which makes the clinical diagnosis, treatment, and study of female sexual dysfunction (FSD) more challenging than other medical problems, such as diabetes mellitus, in which there is an objective clinical value to diagnose the condition and prove efficacy of the intervention.

FSD affects the entire spectrum of ages, races, and socio-economic backgrounds and is influenced—to differing degrees—by biological, physical, and psychosocial factors. Since many conditions and personal experiences adversely affect sexual health, it is not surprising that the prevalence of FSD is high (Table 5-1). The National Health and Social Life study evaluated 1749 women aged 18 to 59 by personal interview technique. From this study, a 43% overall prevalence of female sexual dysfunction was reported, with 22% reporting low sexual desire, 14% reporting arousal difficulties, and 7% reporting sexual pain<sup>1</sup> (Fig. 5-1). Data from a study of 1480 women

showed even higher percentages of various FSDs. In this group of women aged 18 to 87 years, hypoactive sexual desire was reported by 87%, followed by 83% with orgasmic disorders, 75% with insufficient vaginal lubrication, 71% with dyspareunia, 69% with body image concerns, 67% with unmet sexual needs, and 63% with inadequate information on sexual issues.<sup>2</sup> A recent on-line Web-based survey of 3807 women confirmed these high rates of FSD.<sup>3</sup> Of these respondents, who were 88% Caucasian, 5% black, 3% Hispanic, and 1.4% Asian, the most common sexual complaint was low sexual desire (77%). Other prevalent complaints included low sexual arousal (62%), inability to achieve orgasm or difficulty achieving orgasm (56%), and vaginal dryness (46%). Forty percent of the respondents reported that they did not seek help from a physician for these complaints. Of the group who did not seek professional assistance, 54% reported that they would like to, and 33% were not sure whether they would pursue help.<sup>3</sup>

Data suggest that FSD is increased in women who are younger, unmarried, have lower levels of education and social status, are African American, and have a history of sexual abuse or coercion. As expected, the more sexual dysfunctions a woman notes, the more adversely they impact her quality of life. Some classes of medications such as antidepressants and oral contraceptives as well as medical conditions such as diabetes, high blood pressure, multiple sclerosis, endocrine disorders, spinal cord injury, and mastectomy interfere with sexual wellness. Gynecologic conditions such as vaginitis, pregnancy, lactation, and menopause also increase sexual problems in women. Often ignored by women and their clinicians, psychological and social stressors such as depression, anxiety, rape, interpersonal conflicts with partner, and sexual identity disorders commonly lead to sexual dysfunction.

A major contributor to FSD, especially in the aging population, is poor vascular integrity that can lead to adverse anatomic and physiologic changes. Arterial insufficiency from atherosclerosis of the iliohypogastric/pudendal arterial bed may result in decreased blood flow to the clitoris or vagina that can have a major impact on sexual wellness.<sup>4</sup> This vascular insufficiency over time leads to loss of corporal smooth muscle and replacement by fibrous connective tissue in clitoral cavernosal arteries, ultimately leading to vaginal dryness and dyspareunia.<sup>5</sup> Traumatic injury from pelvic fractures, blunt trauma, surgical disruption, and chronic perineal pressure from bicycle riding can also lead to disruption of the iliohypogastric/pudendal arterial bed and result in diminished vaginal and clitoral blood flow and complaints of sexual dysfunction.<sup>6</sup> Verification of this phenomenon was demonstrated in rabbit studies. When the pelvic nerves of an atherosclerotic female rabbit were stimulated, the increase in clitoral and vaginal blood flow was less than in a

normal control.<sup>5</sup> Postmenopausal women with atrophic changes in vaginal and clitoral vasculature frequently report diminished vaginal lubrication and arousal (Table 5-2).

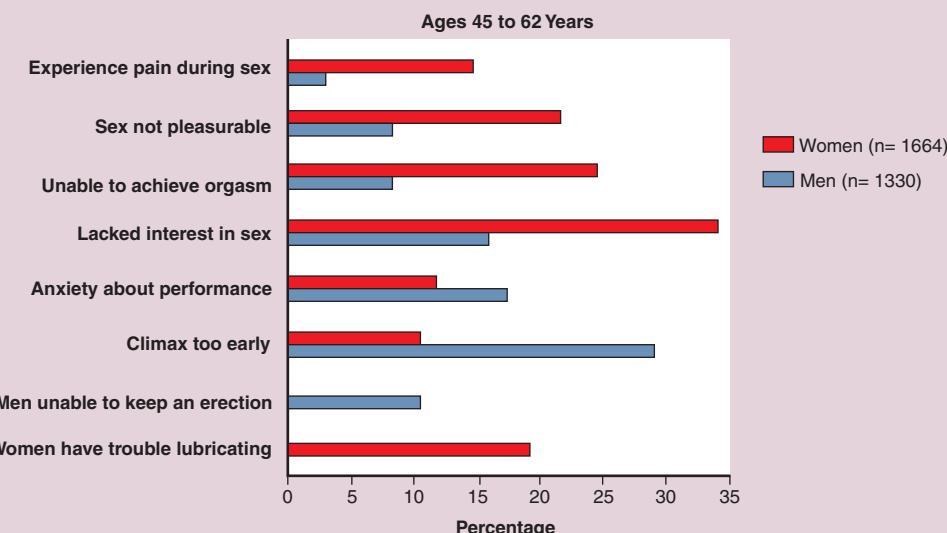

At the neurogenic level, nitric oxide, phosphodiesterase V, and vasoactive intestinal peptide are considered to play a significant role in sexual response. Autonomic innervation of the vagina originates from the hypogastric and sacral plexus, which gives rise to uterovaginal nerves. The uterovaginal nerves contain both parasympathetic and sympathetic nervous system fibers. The pudendal nerve provides somatic sensory innervation to the vulvar/clitoral region, whereas the autonomic innervation to the clitoris is from the sympathetic (T1–L3) and parasympathetic (S2–S4) fibers.

Sympathetic nervous system activation can impair genital blood flow in women with spinal cord injury or diseases of the

central or peripheral nervous system, such as multiple sclerosis, parkinsonism, temporal lobe epilepsy, and spinal cord injuries. In females with multiple sclerosis there is demyelination of the central nervous system pathways. Because of this disruption of pudendal somatosensory afferents in women with multiple sclerosis, orgasmic dysfunction may be reported.<sup>7</sup> Women with complete upper motor neuron injuries affecting sacral spinal segments are unable to achieve psychogenic lubrication. However, when incomplete injuries occur, women usually retain their capacity for psychogenic lubrication, especially if there is sensory preservation at the T11 to L2 dermatomes.<sup>8</sup> Women with spinal cord injuries also report more difficulty achieving orgasm than women with an intact spinal cord.<sup>9</sup>

Both estrogen and testosterone play a role in female sexual response. Other conditions, including endocrine dysfunctions, especially those of the hypothalamic/pituitary axis; diabetes mellitus; hypo- and hyperthyroidism; surgical or medical castration; premature ovarian failure; natural menopause; certain commonly used medications like antihypertensives, psychotropics, antidepressants, and the birth control pill, also can lead to FSD through a primary or secondary effect on the gonadal hormones. Use of oral contraceptives, gonadotropin-releasing hormone (GnRH) agonists, and tamoxifen may also result in decreased desire and libido, vaginal dryness, and lack of sexual arousal. Studies on women with hyperprolactinemia resulting from the use of antipsychotic medication report higher rates of sexual dysfunction than in unaffected women. The level of depression or dose of medication is not as strong a predictor of sexual problems as the level of prolactin. This implies that hyperprolactinemia is the main cause of sexual dysfunction in females taking antipsychotic medication.<sup>10</sup> Clinicians should avoid prescribing antipsychotics that raise the prolactin level, or if no alternative drugs are available, then monitoring prolactin

levels in these women is advisable. Another class of pharmacologic interventions that may contribute to sexual dysfunction is the selective serotonin receptor reuptake inhibitor (SSRI). Some evidence suggests that activation of the 5-hydroxytryptamine 2 (5-HT<sub>2</sub>) receptor produces vasoconstriction of the genital vasculature as compared with stimulation of the 5-HT<sub>1A</sub> receptor, which facilitates sexual functioning.<sup>11</sup> Serotonin produces vasodilation by acting on 5-HT<sub>1</sub> receptors to stimulate release of nitric oxide and also by activating 5-HT<sub>3</sub> receptors. The role of 5-HT<sub>3</sub> receptors in female sexual response is currently not definitively known.

In affected individuals, buspirone, a 5-HT<sub>1A</sub> agonist may be useful in reversing SSRI-induced sexual dysfunction. Another intervention, nefazodone, a 5-HT<sub>2</sub> antagonist, causes up-regulation of 5-HT<sub>1A</sub> receptors. It has been reported to cause fewer sexual side effects than traditional SSRIs. Cyproheptadine acts as a histamine and serotonin (5-HT<sub>2</sub>) antagonist and has been reported to reduce antidepressant-induced sexual dysfunction. Mirtazapine, an α<sub>2</sub>-adrenergic, 5-HT<sub>2</sub>, and 5-HT<sub>3</sub>

receptor antagonist also has been reported to reverse SSRI-induced sexual dysfunction.<sup>12</sup>

During pregnancy and the postpartum period women experience profound physical changes, fluctuating hormone levels, and other coexisting conditions that influence their sexual health. In recently delivered women, postpartum depression and sexual dysfunction are a concern. Treatment may require psychotherapy or pharmacologic intervention.

On the other end of the reproductive spectrum, the prevalence of diminished sexual desire and libido, dyspareunia, and decreased sexual activity and arousal is increased in the menopausal and postmenopausal periods of a woman's life. During menopause, the natural depletion of oocytes and ovarian follicles lead to a decline in serum estrogen levels to a fraction of reproductive-aged levels, causing loss of vaginal moisture and dyspareunia. Declining androgen levels commencing in the fourth decade of a woman's life can also lead to sexual problems. Therefore, in addition to estrogen, androgens are an important contributor to sexual wellness. A recent double-blind, randomized controlled study compared the effects of oral esterified estrogens with and without methyltestosterone on endocrine profiles and dimensions of sexual function in postmenopausal women experiencing hypoactive sexual desire.<sup>13</sup> The concentration of bioavailable testosterone was significantly increased and sex hormone-binding globulin (SHBG) decreased after treatment with combination estrogen/androgen therapy as compared with estrogen alone. As anticipated, mean changes in sexual interest or desire as rated on the Sexual Interest Questionnaire increased from baseline with combination treatment and were significantly greater than those achieved by esterified estrogens alone. Increased circulating level of unbound testosterone and suppression of SHBG by exogenous testosterone appears to be the reason for the improved sexual functioning in women on combination therapy.

Psychiatric illnesses, both long term and acute, such as affective and anxiety disorders, anorexia nervosa, depression, obsessive-compulsive disorder, schizophrenia, and bipolar disease can cause female sexual dysfunction. Interpersonal conflicts not psychiatrically related in a sexual relationship may also lead to changes in sexual interest and response. Religious beliefs and history of rape or other forms of abuse are some of the most common reasons causing FSD in subsets of younger women.

Even short-term emotional problems can lead to sexual problems. The National Health and Social Life Survey (NHSLS) data reported that deteriorating social position and worsening economic status, leading to a high level of stress, can negatively affect sexual functioning.<sup>1</sup>

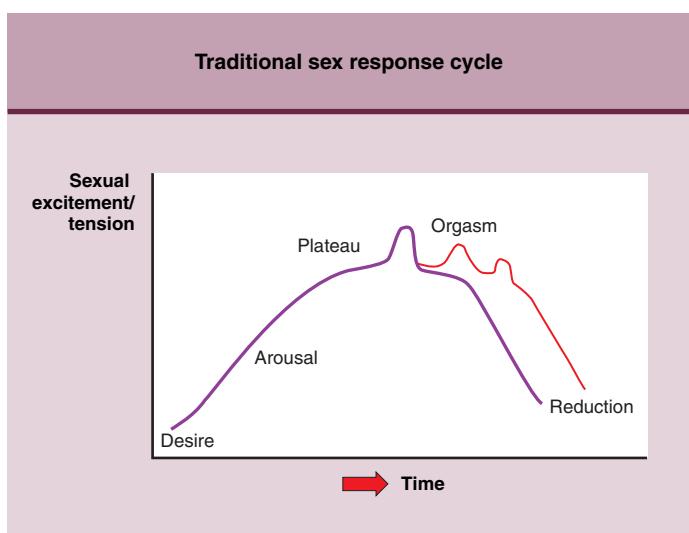

In addition to the anatomic alterations that result from surgical procedures and radiologic treatments such as hysterectomy, vulvectomy, radiation therapy, bladder suspension, cystocele/rectocele repair, and mastectomy, emotional issues also may have a negative impact on a woman's sexual wellness.<sup>14</sup> For example, women who undergo treatment for cervical cancer often experience decreased lubrication and genital swelling owing to damage to peripheral nerves and vasculature during surgery. Disruption of the vasculature due to any pelvic surgery or radiotherapy may have an adverse impact on sexual function. Superimposed on these effects are the psychological issues that

have to be dealt with afterward, including loss or diminution of female identity.<sup>14</sup> Sometimes all that is addressed is the vaginal shortening, reduced vaginal elasticity, and vaginal bleeding that may occur with coitus. Additionally, clinicians could address the anatomic and emotional changes that may occur. Alterations in level of sexual functioning after major surgery can often be predicted by a number of factors that are present prior to surgery. The level of sexual wellness presurgery appears to be the most important one. Treating and counseling women for anxiety, depression, type of surgery, alterations in physical appearance, and changes in sexual function that may result will reduce the number of sexual complaints arising from psychological issues postoperatively. However, it is important to note that after hysterectomy, women often report greater sexual pleasure.

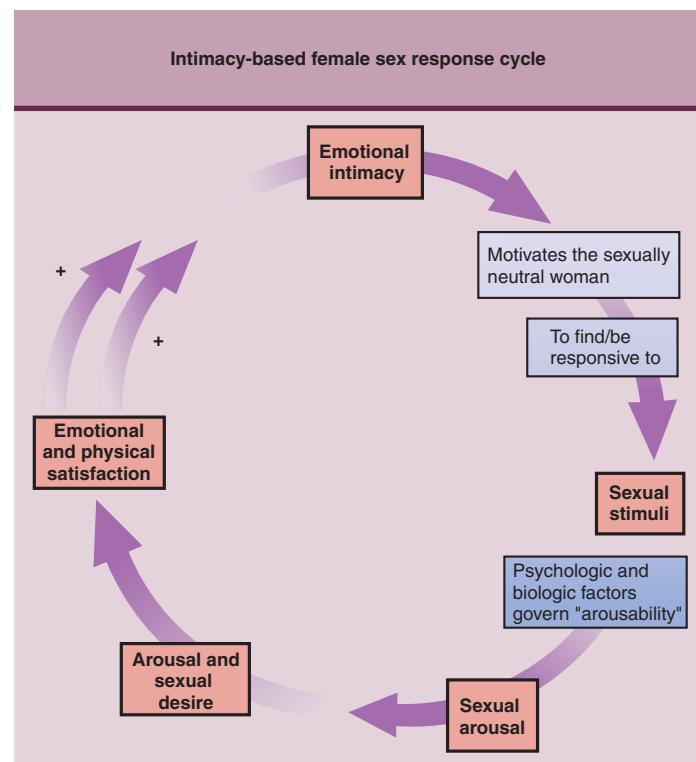

### CLINICAL FEATURES OF SEXUAL RESPONSE

Masters and Johnson in 1966 first characterized the female sexual response as four successive phases: excitement, plateau, orgasm, and resolution.<sup>15</sup> In 1979, Kaplan proposed the aspect of "desire" and the three-phase model consisting of desire, arousal, and orgasm. (Fig. 5-2). Kaplan's three-phase model is the basis of classifications of female sexual dysfunction in the Diagnostic and Statistical Manual of Mental Disorders IV (DSM-IV) and also the World Health Organization International Classification of Diseases 10 (ICD-10). Later, Basson proposed an intimacy-based female sex response cycle<sup>16</sup> (Fig. 5-3). According to her, the female sexual response is a circular, more complex model than the linear sequence of desire, arousal, orgasm, and resolution and the key to female sexual response is emotional intimacy and sexual stimuli.

A major barrier to the development of clinical research in the area of sexual function has been the absence of a well-defined, broadly accepted diagnostic framework and classification for female sexual dysfunction. The International Consensus Development Conference on Female Sexual Dysfunction in 1998 developed a classification system that has four major

**Figure 5-2** Traditional sex response cycle. (From Kaplan HS: The New Sex Therapy: Active Treatment of Sexual Dysfunctions. New York, Brunner/Mazel, 1974.)

**Figure 5-3** Intimacy-based female sex response cycle. (From Basson R: Female sexual response: the role of drugs in the management of sexual dysfunction. Obstet Gynecol 2001;98:350–353.)

categories of dysfunction: desire, arousal, and orgasmic and sexual pain disorders. According to this international panel of sex researchers, therapists, and clinicians, DSM-IV categorizes only psychiatric-related sexual disorders. This group proposed that the classification of sexual dysfunctions be based on both physiological and psychological problems. Definitions of several disorders were altered to include this premise. This consensus classification defines four types of dysfunction and five subtypes. A new category of sexual pain disorder, including noncoital sexual pain, also was added. The DSM-IV requirement that a woman must experience personal distress for a diagnosis of sexual dysfunction was retained.<sup>15</sup>

In 1998, the American Foundation of Urologic Disease Consensus panel also published an updated FSD definition and classification system.<sup>15</sup> Each classification is further subtyped as lifelong or acquired, generalized or situational, and of organic, psychogenic, mixed, or unknown etiology. This classification from the International Consensus Panel is as follows:

#### I. Hypoactive sexual desire disorder

This is defined as persistent or recurring deficiency (or absence) of sexual fantasies/thoughts and/or receptivity to sexual activity, which causes personal distress. It is the most common female problem. Loss of desire may result from psychological/emotional factors, physiologic problems such as hormonal deficiencies, physical illnesses, medications, medical and surgical interventions, stress, fatigue, very restrictive upbringing, and negative or traumatic sexual experiences. In postmenopausal

women, especially those who are surgically menopausal, low testosterone levels are associated with loss of sexual desire. (Fig. 5-4).

A subtype of hypoactive sexual desire is sexual aversion disorder, defined as the persistent or recurring phobic aversion to and avoidance of sexual contact with a sexual partner, which causes personal distress. Sexual aversion disorder is generally a psychologically or emotionally based problem that can result from a variety of causes such as physical abuse, sexual abuse, or other childhood trauma.

## II. Sexual arousal disorder

This is defined as persistent or recurring inability to attain, or maintain, sufficient sexual excitement, causing personal distress. It may be experienced as lack of subjective excitement or lack of genital (lubrication/swelling) or other somatic response. Disorders of arousal include lack of or reduced vaginal secretions, decreased clitoral and labial sensation, decreased clitoral and labial engorgement, and lack of vaginal smooth muscle relaxation. Causes can be psychologic and medical/physiologic and from prior pelvic trauma, pelvic surgery, medications (e.g., SSRIs), and neural and peripheral vascular diseases.

## III. Orgasmic disorder

This is defined as persistent or recurrent difficulty, delay, or absence of orgasmic potential after sufficient sexual stimulation and arousal, which causes personal distress. Primary disorder occurs when the female has never experienced orgasm through any means of stimulation,

and secondary disorder occurs when the female has previously experienced orgasm but is currently non-orgasmic. Medications, chronic illnesses, trauma to the nerves associated with pelvic surgery and spinal cord injury, medical conditions affecting the nerve supply of the pelvis (such as multiple sclerosis, diabetic neuropathy), hormonal imbalance, relationship difficulties, emotional trauma, or sexual abuse are associated with orgasmic failure.

## IV. Sexual pain disorders

These are classified as dyspareunia, vaginismus, and noncoital sexual pain disorders.

### A. Dyspareunia

Dyspareunia is recurrent or persistent genital pain associated with genital touching, entry attempt, deep thrusting, or pain immediately after intercourse. Sites of pain include the vaginal opening, areas on the vestibule, the entire vulva, and the pelvis. Inadequate lubrication is a common cause in the postmenopausal female. Inadequate arousal, pelvic infections, endometriosis, vulvodynia, uterine prolapse, vaginal atrophy, scars, and tumors can cause dyspareunia in women across the adult life cycle.

### B. Vaginismus

Vaginismus is recurrent or persistent involuntary spasm of the outer third of the vagina that interferes with vaginal penetration and causes personal distress. Vaginismus may result from vaginal scarring, previous trauma, surgeries, childbirth, or chronic vaginal infection.

### C. Noncoital sexual pain disorder

Noncoital sexual pain disorder is recurrent or persistent genital pain induced by noncoital sexual stimulation. This new category recognizes that sexual pain can occur in situations other than penile penetration.

## DIAGNOSIS

Sexual assessment is an integral part of the general medical evaluation and should be taken in a quiet atmosphere in which the patient is seated comfortably and assured privacy and confidentiality. Clinicians who are cognizant of their own sexual beliefs are most comfortable with this part of the medical history and are more likely to take a sexual history. Full evaluation of FSD, in addition to history, must include a physical examination, pelvic examination, and in selected cases a hormonal profile (follicle-stimulating hormone, luteinizing hormone, testosterone, and estradiol levels).

Because many women are reluctant to talk about sexual issues, especially if they have a specific problem, a useful way to commence sexual inquiry is with basic, nonthreatening questions such as "Are you sexually active?" and "Is sex satisfying?" Providing information such as, "Many of my patients who stop hormonal therapy complain of pain with sex soon afterward. Has this happened to you?" also is helpful. In some practices, a preconsultation questionnaire including sexual questions has proved useful; however, many women are reluctant to put sexual problems down on paper (Fig. 5-5).

**Figure 5-5 Physician questioning increases patient reporting of sexual dysfunction.** (From Montej Al, Llorca G, Izquierdo JA, et al: [Sexual dysfunction secondary to SSRIs: a comparative analysis in 308 patients.] *Actas Luso Esp Neurol Psiquiatr Cienc Afines* 1996;24:311–321.)

The PLISSIT model for assessment and treatment of sexual health is a useful tool that gives basic structure to sexual inquiry and treatment.<sup>17</sup> PLISSIT stands for permission (to engage in sexual exchange), limited information (education to clarify myths and misconceptions), specific suggestions (addressing the problem of the patient with options for intervention and treatment), and intensive therapy (referring the patient with complex problems who will need long-term care to a professional who deals with FSD).

Permission assists many women who need a clinician to tell them it is OK to experience sexual pleasure without guilt. Limited information is educating and giving information, clarifying misunderstandings and myths about sexuality. Specific suggestions are detailed suggestions relating to a particular concern such as sensate focus training for arousal disorders. Intensive therapy by a qualified sex therapist is helpful for women who do not respond to the first three measures.

Currently, there are no useful, easy to use and interpret, objective measures that a clinician can use in the office setting to measure sexual dysfunction and response to intervention. Measurements that have been used in the research setting include changes in pelvic hemodynamics, measurement of vaginal smooth muscle relaxation, and genital vibratory perception thresholds. Clitoral, labial, urethral, vaginal, and uterine blood velocity (peak systolic velocity) and venous pooling (end-diastolic velocity) are assessed using duplex Doppler ultrasound. The most used and validated estimate of vaginal blood flow is photoplethysmography. Vaginal photoplethysmography measures vasoengorgement, vaginal blood volume, and vaginal pulse amplitude (VPA). However, the data are difficult to interpret when patient movement occurs during the study and so this instrument is not suitable during stimulation or orgasm. As well, photoplethysmography provides relative rather than absolute units of measurement and does not provide anatomic information. Measurements by this tool have not correlated significantly with subjective arousal reports in women.

Other methods for assessment of female genital vasocongestion are labial temperature, clitoral blood flow measures, Doppler ultrasound, and magnetic resonance imaging. Sommers et al described a new device for measuring vaginal and labial blood flow during sexual arousal and orgasm. The device assesses transcutaneous oxygen partial pressure by measuring the amount of electrical power needed to maintain a set temperature. Advantages of this device over the photoplethysmograph are that it is relatively free from movement artifacts and can be calibrated in terms of absolute blood flow.<sup>18</sup>

Vaginal pressure-volume changes and clitoral and labial vibratory thresholds are recorded both at baseline and after sexual stimulation. Results of vibratory testing may support a diagnosis of vascular, hormonal, or neurologic dysfunction as a cause of the FSD.<sup>19</sup>

Vaginal pH, which is the only test that can be routinely done in a physician's office, is an indirect measurement for the assessment of vaginal flora and the support of urogenital atrophy.

Currently, FSDs are mainly diagnosed and interventions assessed for efficacy by clinician inquiry. Questionnaires, some validated and others not, have proliferated in recent years, spurred in large part by the development of new treatments for male sexual dysfunctions. These are most useful in research settings. Recently, a variety of brief, self-report measures that show a high degree of reliability and validity and are sensitive to treatment interventions, have been used for the multidimensional assessment of female sexual function.<sup>20</sup> Self-administered questionnaires, daily diary records, and event log measures of sexual behavior are geared mainly for use in clinical trials on female sexual dysfunction, especially since they are easier to administer and score than clinical measures.

A commonly used questionnaire is the Female Sexual Function Index (FSFI). This self-report questionnaire assesses sexual function in six domains: desire, arousal, lubrication, orgasm, satisfaction, and pain. The use of this questionnaire for clinical trials in female sexual dysfunction has been validated, and it is currently being used in a number of clinical trials. It is easy to administer, is very sensitive, and has a high degree of internal consistency and test-retest reliability.<sup>21</sup>

The Brief Sexual Function Index for Women (BSFI-W) is a self-report instrument that assesses current levels of female sexual functioning and satisfaction such as sexual thought/desires, arousal, frequency of activity, receptivity/initiation, pleasure/orgasm, relationship satisfaction, and sexual problems.<sup>20</sup> The Sexual Function Questionnaire (SFQ), which has been validated by large-scale clinical trials, assesses sexual function in seven domains: desire, physical arousal-sensation, lubrication, enjoyment, orgasm, pain, and partner satisfaction.<sup>22</sup> This questionnaire has demonstrated strong internal consistency and test-retest reliability, making it valuable in evaluating and diagnosing various types of FSD. It is sensitive to treatment interventions, making it valuable in determining their efficacy in clinical trials.

### Daily Diaries and Event Logs

These tools are used to assess variables such as intercourse frequency, successful attempts at intercourse, and medication use and to obtain frequency data in clinical trials.<sup>23</sup> Diaries require the subject to record sexual activity on a daily basis, whereas event logs are completed only on days when sexual

activity occurs. However, they are not suitable for subjective assessment of female sexual response, are restricted in the scope of measurement, and are susceptible to various forms of response bias or error, since they are completed at home.

### Structured Interviews

The Derogatis Sexual Function Interview is a structured interview that has been validated by large-scale clinical trials for the assessment of male and female sexual dysfunction.<sup>24</sup> The advantages of this interview are breadth of the assessment and the clinical validation.

### Personal Distress and Quality of Life

The Female Sexual Distress Scale is a 12-item scale that has shown a high degree of test-retest reliability and internal consistency.<sup>25</sup> It is highly recommended for clinical trials in FSD, since it assesses the subjective distress associated with sexual dysfunction.

## TREATMENT

The treatment options for FSD are limited. However, new interventions are gradually evolving as more clinical and basic science research is being directed to this problem.

### Estrogen

Estrogen (with or without progestogen) therapy is indicated in postmenopausal women (either spontaneous or surgical) who complain of symptoms of urogenital atrophy, dryness, burning, urinary frequency, urgency, and dyspareunia. Diminished sex response, difficulty reaching orgasm, and decreased sexual activity may also be improved with estrogen therapy but usually because of elimination of vasomotor symptoms and not directly from an effect on sexual motivation. Estrogen depletion leads to decreased pelvic blood flow and sensory perception, ultimately leading to dyspareunia. Estrogen therapy improves clitoral sensitivity, increases genital blood flow, improves vaginal cytology, improves lubrication, and decreases pain with intercourse. In women with contraindications to systemic hormone therapy or who need treatment only for urogenital atrophy, local therapy such as with an estrogen cream, ring, or tablet might be considered. Vaginal estrogens have a profound local estrogenic effect on the urogenital tissue with minimal systemic absorption.

### Testosterone

Androgens play a major role in sexual motivation behaviors and sexual desire (Table 5-3). A randomized, double blind, placebo-controlled cross-over trial of transdermal testosterone patches in doses of 150 and 300 µg combined with oral estrogen in 75 women after total abdominal hysterectomy with bilateral oophorectomy found a positive effect on sexual motivational activities. Serum free testosterone levels were substantially increased at both treatment doses. Sexual function measures of sexual desire, orgasm pleasure, and general well-being improved significantly above baseline with 300 µg testosterone.<sup>26</sup>

Methyltestosterone (1.25 or 2.5 mg) used orally in combination with esterified estrogens (0.625 and 1.25 mg) is available as hormonal therapy for menopausal women with vasomotor symptoms. In a study of postmenopausal women who were

From Kaplan HS, Owett T: The female androgen deficiency syndrome. J Sex Marital Ther 1993;19:3-24.

dissatisfied with estrogen alone, improvement was seen in sexual function in women who were switched to estrogen plus androgen as compared with estrogen alone (see Fig. 5-4).<sup>27</sup> With androgen creams increased clitoral sensitivity, decreased vaginal dryness, and increased libido have been reported.<sup>27</sup> Side effects that are dose dependent are similar to those seen with the oral preparation, such as acne, weight gain, voice deepening, clitoral enlargement, increased facial hair, and androgenic alopecia. A decrease in high-density lipoprotein cholesterol and in triglycerides may also occur when high systemic levels of androgens are used. Dehydroepiandrosterone (DHEA) is a precursor to testosterone and is produced in both the ovary and the adrenal gland in women. In cases of adrenal insufficiency, oral DHEA brings testosterone levels into the normal range.<sup>28</sup> Data are not available on DHEA use and FSD.

### Tibolone

Tibolone is a synthetic steroid compound used outside the United States in women who are naturally or surgically menopausal. It has estrogenic, progestogenic, and androgenic effects. The effect of tibolone on women with sexual dysfunction is still inconclusive.

### Sildenafil

Sildenafil is a potent phosphodiesterase type V (PDE-5) inhibitor that causes the accumulation of cyclic 3',5' guanosine monophosphate leading to smooth muscle relaxation. Nitric oxide and phosphodiesterase type V (the enzyme responsible for cyclic 3',5'-guanosine monophosphate degradation and nitric oxide production) have been identified in human clitoral and cavernosal smooth muscle.<sup>29</sup>

After the enormous success of sildenafil citrate in male erectile disorder, the impact on FSD was studied. Although an organ bath study reported that sildenafil causes a dose-dependent relaxation of female rabbit clitoral corpus cavernosum, which would indicate a positive effect on arousal, this consistent positive result has not been observed in women.<sup>30</sup>

In one open-label, nonrandomized sildenafil study of 33 postmenopausal women, no significant improvement in sexual function was found.<sup>31</sup> The most commonly reported side effects

were clitoral discomfort and hypersensitivity, reported in 21% of women. In a double-blind, placebo-controlled, cross-over trial of 53 premenopausal women aged 22 to 28 years with arousal disorder, both sildenafil 25 mg and 50 mg significantly improved sexual function from baseline.<sup>32</sup> Women taking sildenafil reported significantly increased arousal, orgasm, enjoyment, satisfaction, and frequency of intercourse and frequency of sexual fantasies. There was no difference between the two doses. The investigators found that 70.5% women in this study wanted to continue treatment with sildenafil. Another randomized, double-blind, cross-over, placebo-controlled trial of sildenafil was performed in premenopausal women with multiple sclerosis who had an active sexual relationship, normal estrogen and androgen levels, and no significant medical or recent psychiatric history.<sup>33</sup> Sildenafil increased lubrication and sensation in these women with MS and FSD, but there was no improvement in the capacity to reach orgasm, overall enjoyment, or quality of life. The starting dose of sildenafil was 50 mg and was increased or decreased depending on the response.

Potential future treatments for FSD include the following:

1. L-Arginine: an amino acid precursor that leads to the formation of NO, which mediates the relaxation of vascular and nonvascular smooth muscle, leading to vascular dilation.
2. Prostaglandin E<sub>1</sub>: a prostaglandin E<sub>1</sub> intravaginal application is under investigation for treatment of female sexual dysfunction.
3. Phentolamine: functions as a nonspecific  $\alpha$ -adrenergic blocker leading to vascular smooth muscle relaxation and increased vaginal blood flow. A pilot study to analyze the effects of oral phentolamine on postmenopausal women with sexual arousal difficulties have shown improvement in vaginal lubrication and other measures of sexual arousal.<sup>34</sup>
4. Apomorphine: a short-acting dopamine agonist reported to improve sexual function.

### Mechanical Devices

The U.S. Food and Drug Administration (FDA) approved a device known as the EROS clitoral therapy device (EROS-CTD) for the treatment of female sexual arousal disorder.<sup>35</sup> It is designed to treat women who experience reduced sensation, lubrication, and ability to achieve orgasm. Available by prescription, it consists of a small, soft, plastic vacuum pump that is placed over clitoris. With gentle suction to the region, blood flow is increased, aiding in sexual arousal. No adverse effects have been reported from this battery-operated device. EROS may be particularly effective in postmenopausal women, but clinical data are needed to confirm this assumption.

### Dietary Supplements

Dietary supplements such as ginseng, gingko biloba, B vitamins, calcium, and folic acid have no clinical data to support claims that they are useful in the treatment of FSD.

### Pelvic Exercises

Pelvic floor exercises (Kegel exercises) are prescribed to strengthen the pubococcygeal muscles and increase blood flow

to the pelvis. No objective data document improved sexual and orgasmic responses in women doing these exercises.

### Vaginal Dilators

Vaginal dilators are most often used to treat vaginismus. At the commencement of treatment, the smallest dilators are placed in the vagina for 15 minutes twice daily. As the woman becomes comfortable with that size, she gradually replaces it with the next one with an increased diameter.

### Lubricants

Lubricants can be used in conditions of vaginal dryness and dyspareunia. They are best used during coital activity, as their maximal effects are temporary.

## RESEARCH

The Center for Drug Evaluation and Research, a branch of FDA, issued a guidance document in May 2000 that outlines FDA recommendations for conduct of clinical trials in FSD.<sup>36</sup> According to this document, the definition of FSD should include a measure of personal distress that reflects a degree of psychological dissatisfaction with sexual functioning in the affected woman. Appropriate study populations are defined and include premenopausal women and naturally and surgically postmenopausal women taking hormone-containing products for menopausal symptoms. To demonstrate efficacy in clinical trials and to minimize recall bias, it is recommended that subjects record sexual events or encounters on a daily basis during the pretreatment period of 4 to 8 weeks and then during the intervention. According to this document, to find the lowest effective dose for FSD, two adequate, well-controlled, phase III trials should be carried out for about 6 months. This document recognizes the value of questionnaires and self-report measures, which should be validated separately before their use in clinical trials. To demonstrate efficacy in a treatment, women with the following conditions should be excluded from clinical trials: women with significant relationship difficulties or sexual dysfunction in the partner, women using medications that affect sexual function, and women having medical illnesses that affect sexual function. End points for clinical trials should be based on the number of successful and satisfactory sexual events or encounters over time, the determination of which should be by the woman participating in the trial, as opposed to her partner. These events or encounters can be sexual intercourse (with or without orgasm), oral sex resulting in orgasm, or manual stimulation by self or partner resulting in orgasm, and they should be recorded in daily records or event logs.

## PITFALLS AND CONTROVERSIES

Sexuality is an important component of a woman's life and has a significant impact on her quality of life. Research on the cause and treatment of female sexual dysfunction has lagged far behind many other conditions that affect women. Available pharmacologic interventions are increasing as research in this area becomes widespread. Drugs under investigation include gonadal hormones and vasodilators. To understand the impact of drugs, there is a great need to study and understand the myriad

of factors that contribute to a woman's psychological experience of sexual satisfaction.

Inquiry about sexual symptoms should be routine, even though the only treatment at times may be acknowledging and validating the sexual complaint. Patients expect the physician to raise questions related to sexual well-being. Along these lines, more efforts should be made to emphasize training in human sexuality during medical school and residency training. For the field to progress, the use of standardized clinical trial tools must be adopted so that data sets can be compared. Of great importance is the need for large-scale, randomized, placebo-controlled, double-blind trials to determine long-term efficacy and side effects of pharmacologic interventions used to treat FSD.

## KEY POINTS

- Complementary and alternative medicines are commonly used to treat disorders throughout reproductive age.
- Complementary medicines must be used carefully and thoughtfully owing to herb-drug and herb-herb interactions.
- Chasteberry is used to treat premenstrual syndrome.
- Evening primrose oil may diminish cyclic mastalgia symptoms.
- Phytoestrogens, black cohosh, wild yam, and dong quai are proposed to improve menopausal symptoms.

Complementary and alternative medicine (CAM) is becoming widely practiced within the United States. By conservative estimates, Americans spend approximately \$27 billion per year on complementary and alternative medication. A therapy is called complementary when it is used in addition to conventional treatment, and alternative when it replaces conventional treatment. Women especially are turning more often to CAM therapies to treat common ailments. While many herbal therapies offer therapeutic benefits, they are not without risk. It is important for women and their health care providers to have information regarding common herbal therapies, their potential risks, and possible interactions with both conventional and alternative treatment modalities.

## COMMONLY USED THERAPIES

### St. John's Wort (*Hypericum perforatum*)

St. John's wort is a flowering plant found in Europe, Asia, Africa, Australia, and North and South America. The yellow flowers were traditionally gathered for the feast of St. John the Baptist. The leaves and flowers of this plant contain hypericin, pseudohypericin, hyperforin, flavonoids, and other components. Hypericin and hyperforin appear to be the active components. St. John's wort is most often made from the flower and based in an ethanolic extract standardized to 0.3% hypericin. Recently, it has been questioned whether hypericin is the main active ingredient, since it does not cross the blood-brain barrier. Hyperforin actually may be the key component. Hyperforin, however, is less stable, and its concentration may vary considerably in St. John's wort. Importantly, significant differences in concentrations exist depending on when and how St. John's wort is harvested.

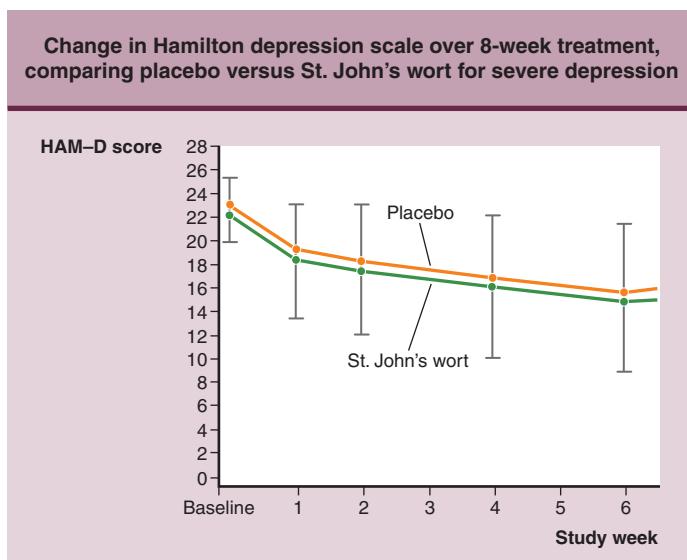

St. John's wort is commonly used for treatment of depression. St. John's wort appears to act similarly to selective serotonin reuptake inhibitors (SSRIs) in that it decreases the rate of reuptake of monoamine neurotransmitters such as serotonin.<sup>1</sup>

Multiple studies have been performed evaluating *Hypericum* extracts for treatment of depression. A German group looked at an extract of *Hypericum* as compared to placebo for treatment of mild-to-moderate depression.<sup>2</sup> The treatment group showed an improvement in depression scores as compared with the placebo group, with no adverse effects in either group. Other groups have evaluated *Hypericum* as compared with SSRIs in the treatment of mild-to-moderate depression. In an evaluation of the LI 160 extract of *Hypericum* as compared with sertraline, clinical response was noted in 47% of patients receiving *Hypericum* and 40% of patients receiving sertraline.<sup>3</sup> In a study investigating the use of *Hypericum* extract as compared with fluoxetine,<sup>4</sup> both treatment groups demonstrated improvement in multiple depression scoring systems. Several meta-analyses similarly suggest that in patients with mild-to-moderate depression, St. John's wort has similar efficacy to low-dose tricyclic antidepressants but may be better tolerated.<sup>5,6</sup>

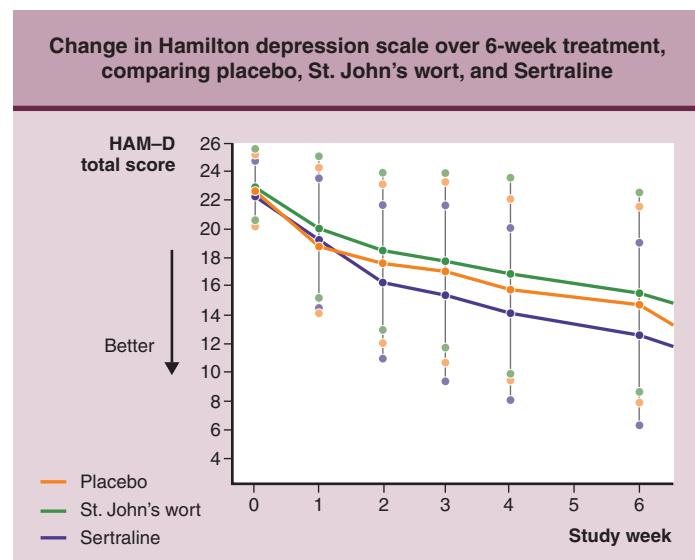

St John's wort, however, does not appear to significantly improve moderate to severe depression. In a randomized, placebo-controlled study evaluating the use of LI 160 as compared with sertraline and placebo for the treatment of moderate-to-severe depression, no difference in depression scores was detected, although a higher rate of full response was noted in the patients with a lower initial depression score.<sup>7,8</sup> Although St. John's wort may not treat moderate-to-severe depression as evaluated by depression scoring scales, most patients using St. John's wort have mild-to-moderate symptoms and therefore may experience some improvement in mood (Figs. 6-1 and 6-2).

Researchers have evaluated St. John's wort in premenstrual syndrome (PMS). Women with PMS note the appearance of symptoms late in the luteal phase with resolution after menses. Mood disorders are frequently reported also. A pilot study was performed evaluating the use of daily *Hypericum* extract for the treatment of PMS.<sup>9</sup> Women completed a daily symptom ratings calendar for one cycle before starting daily *Hypericum* tablets standardized to 900 µg hypericin. Symptoms were rated daily and then scored after one and two cycles of treatment. Overall premenstrual scores decreased by 51% between baseline and completion of the trial, suggesting that *Hypericum* may be useful as a treatment for PMS.

The recommended daily dose is 2 to 4 g St. John's wort or 0.2 to 1 mg hypericin. Adverse effects include photosensitivity, rash, nausea, fatigue, and restlessness.<sup>10</sup> Although well tolerated, St. John's wort appears to have significant drug-herb interactions. St. John's wort induces cytochrome P-450 enzymes and increases the metabolism of protease inhibitors, oral contraceptives, warfarin, digoxin, and theophylline.<sup>11</sup> St. John's wort decreases cyclosporine levels, resulting in organ transplantation

**Figure 6-1 Change in Hamilton Depression Scale (HAM-D) score over 8-week treatment period comparing placebo with St. John's wort for severe depression.** (From Shelton RC, Keller MB, Gelenber A, et al: Effectiveness of St. John's wort in major depression: a randomized controlled trial. JAMA 2001;285:1978–1986.)

**Figure 6-2 Change in Hamilton Depression Scale (HAM-D) score over 6-week treatment period comparing placebo with St. John's wort or sertraline for severe depression.** (From Hypericum Depression Trial Study Group: Effect of *Hypericum perforatum* [St. John's wort] in major depressive disorder: a randomized controlled trial. JAMA 2002;287:1807–1814.)

rejection.<sup>12</sup> Finally, St. John's wort should not be used during pregnancy or lactation.

#### Chasteberry (*Vitex agnus-castus*)

Chasteberry is commonly used for the treatment of PMS symptoms. The active part of the chaste tree is the fruit. The active constituents of chasteberries are iridoid glycosides, flavonoids, and the diterpenes. The active iridoids are aucubin and agnoside, and many chasteberry extracts are standardized to contain 6% agnoside. Chasteberries also contain several essential fatty acids including oleic acid, linolenic acid, palmitic acid, and stearic acid.<sup>13</sup>

The mechanism of action of chasteberry seems to be through indirect effects on neurotransmitters and hormones. Chasteberry extracts may have agonistic activity at the pituitary dopamine (D2) receptors. At high doses, chasteberry may suppress prolactin release.<sup>14</sup> Chasteberry also appears to selectively bind to the β-estrogen receptor (β-ER). The isolated ligand for the β-ER appears to be linoleic acid.<sup>15</sup> Linoleic acid has been shown to stimulate mRNA β-ER expression in a breast cancer cell line.

Chasteberry has been evaluated for the treatment of PMS. In one large, nonrandomized trial, over 1600 German women used chasteberry extract for treatment of PMS.<sup>16</sup> After 3 months of treatment, 81% of women reported feeling much better than at the start of treatment. Another group investigated *Vitex agnus-castus* extract Ze 440 in 50 women with PMS.<sup>17</sup> These women took one tablet daily containing 20 mg native extract for three menstrual cycles. The 43% of the women who continued the study responded with a reduction of at least 50% on the Moos menstrual distress questionnaire. Symptoms gradually recurred after cessation of treatment; however, a difference from baseline did persist for up to three additional cycles. No difference

was seen between women taking or not taking oral contraceptives. However, this group was also not compared with a placebo group. More recently, a prospective, randomized, placebo-controlled study evaluated daily treatment of chasteberry fruit extract Ze 440 in 170 women with PMS.<sup>18</sup> Women rated six symptoms using a visual analog scale. After 3 months of treatment, women receiving chasteberry extract noted a greater than 50% improvement in their symptoms.

Chasteberry extracts are generally well tolerated. Some patients complain of gastrointestinal (GI) upset, headache, nausea, itching, and rash. Some patients also complain of fatigue. Women may note irregular bleeding when chasteberry is first started. Chasteberry should be avoided during pregnancy, since it may have uterine stimulating properties. In addition, it should be avoided during lactation because it appears to be a dopamine agonist and may inhibit prolactin release.

#### Evening Primrose Oil (*Oenothera biennis*)

Evening primrose oil is obtained from the seed of *Oenothera biennis*. It contains 2% to 16% γ-linolenic acid, 65% to 88% linoleic acid, and vitamin E. Evening primrose oil has been suggested as a treatment option for women with cyclic mastalgia. The hypothesis is that women with cyclic mastalgia have an altered proportion of fatty acid esters as compared with unaffected women. Therefore, one therapeutic option is supplemental fatty acid intake. Australian data suggest evening primrose oil at a dose of 1000 mg three times daily improves cyclic mastalgia.<sup>19</sup> In addition, a cohort of 66 Australian women treated with gamolenic acid demonstrated a marked reduction in cyclic mastalgia after 6 months of treatment.<sup>20</sup>

Evening primrose oil is generally well tolerated orally, but nausea, indigestion, and headache have been reported. Usually

these side effects are easily tolerated and do not result in discontinuation of therapy. Evening primrose oil may have anticoagulant effects owing to its  $\gamma$ -linolenic acid component. Therefore, evening primrose oil may theoretically increase anti-coagulant or antiplatelet effects of other drugs such as aspirin, nonsteroidal anti-inflammatory drugs, clopidogrel, heparin, warfarin, and enoxaparin. Caution should be used with concomitant use of other herbal products with coumarin activity such as dong quai. Finally, evening primrose oil should not be used in schizophrenic patients being treated with phenothiazine drugs because this combination has been reported to cause seizures.<sup>13</sup>

### Ginkgo

Ginkgo is derived from the leaf of *Ginkgo biloba*. *Ginkgo biloba*, which is also known as the maidenhair or fossil tree, is the oldest living species of tree. Ginkgo leaf and its extracts contain several active constituents including flavonoids, terpenoids, and organic acids. The terpenoids include ginkgolides A, B, C, M, and J, and bilobalide. The major flavonoids are kaempferol, quercetin, and isohamnetine derivatives. Ginkgo leaf flavonoids have antioxidant and free radical scavenging effects as seen by their ability to inhibit the expression of inducible nitric oxide synthase.<sup>13</sup> Ginkgolide B competitively inhibits platelet activating factor (PAF) in laboratory animals. PAF inhibition decreases platelet aggregation and protects against hypoxia-induced neuronal injury as well as decreasing free radical production.<sup>21</sup> This effect on platelet aggregation may also increase the risk of spontaneous bleeding. One case has been reported of excessive bleeding requiring transfusion after laparoscopy.<sup>22</sup> Gingko extracts should be used cautiously in patients taking other anticoagulant or antiplatelet drugs. Gingko extracts also contain ginkgotoxin, a neurotoxin. Ginkgotoxin is more concentrated in gingko seed than in gingko leaf; therefore, it is unlikely to be at high enough concentration to cause toxicity.<sup>23</sup> However, there are reports of patients having seizures who were previously well controlled on antiseizure medications.<sup>24</sup> Therefore, patients with seizure disorders or taking other medications known to lower seizure threshold should avoid using ginkgo extracts. Other side effects of oral ginkgo supplements include GI upset, headache, dizziness, constipation, and allergic skin reactions.

While gingko leaf is most commonly used for dementia, gingko has been used to treat sexual dysfunction caused by SSRIs. In one open trial, gingko extracts improved sexual response in women taking SSRI antidepressants.<sup>25</sup> A more recent placebo-controlled, randomized trial did not demonstrate a difference after 8 weeks of therapy between placebo and gingko groups. In fact, both treatment arms showed improvement in sexual function.<sup>26</sup> Gingko should be used cautiously in patients with infertility, since it might interfere with oocyte fertilization.<sup>27</sup>

### Dong Quai

Dong quai, which is extracted from the root of *Angelica sinensis*, is a Chinese herb often used to treat gynecologic conditions such as menstrual disorders and menopausal symptoms. The primary active ingredients are coumarin derivatives including psoralen, osthols, and bergapten. Osthols appear to inhibit platelet aggregation. Psoralen and bergapten are photosensitizing, which

may result in phototoxicity with external application of dong quai. Bergapten and other dong quai constituents have been shown to be carcinogenic; however, what concentration or duration of use is unsafe is unknown.<sup>13</sup> Because of the coumarin derivatives, there is a theoretical risk of bleeding. Therefore, dong quai should be used cautiously or not at all in patients taking other anticoagulants or antiplatelet drugs.

It has been suggested that dong quai has estrogenic effects resulting in improvement in menopausal symptoms. A randomized, placebo-controlled study evaluated the effects of dong quai 4.5 g/day as compared with placebo for treatment of hot flashes (hot flushes) and menopausal side effects. Patients were evaluated at 6, 12, and 24 weeks. Both dong quai and placebo decreased hot flashes with no differences noted in endometrial thickness, vaginal maturation index, or Kupperman index.<sup>28</sup> The Kupperman index classifies 11 menopausal symptoms including vasomotor symptoms, nervousness, insomnia, melancholia, paresthesias, formication, fatigue, headache, palpitation, arthralgia, and vertigo. Therefore, dong quai does not alleviate menopausal symptoms. When investigators in Houston evaluated the estrogenicity of dong quai through its ability to proliferate MCF-7 breast cancer cells in vitro,<sup>29</sup> dong quai significantly stimulated the human breast cell cancer line. Dong quai did not, however, activate either the  $\alpha$ - or  $\beta$ -ER and did not increase uterine weight in treated mice. At this time, dong quai should be used cautiously or not at all in patients with known breast cancer.

### Phytoestrogens

Phytoestrogens are one of the main alternatives women use for estrogen replacement therapy. Phytoestrogens are diphenolic compounds found in grains, legumes, and grasses. Because they possess a phenolic ring, they are able to bind to estrogen receptors specifically, binding with greater affinity to  $\beta$ -ER than to  $\alpha$ -ER. Even though these compounds bind to the estrogen receptor, they are much weaker than human estrogens. Phytoestrogens are classified into three groups: isoflavones, lignans, and coumestans. Isoflavones are plant sterol molecules found in soy and legumes (Fig. 6-3). Lignans are a constituent of the plant cell wall and are found in grains and the husks of seeds such as flaxseed. Coumestans are found in sprouts such as alfalfa and red clover.<sup>30</sup>

#### Chemical structure of Isoflavone

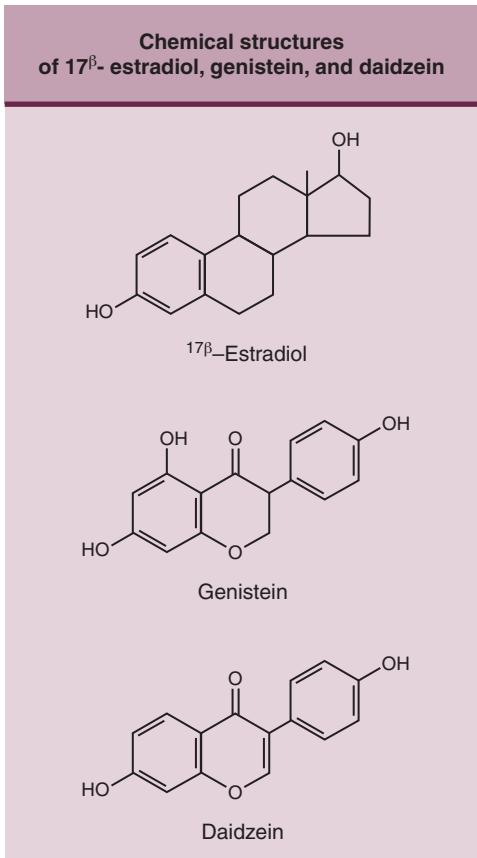

**Figure 6-3** Chemical structure of isoflavone.

Soybeans, which contain 1 to 2 mg of isoflavone per gram of soy protein, are the richest food source of isoflavones. The amount of phytoestrogen in a soy product depends on how it is processed. Soy milk and soy flour contain less phytoestrogen than do soybeans. Some soy capsules and powders have no remaining active phytoestrogen after being processed with an alcohol extract. Soybeans contain three different types of isoflavones: genistein, daidzein, and glycine. Red clover extracts also contain genistein and daidzein in addition to their methylated precursors, formononetin and biochanin (Fig. 6-4).

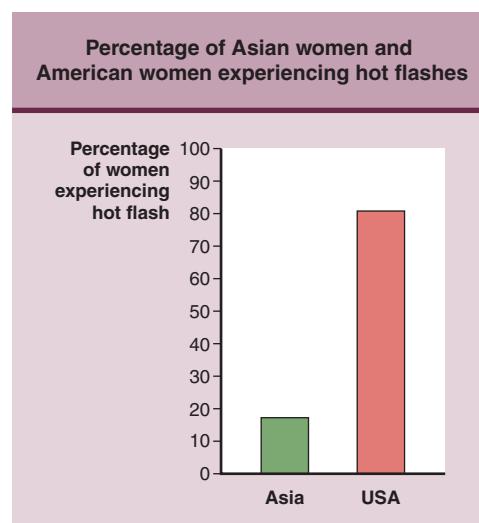

Genistein has 1/400 to 1/1000 the potency of 17 $\beta$ -estradiol and binds with greater affinity to  $\beta$ -ER than to  $\alpha$ -ER. Genistein may act as either an estrogen or antiestrogen depending on the tissue type and amount of endogenous circulating estrogens.

Hot flashes and night sweats are the most bothersome symptoms of menopause. The severity of symptoms, however, differs among national groups. Only 10% to 25% of Asian women report hot flashes as compared with 70% to 80% of American women. Since Asian women have a much greater dietary intake of soy, there has been interest in evaluating the efficacy of phytoestrogens for treating menopausal symptoms (Fig. 6-5; Table 6-1).

An early study evaluated the effects of a short-term, phytoestrogen-rich diet on menopausal symptoms. Women were randomized to either a diet rich in phytoestrogens or to a regular diet with instructions to avoid specific soy products and flax seed. The phytoestrogen-rich diet included 80 g of

**Figure 6-4 Chemical structures of 17 $\beta$ -estradiol, genistein, and daidzein.**

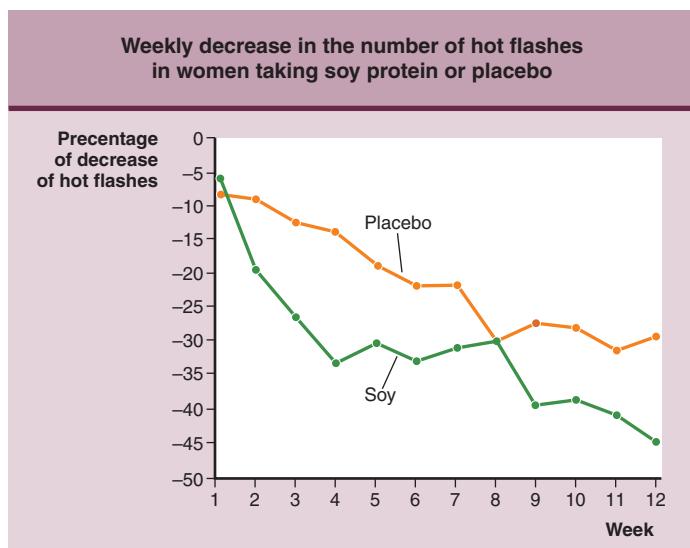

**Figure 6-5 Percentage of Asian women and American women experiencing hot flashes.**

tofu daily (containing approximately 75 mg/g daidzein and 200 mg/g genistein), one teaspoon of miso (40 mg/g daidzein and 35 mg/g genistein), and two teaspoons of ground flax seed (4 mg/g lignans). Throughout the study period, women recorded the frequency and severity of their menopausal symptoms. Symptoms improved in both groups with a significantly greater improvement in vaginal dryness and hot flashes in the phytoestrogen group as compared with the control group.<sup>31</sup> However, another investigator found no significant difference between frequency of hot flashes or night sweats in women randomized to diets containing either isoflavone-rich soy protein (80.4 mg/day) or isoflavone-poor soy protein (4.4 mg/day) or a control diet containing whey protein. Albertazzi performed a double-blind, placebo-controlled trial in which 104 women were randomized to either 60 g of isolated soy protein daily consisting of 76 mg of isoflavone or to 60 g of casein as a placebo. Women recorded both the number and severity of hot flushes and night sweats during the 12-week study period. Women in the isoflavone group demonstrated a 45% decrease in hot flashes as compared with a 30% decrease reported by women in the placebo group.<sup>32</sup> Albertazzi then evaluated the change in serum levels of isoflavones after 60 g/day soy supplementation. Marked

<b>Table 6-1</b> <b>Isoflavone Content of Soy Products</b>

From Bieber EJ, Gell JS: Complementary and alternative medicine in the perimenopause and menopause. In Yuan CS, Bieber EJ (eds): Textbook of Complementary and Alternative Medicine. New York, Parthenon, 2003, pp 319–332.

**Figure 6-6 Weekly decrease in number of hot flashes experienced by women taking soy protein or placebo.** (From Albertazzi P, Pansini F, Bonaccorsi G, et al: The effect of dietary soy supplementation on hot flush. *Obstet Gynecol* 1998;91:6–11.)

increases were seen in genistein, daidzein, and equol; however, these marked increases did not correlate with decreased vasomotor symptoms<sup>33</sup> (Figs. 6-6 and 6-7).

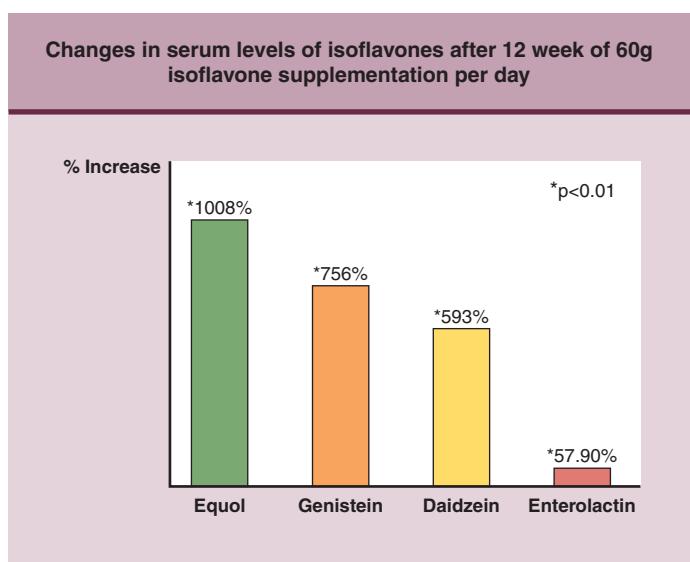

A review of the literature on phytoestrogens and menopausal symptoms was performed. Trials were eligible if they were placebo controlled, reported hot flash frequency, and lasted at least 4 weeks. Neither the soy food nor the soy extract trials demonstrated improvement in menopausal symptoms. Reasons for no benefit may be inadequate amount of soy

ingested for a response or poor bioavailability of phytoestrogen preparations.<sup>34</sup>

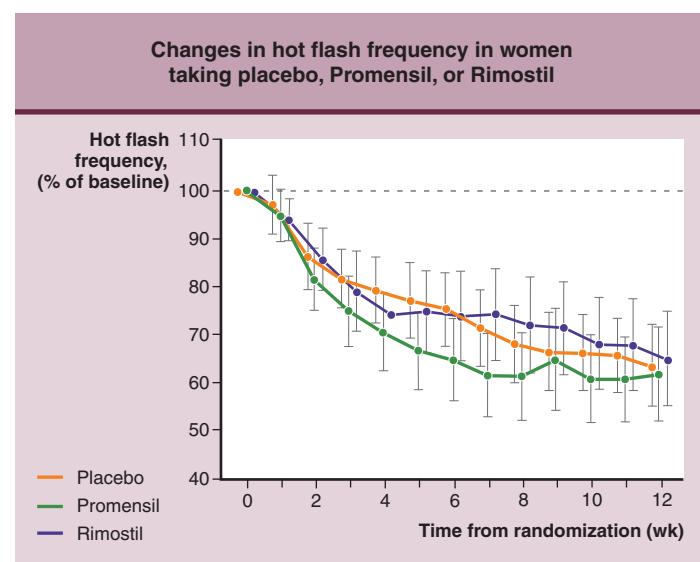

Another source of isoflavones is red clover. Unlike soy, red clover is not a dietary staple and if ingested at all may be consumed in small quantities as a flavoring. Standardized extracts of red clover have been developed to treat menopausal symptoms. A randomized controlled trial evaluated the use of Promensil (82 mg of total isoflavones per day) with Rimostil (57 mg of total isoflavones per day) to placebo. After 12 weeks of therapy, all three groups showed a similar decrease in daily hot flashes. Women taking Promensil reported a more rapid reduction of hot flashes as compared with placebo; Rimostil did not appear to have this effect<sup>35</sup> (Fig. 6-8).

Since isoflavones have estrogenic effects, one concern with long-term use is their ability to stimulate the endometrium. Wilcox found an increase in the maturation index in women supplementing their diet with soy flour, red clover sprouts, and linseed. However, other studies have not demonstrated any increase in vaginal maturation index with increasing isoflavone supplementation. No difference has been seen in endometrial thickness after treatment with either placebo or soy supplementation. Finally, endometrial histology has not been reported to change after ingestion of an isoflavone-enriched diet.<sup>36</sup>

A final concern is the use of phytoestrogens in women with breast cancer. Many newly menopausal women are diagnosed with breast cancer and are advised to avoid the use of estrogen therapy, turning instead to soy products as an alternative treatment for hot flashes. Patients beginning tamoxifen therapy may experience significant worsening of vasomotor symptoms. One trial enrolled 177 breast cancer survivors in a randomized, double-blind, crossover trial in which they consumed 150 mg/day of soy (equivalent to approximately three glasses of soy milk). Soy was no more effective than placebo in diminishing hot flashes. Unfortunately, minimal clinical safety data exist

**Figure 6-7 Change in serum level of isoflavone after 12 weeks of isoflavone supplementation 60 g/day in women with moderate to severe hot flashes.** (From Albertazzi P, Pansini F, Bottazzi M, et al: Dietary soy supplementation and phytoestrogen levels. *Obstet Gynecol* 1999;94:229–231.)

**Figure 6-8 Change in hot flash frequency over 12-week treatment period comparing placebo, Promensil, and Rimostil.** (From Tice JA, Ettinger B, Ensrud K, et al: Phytoestrogen supplements for the treatment of hot flashes—the isoflavone clover extract [ICE] study: a randomized controlled trial. *JAMA* 2003;290:207–214.)

regarding the use of phytoestrogens and risk of recurrence of breast cancer.<sup>37</sup>

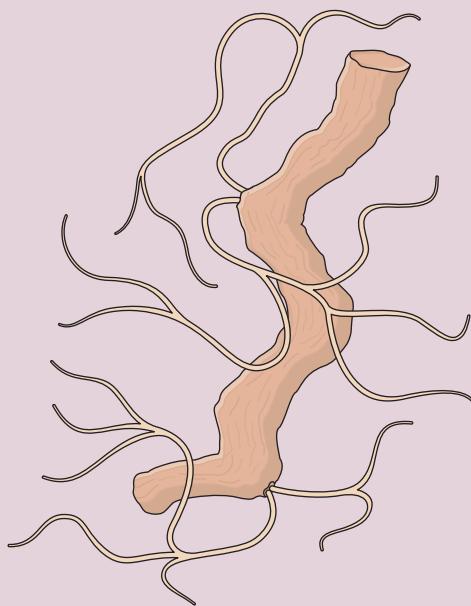

### **Wild Yam (*Dioscorea villosa*)**

Wild yam root and tubers are known to contain diosgenin, a steroid precursor used in early commercial production of steroid hormones. For this reason, wild yam extracts have been used topically to treat menopausal symptoms. However, conversion of diosgenin to estrogen, progesterone, or any other steroid does not occur in the human body. Diosgenin may enhance estradiol binding to estrogen receptors and may stimulate growth of mammary tissue.<sup>13</sup> A double-blind, placebo-controlled, crossover study evaluated the effects of wild yam cream on menopausal symptoms.<sup>38</sup> Women were treated with either active or placebo cream for 12 weeks in random order and instructed to keep a diary of symptoms. Hormone assays were performed on both serum and saliva samples. Both study groups showed minimal improvement on flushing severity and number with no significant difference between wild yam extract and placebo. After 3 months of therapy, there was no change in FSH, estradiol, or serum or salivary progesterone. Therefore, while wild yam extract appears to be well tolerated without significant side effects, it also does not appear to be beneficial for the treatment of menopausal symptoms (Fig. 6-9).

### **Black Cohosh (*Cimicifuga racemosa* Rhizome)**

Black cohosh is a herb native to Eastern North America and traditionally has been used by Native Americans to treat

The Mexican wild yam (*Dioscorea villosa*)

**Figure 6-9 Mexican wild yam (*Dioscorea villosa*).** (From Bieber EJ, Gell JS: Complementary and alternative medicine in the perimenopause and menopause. In Yuan CS, Bieber EJ [eds]: Textbook of Complementary and Alternative Medicine. New York, Parthenon, 2003, pp 319–332.)

**Figure 6-10 Label from Lydia Pinkham's Vegetable Compound.**

gynecologic conditions including menopause. Black cohosh was commercially available during the 19th century as Lydia Pinkham's Vegetable Compound (Fig. 6-10) and during the early 20th century as Huntington's 11, and currently is available as Remifemin.

The primary active constituents are flavonoids and triterpenes such as 27-deoxyactein.<sup>13</sup> Remifemin is standardized to contain 1 mg of 27-deoxyactein per 20 mg tablet. The estrogenic activity remains unclear. Black cohosh did not demonstrate estrogenic activity in a study utilizing several different assay systems.<sup>39</sup> Another study evaluated the effects of 17 $\beta$ -estradiol as compared with *Cimicifuga racemosa* extract BNO 1055 on ovariectomized rats.<sup>40</sup> While estradiol-treated rats demonstrated increased uterine weight and expression of progesterone receptor, no such effects were seen in the *Cimicifuga racemosa*-treated rats. In an additional study, black cohosh did not appear to induce the growth of a human breast cancer cell line or activate the  $\alpha$ - or  $\beta$ -ER.<sup>29</sup>

Clinically, black cohosh has been used to treat menopausal symptoms. German investigators reported decreased frequency and severity of hot flashes in women taking black cohosh as compared with placebo.<sup>41</sup> In another trial evaluating black cohosh as treatment for menopausal symptoms in breast cancer survivors most of whom were on tamoxifen therapy,<sup>42</sup> placebo and black cohosh reduced hot flashes to the same extent.

Black cohosh appears to be safe and well tolerated; however, there are no long-term safety data. Therefore, the recommended length of treatment is not to exceed 6 months. Side effects are limited but include GI upset, bradycardia, headache, and nausea. Black cohosh may also cause uterine contractility and should not be used during pregnancy. Black cohosh should not be confused with blue cohosh, which has potent vasoconstrictive constituents.<sup>13</sup>

**Table 6-2**  
**Possible Interactions Between Conventional Medicines and Botanicals**

Herb	Relevant Pharmacologic Effects	Perioperative Concerns	Preoperative Discontinuation
Gingko	Inhibits platelet-activation factor	Potential to increase risk of bleeding especially in combination with other anticoagulants or antiplatelet drugs	At least 36 hours before surgery
St. John's wort	Decreases rate of uptake of monoamine neurotransmitters such as serotonin	Induction of cytochrome P-450 enzymes affecting cyclosporine, warfarin, steroids, digoxin	At least 5 days before surgery
Evening primrose oil	May have anticoagulant effects owing to its $\gamma$ -linolenic component	May increase anticoagulant or antiplatelet effects of other drugs	No data
Dong quai	Primary active ingredients are coumarin derivatives	May increase anticoagulant or antiplatelet effects of other drugs	No data

## HERBAL MEDICINES AND PREOPERATIVE CARE

With the ever-increasing use of herbal products, presurgical patients are also likely to be ingesting herbal medications. In a recent survey, 32% of patients in an ambulatory surgical setting admitted to using herbal medications; however, more than 70% did not report herbal medications during a perioperative evaluation. Because of potential interactions with conventional medications causing increased risk during surgical care, health care professionals should specifically ask about use of botanical products<sup>45</sup> (Table 6-2).

**KEY POINTS**

- Intimate partner violence is prevalent among women in the United States.
- Intimate partner violence is associated with significant morbidity and mortality.
- Obstetricians and gynecologists have unique opportunities and responsibilities to address intimate partner violence.
- Asking about intimate partner violence in a supportive, nonjudgmental manner may increase awareness of the problem and offer a message of caring and support.
- Interventions for intimate partner violence should emphasize validation, information/resources, options, and autonomy.

**EPIDEMIOLOGY AND RISK FACTORS**

Authors in the health care and social science literature have used many different terms to represent violence against women perpetrated by her partner. These include *domestic violence*, *spouse abuse*, *wife battering*, *battered women*, *partner abuse*, *wife abuse*, *partner violence*, and *women abuse*. Recognition of these variations and the resulting inconsistencies in prevalence and incidence estimations prompted the Centers for Disease Control and Prevention to develop and publish *Intimate Partner Violence Surveillance: Uniform Definitions and Recommended Data Elements*. An *intimate partner* includes current spouses, common-law spouses, nonmarital dating partners or boyfriends/girlfriends, former marital partners, former nonmarital partners, opposite-sex partners, and same-sex partners. *Violence* includes physical violence, sexual violence, threats of physical/sexual violence, and psychological/emotional abuse.<sup>1</sup>

A recent report describing the findings of the National Violence Against Women Survey estimated that 1.5 million women experience physical or sexual violence from a current or former intimate partner each year in the United States. This same study revealed that approximately 25% to 30% of women in the United States experience intimate partner violence.<sup>2</sup> Of women seen in emergency departments (EDs) and in community clinics, 15% to 30% have a history of intimate partner violence.<sup>3-5</sup> Between 42% and 52% of female victims of intimate partner violence sustained an injury,<sup>2,6</sup> and 41% required medical care as a result of a physical assault by their intimate partner.<sup>6</sup>

National reports from the U.S. Department of Justice repeatedly find that intimate partner violence affects women of various ages, races, cultures, and socioeconomic levels. These reports find higher incidence rates of intimate partner violence among women in the reproductive-age group, particularly those

between ages 19 and 29, compared to other age groups. Other characteristics associated with a higher incidence of intimate partner violence include lower socioeconomic and education status.<sup>7-9</sup> However, these reports relied on violent crime data and report univariate rates without comparing to nonvictims and without controlling for other factors. Reviews of studies that included less severe forms of intimate partner violence and compared factors between assaulted and nonassaulted groups show no consistent factors to predict a woman's risk for experiencing intimate partner violence.<sup>10</sup>

Among pregnant women who present for medical care, between 14% and 46% report a past history of intimate partner violence.<sup>11-14</sup> Prevalence rates of intimate partner violence that occur during pregnancy vary from 0.9% to 20.1%, with most estimates between 4% and 8%,<sup>15-18</sup> similar to prevalence rates for routinely screened conditions such as preeclampsia<sup>19</sup> and gestational diabetes.<sup>20</sup> Although most women who report experiencing violence during the pregnancy also experienced violence before the pregnancy, between 12.5% and 28.9% report that the violence first began during the pregnancy.<sup>21-24</sup>

Several studies examining homicide data reveal that between 30% and 66.9% of women who are killed are killed by a current or former intimate partner.<sup>8,25-27</sup> Of the women killed by their partner, two thirds reported physical assault prior to murder and 83% were threatened by the man who eventually killed them.<sup>26</sup> In one study, half of the couples in which murder occurred had a separation event (e.g., divorce, break-up, separation) preceding the murder. In another study, 44% of intimate partner violence murder victims had presented to an ED within 2 years of their murder.<sup>28</sup> Estimates of the cost of care for women suffering from partner abuse are generally higher than for the nonabused population. One study calculated \$1.8 billion per year for direct medical care of injuries.<sup>29</sup> Another study found that female victims of violence were twice as likely to use outpatient health care services as were nonvictims, with 2.5 times the health care costs.<sup>30</sup> Another study examining female enrollees in a single large health plan showed that victims of intimate partner violence had significantly higher mental health service use and cost the health plan 92% more than a random sample of general female enrollees.<sup>31</sup> Additional factors that could also affect cost include days of work missed, utilization of police and/or ambulance services, and costs of care for children exposed to violence.

**CLINICAL FEATURES**

Despite studies (Table 7-1) showing that between 41% and 51% of women who experience intimate partner violence suffer physical injury from their attacks,<sup>2,6,8</sup> only 28% of those who

Table 7-1 Health Conditions Associated with Intimate Partner Violence	
General and Mental Health Associations	Reproductive Health Associations
<ul style="list-style-type: none"> <li>• Death</li> <li>• Major and minor injuries</li> <li>• Gastrointestinal disorders</li> <li>• Chronic pain disorders</li> <li>• Depression</li> <li>• Anxiety disorders</li> <li>• Post-traumatic stress disorder</li> <li>• Suicide</li> <li>• Alcohol and substance abuse</li> </ul>	<ul style="list-style-type: none"> <li>• Sexually transmitted infections</li> <li>• HIV/AIDS</li> <li>• Delayed or lack of prenatal care</li> <li>• Low birthweight babies</li> <li>• Pelvic pain</li> <li>• Unplanned/unwanted pregnancies</li> <li>• Lack of reproductive control</li> </ul>

were injured sought medical care.<sup>2</sup> Findings from the National Violence Against Women Survey revealed that the majority of women experiencing an injury from intimate partner violence described relatively minor injuries such as bruises, scratches, or welts. However, 11% suffered broken bones or dislocated joints, 8.8% reported lacerations or knife wounds, and 8.8% described head and spinal cord injuries.<sup>2</sup>

Because injuries are often absent or no longer apparent when a victim of intimate partner violence presents for care, more attention has been placed on other clinical signs of intimate partner violence. Studies have demonstrated associations between partner violence and other medical problems, including gastrointestinal disorders,<sup>32</sup> depression,<sup>33</sup> anxiety, chronic pain syndromes,<sup>34</sup> increased substance abuse, and suicidal ideation.<sup>35</sup>

The Commonwealth Fund's 1993 National Survey of Women's Health found that women who have experienced partner violence were more likely to report having gynecologic problems, sexually transmitted diseases, and pelvic pain.<sup>36</sup> Other studies have indicated an association between intimate partner violence and unintended pregnancies,<sup>37,38</sup> elective pregnancy terminations,<sup>39,40</sup> and delayed entry into prenatal care.<sup>41</sup> In one study surveying more than 1400 women, 23% of the women who reported intimate partner violence described experiencing either sexual assault or rape from their partner.<sup>42</sup> Additionally, one qualitative study revealed that abusive partners often controlled access to and use of contraception.<sup>37</sup> Two studies examining the prevalence of intimate partner violence among women seeking services from abortion clinics found that 30% to 39% report a history of intimate partner violence.<sup>39,40</sup> Additionally, women who experienced physical intimate partner violence were 1.8 times more likely (95% confidence interval [CI], 1.5–2.1) to have delayed entry into prenatal care compared to those who had not experienced violence.<sup>41</sup>

Studies examining associations between intimate partner violence and pregnancy outcomes have not shown consistent results. According to a review of published studies on pregnancy outcomes and intimate partner violence, only mean birthweight and low birthweight achieved statistical significance in more than one study.<sup>43</sup> Recent studies examining causes of maternal death, however, have shown that homicides represent between 13% and 25% of deaths in pregnant or recently pregnant women.<sup>44–46</sup> A statewide analysis in Maryland between 1993 and 1998 revealed that homicide was the leading cause of all

pregnancy-associated deaths (20.2%) with cardiovascular disorders representing the second most common cause of maternal death (19.4%).<sup>46</sup> Women who experienced intimate partner violence during pregnancy had three times higher odds of suffering a life-threatening attack compared to intimate partner violence victims who did not report experiencing abuse during pregnancy.<sup>47</sup> This study also suggested that intimate partner violence that occurs during pregnancy may represent a more severe and potentially dangerous type of partner abuse.

## DIAGNOSIS

In recognition of intimate partner violence as a public health problem, various advocacy groups and medical organizations have called for health care facilities and providers to develop and implement routine screening and intervention for violence. The Family Violence Prevention Fund released clinical guidelines that recommend screening "all women over the age of 14, whether or not symptoms or signs are present and whether or not the provider suspects abuse has occurred."<sup>48</sup> Medical organizations such as the American Medical Association,<sup>49,50</sup> American College of Obstetricians and Gynecologists,<sup>51</sup> the American College of Emergency Room Physicians,<sup>52</sup> the American Academy of Family Physicians,<sup>53</sup> and the American Nurses' Association<sup>54</sup> advocate similar recommendations for routine screening. Additionally, since 1992, the Joint Commission on Accreditation of Healthcare Organizations has required hospital departments and clinics to provide interventions for identified victims of intimate partner violence.<sup>55</sup>

Compared to other medical specialists, obstetrician/gynecologists have an increased opportunity to identify and provide intervention for women at risk for intimate partner violence. A study in 1995 estimated that approximately 72% of women in the United States aged 15 to 44 received at least one reproductive health visit during that year.<sup>56</sup> Obstetrician/gynecologists provide the majority of women's reproductive health services to women of all ages, as well as the majority of nonreproductive health care to women between ages 18 and 44.<sup>57</sup> According to a National Vital Statistics Report in 2000, the mean number of care visits received in pregnancy in 1995 was 12.3,<sup>58</sup> representing numerous opportunities for an obstetrician/gynecologist to develop patient trust, address the issue of intimate partner violence, and, if needed, offer resources and intervention. Additionally, pregnancy is often regarded as an opportunity to address and intervene for a number of behavioral health issues, such as smoking,<sup>59–64</sup> substance abuse,<sup>65</sup> and depression.<sup>66,67</sup> Studies also suggest that pregnant patients may be more motivated to consider and initiate certain health behavioral changes.<sup>62–65</sup>

The majority of studies exploring how health providers address the topic of intimate partner violence focus on how often they ask. These studies show that rates of routine screening for intimate partner violence by health care providers range between 1% and 40%, with increased rates of screening among patients when the provider suspects abuse.<sup>5,12,68–71</sup> Among the reasons physicians cite for their reluctance to broach the subject with their patients are lack of training regarding how to address the issue, uncertainty in their ability to help, and frustration with their perception of the patient's lack of change or

Table 7-2 Barriers to Provider Screening and Patient Disclosure of Violence	
Provider Barriers to Screening	Patient Barriers to Disclosure
<ul style="list-style-type: none"> <li>• Concern about offending patients or belief that asking invades family privacy</li> <li>• Personal discomfort about discussing topic, lack of experience with abused patients, or concern about misdiagnosis</li> <li>• Feeling powerless to help</li> <li>• Frustration with patients who return to abuser</li> <li>• Concern that identification may compromise the victim's ability to get/keep health insurance</li> <li>• Fear for their own personal safety</li> <li>• Cultural differences between patients and clinicians</li> <li>• Reluctance to become involved with justice system</li> <li>• Belief that abuse is not a medical problem</li> <li>• Lack of awareness about violence against women</li> <li>• Inadequate provider training</li> <li>• Shortage of time during patient visits</li> <li>• Underestimation of the prevalence of violence among their female patients</li> <li>• Lack of 24-hour access to social worker</li> <li>• Marginalization of practitioners who take leadership roles in dealing with family violence</li> </ul>	<ul style="list-style-type: none"> <li>• Fear of escalating violence</li> <li>• Feelings of shame and embarrassment</li> <li>• Fear of losing custody of their children</li> <li>• Concern about confidentiality</li> <li>• Fear of police involvement</li> <li>• Sense of family duty or responsibilities</li> <li>• Lack of access or partner preventing access to health care</li> <li>• Denial of abuse</li> <li>• Thinking abuse was controllable</li> <li>• Feeling that physician could not help and that it was not part of the physician's job</li> <li>• Negative physician attitude or negative past experience with a physician</li> </ul>

response<sup>70–72</sup> (Table 7-2). Compared to other medical specialties, such as family practice and internal medicine, obstetrician/gynecologists are most likely to perform routine screening for intimate partner violence,<sup>71</sup> and they are more likely to do so during the first prenatal visit.<sup>68</sup>

Female participants in many studies reported that they think providers should routinely ask about violence and provide information on community and legal resources.<sup>73–76</sup> One study by Rodriguez and colleagues suggested that if asked directly whether they have been abused, women who experience intimate partner violence will disclose.<sup>77</sup> However, several other studies found that many women experiencing current partner violence will deny their abuse even when asked.<sup>76,78,79</sup> Studies exploring patients' perceived barriers to disclosure of partner abuse showed that fear of escalating violence,<sup>73,76,78,79</sup> feelings of shame and embarrassment,<sup>73,75,76,78</sup> fear of losing the children, concern about confidentiality,<sup>76,79</sup> and fear of police involvement<sup>76</sup> were common reasons for denying the abuse (see Table 7-2).

## TREATMENT

### Asking About Intimate Partner Violence May Itself Be an Intervention

Multiple qualitative studies suggest that just the act of asking about intimate partner violence in a nonjudgmental and com-

passionate manner is helpful to women experiencing intimate partner violence.<sup>78,80–82</sup> Gerbert and colleagues interviewed women who had experienced intimate partner violence and who had helpful encounters with health care providers. The women described that providers were most helpful by validating and helping them recognize that the violence was a problem they did not deserve.<sup>83,84</sup> Chang and colleagues found that just asking about intimate partner violence not only helps women recognize the abuse, but also begins to decrease her isolation. This also allows the patient to feel that her provider cares about the situation.<sup>82</sup> As a result of these findings, experts have begun to recommend that health care providers view asking about intimate partner violence not merely as a screening tool, but also as potentially therapeutic in and of itself.<sup>80,82,83,85–87</sup>

### How to Ask About Intimate Partner Violence

The American College of Obstetricians and Gynecologists (ACOG) recommends asking all patients about intimate partner violence. They suggest that for women who are not pregnant, these inquiries occur at routine gynecologic visits, family planning visits, and preconception visits. Pregnant women can be asked at the first prenatal visit, at least once per trimester, and at the postpartum checkup.<sup>51</sup> Several screening tools have been developed to assist clinicians in assessing for intimate partner violence.<sup>4,88–92</sup> One of the most common assessment tools is the Abuse Assessment Screen, developed by the Nursing Research Consortium on Violence for use with pregnant patients (Table 7-3).<sup>90</sup> The ACOG has adapted this screening tool into three recommended questions preceded by an explanatory statement (Table 7-4).<sup>93</sup>

Some studies suggest that the style of asking about intimate partner violence may make a difference. Chang and colleagues found that while women identified positive consequences with

Table 7-3  
Abuse Assessment Screen

1. Have you ever been emotionally or physically abused by your partner or someone important to you? (yes/no)
2. Within the last year, have you been hit, slapped, kicked, or otherwise physically hurt by someone? (yes/no)
  - a. If yes, by whom? (husband/ex-husband/boyfriend/stranger/other/multiple)
  - b. Number of times?
3. Since you've been pregnant, have you been hit, slapped, kicked, or otherwise physically hurt by someone? (yes/no)
  - a. If yes, by whom? (husband/ex-husband/boyfriend/stranger/other/multiple)
  - b. Number of times?
- c. Mark the area of injury on the body map.
- d. Score the most severe incident to the following scale:
  - 1 = Threats of abuse including use of a weapon
  - 2 = Slapping, pushing; no injuries and/or no lasting pain
  - 3 = Punching, kicking, bruises, cuts, and/or continuing pain
  - 4 = Beaten up, severe contusions, burns, broken bones
  - 5 = Head, internal, and/or permanent injury
  - 6 = Use of weapon, wound from weapon
4. Within the past year, has anyone forced you to have sexual activities? (yes/no)
  - a. If yes, who? (husband/ex-husband/boyfriend/stranger/other/multiple)
  - b. Number of times?
5. Are you afraid of your partner or anyone you listed?

**Table 7-4****ACOG Recommended Screening Questions for Intimate Partner Violence**

1. Within the past year—or since you have been pregnant—have you been hit, slapped, kicked, or otherwise physically hurt by someone?
2. Are you in a relationship with a person who threatens or physically hurts you?
3. Has anyone forced you to have sexual activities that made you feel uncomfortable?

some methods of inquiry, other styles of discussing intimate partner violence resulted in negative consequences, such as feeling judged by the provider, increased anxiety about the unknown, and disappointment in the provider's response.<sup>82</sup> Hamberger and colleagues surveyed 115 battered women to identify desirable and undesirable physician behaviors and practices. They found that battered women valued assessment for violence as a part of their complete medical history as long as it did not create "an atmosphere of interrogation."<sup>94</sup> In focus groups, immigrant Latino and Asian women who were victims of intimate partner violence described feeling that open communication about intimate partner violence was facilitated by compassionate and supportive provider behavior, provider initiation of discussion of intimate partner violence, and a continued relationship with the same provider.<sup>95</sup> Generally, health providers should address intimate partner violence in a nonjudgmental, sensitive manner, taking care to ensure the patient's safety, confidentiality, and dignity. Women should be asked about intimate partner violence without others present, particularly her partner. Professional interpreters should be used for women who do not speak English.

**What to Do When a Woman Says "Yes"**

No good studies have tested responses to a woman's disclosure of violence to determine the best response. However, the general feeling among female survivors, advocates, and health care providers who care for abused women is that one needs to include the following in one's response:

- Validation—Acknowledge the woman's disclosure and emphasize to her that she did not deserve the abuse or violence. Emphasize that she did not do or say anything "wrong." She is not the one with a problem in the relationship—the perpetrator has the problem.
- Support—Express a willingness to support her. Offer an invitation to use the health care setting as a resource and a source of support and safety.
- Information—Provide referral information and/or hotline numbers to community domestic violence programs. Ask if she can take the information safely. Write the numbers down without labeling them if she is afraid to take anything. The National Domestic Violence Hotline is a 24-hour toll-free resource that will help women locate and contact shelters and other support services in their own community. Other national organizations such as the Family Violence Prevention Fund and the National Coalition Against Domestic Violence will also provide links to local resources (Table 7-5).

- Safety planning—Ask if she is currently safe and/or if she needs shelter. If she intends to return to the batterer, ask if she has a plan for what to do/how to escape if the violence occurs again (Table 7-6). Suggest having money hidden or put somewhere else to have if she needs to leave quickly; having copies of birth certificates, immunizations, Social Security numbers, and other important documents that she could keep somewhere else or quickly take; having a hidden spare car key; making a list of hotline numbers; developing a code with friends, family, and/or neighbors to get help in an emergency. McFarlane and colleagues found increased safety behaviors (e.g., hiding money, removing weapons from the home, and establishing a coded method of calling for help from friends and family) among pregnant victims of intimate partner violence who underwent a brief intervention focused on safety planning.<sup>96</sup>
- Danger assessment—in various studies, Campbell and colleagues have examined potential risk factors associated with increased risk of homicide<sup>97</sup> (Table 7-7). From this work, these investigators have developed a danger assessment tool to aid in counseling women regarding their lethality risk in their intimate partner violence situation<sup>98</sup> (Fig. 7-1). Although currently no outcome data is available regarding the benefits or risks of using this instrument, the objective regarding its use is to increase women's awareness of their danger and individualize their safety counseling.
- Documentation—Although this is still a somewhat controversial issue, both victims advocates and legal counselors working on behalf of victims of intimate partner violence

emphasize that documentation by a medical provider can help a woman in her legal case.<sup>99,100</sup> However, there have been past concerns regarding confidentiality breaches and some cases of insurance denial. Many clinical settings use the screening/documentation form developed by the Family Violence Prevention Fund (Fig. 7-2).

Studies in which women described bad experiences with health care providers included situations during which clinicians ignored or minimized the intimate partner violence, made excuses for the batterer, or blamed the woman.<sup>73,78,79,81,94</sup> Women described feeling criticized and blamed when they are

asked questions such as "What did you do to deserve this?" and "Why don't you just leave?"<sup>78</sup>

Experts recommend offering women various options for dealing with the intimate partner violence.<sup>101</sup> Although a natural inclination would be to recommend that a woman leave her violent relationship, many women experiencing intimate partner violence are either unwilling or unable to do so. A few homicide studies also suggest that leaving the batterer can still be dangerous. In Morocco's study of femicide in North Carolina, half of women killed by their partners had some form of separation event (e.g., divorce, break-up, separation) immediately before the murder.<sup>26</sup>

**Danger assessment tool**

**Danger Assessment**  
From: Jacquelyn C. Campbell, PhD, RN, FAAN  
Copyright 2004 Johns Hopkins University, School of Nursing

Several risk factors have been associated with increased risk of homicides (murders) of women and men in violent relationships. We cannot predict what will happen in your case, but we would like you to be aware of the danger of homicide in situations of abuse and for you to see how many of the risk factors apply to your situation.

Using your calendar, please mark the approximate dates during the past year when you were abused by your partner or ex-partner. Write on that date how bad the incident was according to the following scale:

1. Slapping, pushing; no injuries and/or lasting pain
2. Punching, kicking; bruises, cuts, and/or continuing pain
3. "Beating up"; severe contusions, burns, broken bones, miscarriage
4. Threat to use weapon; head injury, internal injury, permanent injury, miscarriage
5. Use of weapon; wounds from weapon

(If **any** of the descriptions for the higher number apply, use the higher number.)

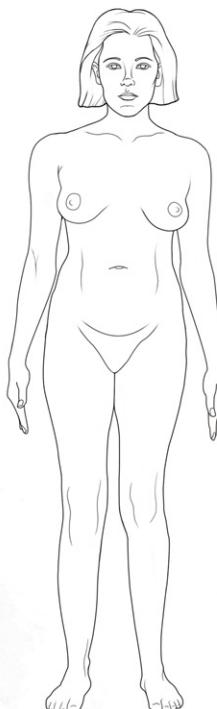

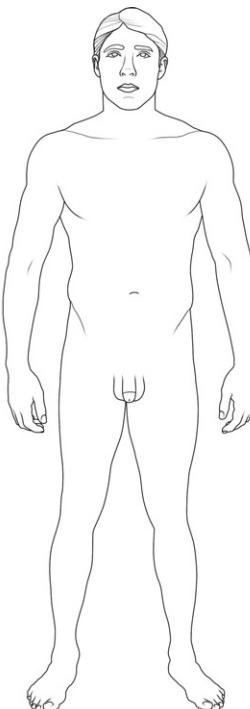

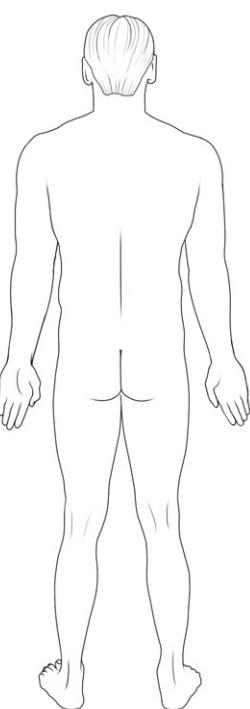

Mark **Yes** or **No** for each of the following.  
("He" refers to your husband, partner, ex-partner, or whoever is currently physically hurting you.)

Yes	No	
_____	_____	1. Has the physical violence increased in severity or frequency over the past year?
_____	_____	2. Does he own a gun?
_____	_____	3. Have you left him after living together during the past year? 3a. (If have never lived with him, check here: _____)
_____	_____	4. Is he unemployed?
_____	_____	5. Has he ever used a weapon against you or threatened you with a lethal weapon? 5a. (If yes, was the weapon a gun? _____)
_____	_____	6. Does he threaten to kill you?
_____	_____	7. Has he avoided being arrested for domestic violence?
_____	_____	8. Do you have a child that is not his?
_____	_____	9. Has he ever forced you to have sex when you did not wish to do so?
_____	_____	10. Does he ever try to choke you?
_____	_____	11. Does he use illegal drugs? By drugs, I mean "uppers" or amphetamines, speed, angel dust, cocaine, "crack", street drugs or mixtures.
_____	_____	12. Is he an alcoholic or problem drinker?
_____	_____	13. Does he control most or all of your daily activities? (For instance: does he tell you who you can be friends with, when you can see your family, how much money you can use, or when you can take the car?) (If he tries, but you do not let him, check here: _____)
_____	_____	14. Is he violently and constantly jealous of you? (For instance, does he say, "If I can't have you, no one can.")
_____	_____	15. Have you ever been beaten by him while you were pregnant? (If you have never been pregnant by him, check here: _____)
_____	_____	16. Has he ever threatened or tried to commit suicide?
_____	_____	17. Does he threaten to harm your children?
_____	_____	18. Do you believe he is capable of killing you?
_____	_____	19. Does he follow or spy on you, leave threatening notes or messages on answering machine, destroy your property, or call you when you don't want him to?
_____	_____	20. Have you ever threatened or tried to commit suicide?
		TOTAL "Yes" Answers

Thank you. Please talk to a nurse, advocate, or counselor about what the Danger Assessment means in terms of your situation.

<b>Table 7-7</b> <b>Intimate Partner Violence Risk Factors Associated with Homicide</b>	
<b>Risk factors</b>	
Abuser unemployed, not seeking job	
Abuser access to gun	
Victim had a child by a previous partner in the home	
Abuser is controlling	
Separation after living together	
History of abuser threatening victim with weapon	
History of abuser threatening to kill victim	
History of forced sex	
<b>Incident-level risk factors</b>	
Abuser used gun	
Trigger: jealousy—victim left for another relationship	
Trigger: victim left abuser for other reasons	

### What to Do When a Woman Says “No”

Women who have experienced intimate partner violence often describe experiences of denying the violence to others because of fear and denial. So denial of violence, even in highly suspicious cases, can be expected. The women also describe that this denial is not because they do not want help—often they do want help but are confused and afraid to ask for it.<sup>101</sup> Easy, anonymous access to information on intimate partner violence and to resources through posters, flyers, brochures, and information booklets would allow any woman—regardless of disclosure—to obtain help.

### PITFALLS AND CONTROVERSIES

Few states have mandatory reporting laws for intimate partner violence. These laws have generated controversy because there is uncertainty regarding whether they help or harm victims of intimate partner violence.<sup>102–104</sup> Although not explicit to intimate partner violence, many states require physicians to report to law enforcement specific injuries (e.g., gunshot or stab wounds) that may have resulted from a criminal act. If possible, the victim should be informed of the reporting laws and her rights as a crime victim before the report is made.

Little information exists regarding outcomes and consequences of health care screening and counseling for intimate partner violence.<sup>105,106</sup> Three recent reviews on interventions and screening for intimate partner violence<sup>105–107</sup> highlight the lack of measurable evidence showing effectiveness of these practices. Two reviews focused on intimate partner violence screening and interventions in health care settings. Ramsay and colleagues examined 20 papers, of which 9 addressed screening for intimate partner violence and 6 addressed interventions for intimate partner violence. The screening and intervention papers were included if they were conducted in a health care setting, had a comparison group, and measured a quantifiable outcome. Of the screening studies, only one was a randomized, controlled trial, with most of the remaining studies comparing women who underwent intimate partner violence screening with historical controls.<sup>105</sup> All six intervention studies were felt to be poor in quality, and most focused on referral rates and

service utilization as outcomes.<sup>105</sup> Nelson and colleagues selected studies that focused on studies that tested screening instruments for intimate partner violence and the effectiveness of health care interventions for victims of intimate partner violence. Of the 14 studies on screening instruments, 4 were rated to be good in quality and all involved the comparison of one screening instrument with another. The two intervention studies and the other screening studies were deemed to be fair or poor in quality.<sup>106</sup> All three reviews illustrated the dearth of studies examining health and safety outcomes for women experiencing intimate partner violence.

These reviews highlight the challenges of defining measurable outcomes for intimate partner violence screening and intervention programs and protocols. Nelson and colleagues admit that the definition of outcomes should not focus merely on violence incidents but should be broadened to include “improved quality of life, mental health, social support, self-esteem, and productivity.” Currently, however, measures specific to women experiencing intimate partner violence do not exist.

Despite these reviews and the lack of large randomized, controlled trials in intimate partner violence, our knowledge and understanding regarding intimate partner violence should not merely depend on quantitative studies. A large body of well-done qualitative studies are available that examine how health care providers can help women experiencing intimate partner violence. Multiple qualitative studies suggest that although a single clinical encounter may not be associated with direct health and safety outcomes, there may be important intermediate cognitive and emotional changes, such as increased awareness of intimate partner violence as a problem, realizing the existence of options, and feeling that change is possible.<sup>82–84,108</sup> Several experts have found that seeking help for and finding safety from intimate partner violence may occur in stages or steps.<sup>109–113</sup> Thus a health care provider’s inquiry about and offering interventions for intimate partner violence could contribute to changes in a patient’s attitude, thoughts, and feelings that may facilitate future help-seeking actions.

**KEY POINTS**

- The distinction between ovulatory and anovulatory abnormal uterine bleeding is critical because causes and therapies are distinct.
- The diagnosis of menorrhagia is usually subjective, with the only objective indicator readily available to the physician being a low hemoglobin.
- Uterine fibroids, endometrial polyps, and adenomyosis are common anatomic abnormalities causing menorrhagia.
- Nonanatomic causes of menorrhagia include bleeding disorders, hypothyroidism, and essential menorrhagia.
- Evaluation of the uterine cavity by means of saline infusion sonography, TSH level, and coagulation studies is the core workup in patients with menorrhagia.
- Medical therapy is usually effective in patients with menorrhagia.
- Any cause of normoestrogenic anovulation can present as dysfunctional uterine bleeding.
- In anovulatory patients with dysfunctional uterine bleeding, prolactin, TSH, and FSH should be measured.
- In anovulatory patients and patients with menorrhagia over the age of 40 years, endometrial biopsy should be considered to rule out hyperplasia.
- Medical therapy is the first-line therapy for dysfunctional uterine bleeding.

Abnormal uterine bleeding is a common and vexing problem. In England, about 30 per 1000 female patients per year consult with their general practitioners for evaluation of abnormal uterine bleeding. About 20% of referrals from general practitioners to gynecologists are for abnormal uterine bleeding; and of those referred, about half undergo hysterectomy.<sup>1</sup> About 11% of hysterectomies performed in the United States are for abnormal bleeding.<sup>2</sup> Abnormal uterine bleeding has significant economic impact, with work loss estimated to be almost U.S.\$1700 annually for women with menorrhagia.<sup>3</sup>

**CLINICAL FEATURES****Definitions and Scope**

Uterine bleeding associated with early pregnancy may be due to threatened abortion, incomplete abortion, or ectopic pregnancy. This chapter is concerned only with abnormal uterine bleeding in nonpregnant, reproductive-aged women. The critical distinction to be made in the evaluation and treatment of abnormal uterine bleeding is whether it is associated with ovulation or

anovulation. In this chapter, abnormal uterine bleeding associated with anovulation is referred to as dysfunctional uterine bleeding. However, the term *dysfunctional uterine bleeding* sometimes also is used for essential menorrhagia, which is menorrhagia without evidence of an anatomic or other cause.<sup>4</sup> Menorrhagia is heavy menses in ovulatory women, whereas metrorrhagia is irregular bleeding during an ovulatory cycle (Table 8-1). The distinction between ovulatory and anovulatory bleeding is critical because causes and therapies are distinct.

**Menometrorrhagia**

The diagnosis of menorrhagia is usually made by the patient. Menstrual bleeding lasting longer than 7 days or associated with clotting is common in menorrhagia. The average menstrual blood loss is about 40 mL per cycle; any loss greater than 80 mL is associated with an increased risk of anemia and is considered menorrhagia.<sup>5,6</sup> Menstrual blood loss can most accurately be quantified by the alkaline hematin method, in which catamenial receptors are soaked in 5% sodium hydroxide to convert the blood to alkaline hematin and optical density is measured. Weighing of total menstrual fluid also has been described as being sufficient for the diagnosis of menorrhagia. A pictorial blood loss assessment chart has been developed that provides a semiquantitative measurement of menstrual blood loss and may be better suited to clinical practice.<sup>4</sup> However, all these methods are inconvenient and cumbersome, and the diagnosis of menorrhagia is usually subjective, with the only objective indicator readily available to the physician being a low hemoglobin.

Metrorrhagia may be physiologic when it presents as mid-cycle spotting, which is probably the result of falling estradiol levels during the time of the luteinizing hormone surge. All intrauterine devices (IUDs), except those containing progestins, increase the prevalence of menorrhagia. Depending on the type used, menorrhagia occurs in 25% to 50% of IUD users after 1 year.<sup>6</sup>

Uterine leiomyomata, particularly those that distort the uterine cavity, endometrial polyps, and adenomyosis all have been associated with menometrorrhagia. Both polyps and myomas are more common in women with abnormal uterine bleeding than in asymptomatic women. In a study using sonohysterography in 80 women with abnormal uterine bleeding and 100 asymptomatic, age-matched controls, endometrial polyps (32% vs 10%), intracavitory myomas (21% vs 1%), and intramural myomas (57% vs 13%) were all significantly more common in women with abnormal uterine bleeding.<sup>7</sup> In studies of women undergoing hysteroscopy for menorrhagia, 10% to 15% had submucosal myomas and 15% to 30% had endometrial polyps.<sup>8</sup>

Adenomyosis is the benign invasion of endometrial glands and stroma into the myometrium. Most cases (90%) occur in

multiparous women, and about 80% of women with adenomyosis are 40 to 50 years old.<sup>9</sup> The most frequent symptoms are menorrhagia, dysmenorrhea, and metrorrhagia. Classically the uterus is diffusely enlarged and tender to palpation. The role of adenomyosis in the pathogenesis of menometrorrhagia is perplexing, in part because it frequently occurs in asymptomatic women.<sup>9</sup> Adenomyosis has been found in 54% of uteri examined at autopsy.<sup>10</sup> In a prospective study of patients undergoing hysterectomy, there was no difference in duration of menstrual bleeding or presence of dysmenorrhea in the 28 patients found to have adenomyosis and the 157 without adenomyosis or endometriosis.<sup>11</sup>

On the other hand, adenomyosis often is associated with abnormal uterine bleeding. Adenomyosis was found in hysteroscopic biopsy specimens in 37% of 90 menorrhagic women. However, if the uterine cavity was normal, the number of patients who had significant adenomyosis increased to 66%.<sup>8</sup> Adenomyosis was found in 20 of 43 women with an enlarged uterus without evidence of leiomyomata on ultrasound who had hysterectomy for persistent menorrhagia.<sup>12</sup> Ultimately, the role of adenomyosis in abnormal uterine bleeding may prove to be quantitative, with more extensive disease and greater depth of myometrial invasion more likely to cause abnormal bleeding.<sup>9</sup>

Hyperthyroidism rarely causes menometrorrhagia. Polymenorrhea or hypermenorrhea was noted in only 8% of 214 reproductive-aged women with hyperthyroidism.<sup>13</sup> Hypothyroidism causes a range of menstrual abnormalities from amenorrhea to menometrorrhagia. In a study of 171 reproductive-aged women with hypothyroidism, 23% had menstrual abnor-

malities. Menorrhagia accounted for about one third of the abnormalities.<sup>14</sup> Early hypothyroidism has been found in 22% of women with menorrhagia<sup>15</sup> and overt hypothyroidism in 2% of women with menorrhagia evaluated for endometrial ablation.<sup>8</sup>

Bleeding disorders should always be considered in women with menorrhagia without an anatomic cause. In particular, bleeding disorders should be considered in adolescents admitted to the hospital with acute menorrhagia. A primary coagulation disorder has been reported in 19% to 28% of such patients, with 50% of patients hospitalized with excessive bleeding at menarche having clotting disorders.<sup>16,17</sup> Of the 18 adolescents described in the two reports, 11 had thrombocytopenia due to idiopathic thrombocytopenia purpura ( $n = 8$ ) or to leukemia, thalassemia major, or Fanconi's anemia (one each), and 5 had von Willebrand's disease.

In adults with objectively proved menorrhagia, inherited bleeding disorders have been found in 13% to 20%.<sup>18-20</sup> The prevalence is somewhat less, about 11%, in women who have menorrhagia without objective verification.<sup>21</sup> The majority of patients had von Willebrand's disease, but deficiencies of factor VII, X, and XI and platelet dysfunction also were found. Inherited bleeding disorders were more likely in women with a history of menorrhagia since menarche or with a history of excessive bleeding after tooth extraction, surgery, or childbirth.<sup>19</sup> Menorrhagia has been demonstrated objectively in 5 of 11 women of reproductive age undergoing treatment with oral anticoagulants.<sup>22</sup>

There is debate about whether tubal sterilization increases a woman's risk of increased menstrual and intermenstrual bleeding, often referred to as the post-tubal-sterilization syndrome. A study of more than 9500 women who underwent tubal sterilization and 573 whose partners underwent vasectomy found no increased risk of abnormal bleeding in the tubal sterilization group. The women who underwent sterilization had significantly fewer days of bleeding and significantly lesser amounts of bleeding and dysmenorrhea.<sup>23</sup>

Essential menorrhagia is probably the most common cause of menorrhagia. About 50% of cases of objectively proved menorrhagia have no pathologic cause at hysterectomy.<sup>4</sup> Essential menorrhagia has been reported to occur in about 10% of western European women.<sup>6</sup> Pathogenic mechanisms include increased production of prostaglandins E<sub>2</sub> and F<sub>2</sub>α and prostacyclin by the endometrium and myometrium, increased myometrial concentrations of prostaglandin receptors, and elevated fibrinolytic activity in the endometrium.<sup>4</sup>

### Dysfunctional Uterine Bleeding

Any cause of anovulation with normal estrogen levels can present as dysfunctional uterine bleeding (see Table 8-1). Typically patients have irregular, unpredictable bleeding without symptoms of ovulation such as breast tenderness, mood changes, or dysmenorrhea. Anovulatory cycles are considered physiologic in the first year after menarche and in the perimenopause and do not require hormonal evaluation.<sup>24</sup> However, the cause of anovulatory cycles at other times in a woman's reproductive life should be investigated. Dysfunctional bleeding may occur during the transition to premature ovarian failure, just as it does at the time of physiologic menopause. Dysfunctional uterine bleeding is a common symptom of androgen excess. In women with

Table 8-2 Evaluation of Abnormal Uterine Bleeding

If anovulatory for more than 1 year: consider endometrial biopsy	
If unresponsive to medical therapy: rule out anatomic defect	

dysfunctional bleeding and evidence of hirsutism or acne, the most likely diagnosis is polycystic ovary syndrome.

If there is no evidence of hyperprolactinemia, hypothyroidism, premature ovarian failure, or androgen excess, dysfunctional uterine bleeding is characterized as hypothalamic dysfunction. The patient may be anovulatory as a result of stress, weight loss, or exercise or the cause may be idiopathic. These patients can be reassured that, as long as they continue to withdraw to a progestin challenge, there is no serious cause for their anovulation.

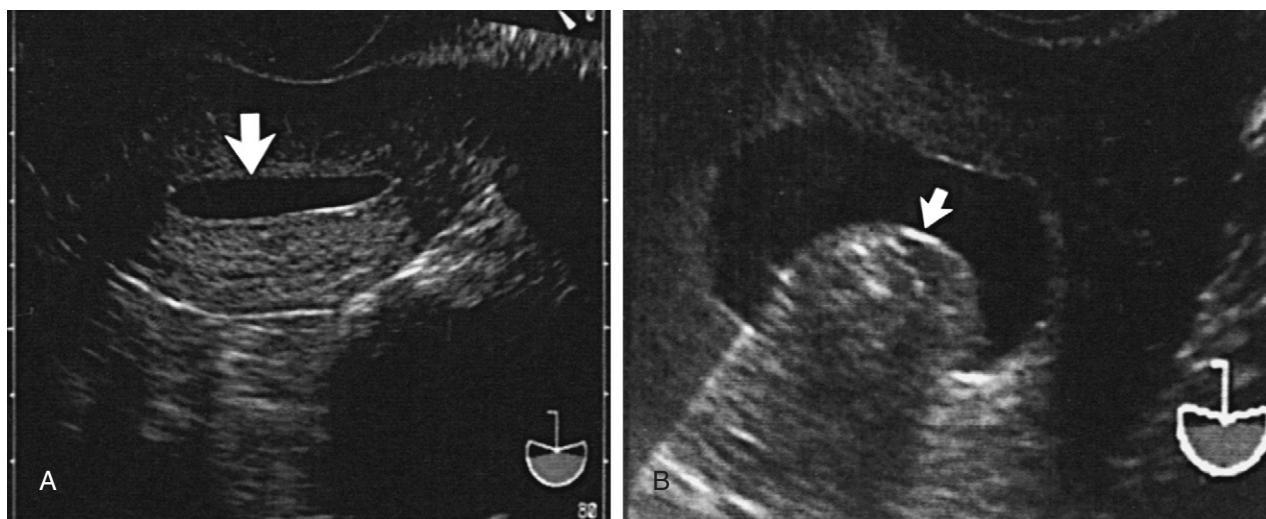

The long-term consequence of chronic anovulation is endometrial hyperplasia and carcinoma. Chronically anovulatory women have a threefold increased risk of endometrial cancer.<sup>25</sup> Endometrial hyperplasia occurs in about 5% and endometrial cancer in about 0.5% of premenopausal women who undergo sampling for abnormal uterine bleeding. Risk factors include age of 45 years or older, weight of 90 kg or greater, a history of infertility, family history of cancer of the colon, and nulliparity.<sup>26</sup>

## DIAGNOSIS

### Menometrorrhagia

Menometrorrhagia is often difficult to distinguish from dysfunctional uterine bleeding. Ovulation should be confirmed in uncertain cases by an ovulatory serum progesterone level or finding secretory endometrium on biopsy. Basal body temperature charting is useful to time the preceding tests during the midportion of the temperature rise (Table 8-2).

The patient with menometrorrhagia should be evaluated for the presence of an anatomic abnormality. Oftentimes, this is easily accomplished by palpating a fibroid uterus on physical examination. However, symptomatic submucosal fibroids or endometrial polyps can be present in a normal-size uterus (Fig. 8-1). Therefore, all patients with menometrorrhagia should undergo imaging of the uterine cavity. Transvaginal ultrasound with saline infusion of the uterine cavity (saline infusion sonography [SIS] or sonohysterography) is the best initial choice among current options. A large meta-analysis found a sensitivity of 0.95 and a specificity of 0.88 for SIS compared with the gold standard of either hysteroscopy or hysterectomy, and only about 7% of uterine cavity abnormalities were missed by SIS.<sup>27</sup> SIS can be performed successfully in 95% of premenopausal women and is as accurate as diagnostic hysteroscopy.<sup>27</sup> SIS is more reliable than magnetic resonance imaging (MRI) in detecting endometrial polyps, is equivalent to MRI in detecting submucosal

**Figure 8-1** Images from saline-infused sonograms from two different patients. *A*, Normal study, with saline filling the uterine cavity (arrow). The borders are regular, and no masses protrude into the cavity. *B*, In this magnified view, a myoma protrudes into the cavity from the posterior uterine wall. (From Bayer SR: Clinical management of abnormal uterine bleeding. In Gershenson DM, DeCherney AH, Curry SL, Brubaker L [eds]: Operative Gynecology, 2nd ed. Philadelphia, W.B. Saunders, 2001, p 478.)

fibroids, and can provide information regarding intramural extension.<sup>28</sup> SIS also is easier to perform and better accepted by patients than hysteroscopy or MRI.<sup>27</sup>

Preoperative diagnosis of adenomyosis may be difficult to make. The physical finding of a diffusely enlarged, tender uterus is not always present. Transvaginal ultrasound is about 80% sensitive in detecting adenomyosis, with a 26% false-positive rate.<sup>12</sup> The most reliable preoperative method for detecting adenomyosis is MRI.<sup>29</sup> Based on histopathologic diagnosis, MRI correctly revealed adenomyosis in 88% of cases versus 53% of cases uncovered by transvaginal ultrasonography. MRI correctly distinguished between leiomyomata and adenomyosis in 92 of 93 patients with an enlarged uterus.

Thyroid-stimulating hormone (TSH) should be measured in all patients with menometrorrhagia as a screening test for both hypothyroidism and hyperthyroidism.

In patients with an otherwise normal evaluation, consider testing for bleeding disorders before making the diagnosis of essential menorrhagia. As mentioned above, the mostly likely bleeding disorders are thrombocytopenia from various causes and von Willebrand's disease. Menorrhagia since menarche, bleeding following surgical or dental procedures, and postpartum hemorrhage are predictive of von Willebrand's disease in adult women with menorrhagia.<sup>30</sup> If there is suspicion of a clotting disorder, a prothrombin time, partial thromboplastin time, platelet count, and platelet function analysis should be performed.<sup>30</sup> The ristocetin cofactor assay of von Willebrand's factor function may be the best single screening test for von Willebrand's disease.<sup>31</sup> Consultation with a hematologist is helpful if there is concern that a bleeding disorder may be the cause of menorrhagia.

### Dysfunctional Uterine Bleeding

Prolactin, follicle-stimulating hormone (FSH), and TSH should be measured in all patients with anovulation whether they have amenorrhea, oligomenorrhea, or dysfunctional uterine bleeding to rule out hyperprolactinemia, hypothyroidism, and premature ovarian failure. The diagnosis of polycystic ovary syndrome is clinical and is based on a history of anovulation, symptoms or signs of androgen excess, and the finding of polycystic ovaries on ultrasound. Laboratory confirmation is made by finding elevated total or free testosterone levels.<sup>32</sup> Late-onset or nonclassic 21-hydroxylase deficiency is an uncommon cause of androgen excess, occurring in less than 5% of hyperandrogenic women. It can be reliably ruled out by a 17-hydroxyprogesterone of less than 2 ng/mL.<sup>33</sup>

Endometrial biopsy should be considered for all patients with abnormal uterine bleeding and a risk factor for endometrial cancer, particularly those 45 years of age or older and those who weigh 90 kg or more. Some authors recommend that an endometrial biopsy be done in a patient of any age with a history of anovulatory bleeding of more than 1 year's duration because there have been reports of endometrial cancer in patients as young as 15 years of age.<sup>24,34</sup> The Pipelle endometrial sampling device is superior to other biopsy techniques. It is an office procedure that is easily performed and well tolerated. It has a sensitivity of 91% for the diagnosis of premenopausal endometrial carcinoma, sensitivity of 81% for the diagnosis of atypical endometrial hyperplasia, and specificity for both of greater than 98%.<sup>35</sup> Although an endometrial thickness of 5 mm or greater

on transvaginal ultrasound detects 96% of endometrial cancer in postmenopausal women, there are no data concerning its role in the diagnosis of endometrial cancer in premenopausal women.<sup>36</sup>

## TREATMENT

### Menometrorrhagia

The two general approaches to treatment of menometrorrhagia are surgical and medical therapy (Table 8-3). Hysteroscopic resection of a submucosal myoma or polyp in patients with menometrorrhagia has become standard practice (see Chapter 38). About 80% of women with menometrorrhagia treated with resection of endometrial polyps report the return to a normal pattern of menstrual bleeding, with a mean follow-up of 5 years.<sup>37</sup> After hysteroscopic resection of a submucosal myoma, the 3-year probability of recurrence of myomas and menorrhagia is 34% and 30%, respectively.<sup>38</sup>

As a general rule in patients with menometrorrhagia without obvious uterine myomas and no intracavitary lesions, medical treatments should be attempted before surgical therapy. If

**Table 8-3**  
**Treatment of Abnormal Uterine Bleeding**

#### Menometrorrhagia

##### Anatomic defect

- Endometrial polyp or submucosal myoma
- Hysteroscopic resection

##### Other uterine myoma

- More children desired: myomectomy
- No more children desired: hysterectomy

##### Adenomyosis

- More children desired: medical therapy (see essential menorrhagia)
- No more children desired: hysterectomy

##### Bleeding disorders

- Consultation with hematologist
- Oral contraceptive pill

##### Intranasal desmopressin

##### Tranexamic acid

##### Endometrial ablation

##### Hypothyroidism

##### Thyroid replacement therapy

##### Essential menorrhagia

- Oral contraceptive pill

##### NSAIDs

- Combination of oral contraceptive pill and NSAID

##### Levonorgestrel IUD

- Failure of above treatments and more children desired: GnRH agonist and add-back therapy; danazol

- Failure of above treatments and no more children desired: endometrial ablation

#### Dysfunctional uterine bleeding

##### Hyperprolactinemia

##### Carbergoline

##### Bromocriptine

##### Hypothyroidism

##### Thyroid replacement therapy

##### Other causes of anovulation

- Oral contraceptive pill

##### Cyclic progestins

- Failure of above treatments and more children desired: levonorgestrel IUD; GnRH agonist and add-back therapy

- Failure of above treatments and no more children desired: hysterectomy

hypothyroidism is present, patients respond very quickly to thyroid hormone replacement therapy, with a rapid decline in menstrual blood loss.<sup>39,40</sup> Medical therapies for von Willebrand's disease include the oral contraceptive pill, intranasal desmopressin, and antifibrinolytics such as tranexamic acid. Endometrial ablation also may be effective.<sup>31,41</sup>

Medical therapies for menorrhagia include the oral contraceptive pill, oral progestins, progestin-containing IUDs, nonsteroidal anti-inflammatory drugs (NSAIDs), danazol, tranexamic acid, and gonadotropin-releasing hormone (GnRH) agonists. The oral contraceptive pill is probably the first line of therapy for treating menorrhagia, and its efficacy is supported by wide clinical experience.<sup>4</sup> However, few objective data support this common clinical practice. A recent review found a single randomized trial of the oral contraceptive pill in menorrhagia. The oral contraceptive pill reduced menstrual blood loss by 43% and did not differ in efficacy from danazol, mefenamic acid, or naproxen.<sup>42</sup>

An oral progestin given only during the luteal phase is not effective in the treatment of menorrhagia. However, when started on cycle day 5 and continued for 21 days, norethindrone acetate 5 mg three times a day resulted in an 87% reduction in menstrual blood loss compared with baseline. Oral norethindrone acetate was less efficacious than the levonorgestrel-releasing IUD and had a lower proportion of patient acceptability.<sup>43</sup>

The levonorgestrel-releasing IUD reduces menstrual blood loss by 96% after 12 months in patients with essential menorrhagia and to a significantly greater degree than an NSAID or tranexamic acid.<sup>44</sup> After an initial randomized treatment period of 6 months, 64% of women scheduled for hysterectomy because of menorrhagia postponed surgery and continued treatment with the levonorgestrel-releasing IUD compared with 14% undergoing other medical treatments ( $P < 0.001$ ).<sup>45</sup> In a randomized trial in women with menorrhagia, the levonorgestrel IUD was as effective as endometrial resection as determined by hemoglobin concentrations after 6 months of therapy and by rates of satisfaction with treatment.<sup>46</sup> However, women with menorrhagia who underwent endometrial resection had a significantly greater reduction in menstrual blood loss, higher rates of amenorrhea, and fewer progestogenic side effects.<sup>47</sup> Five-year follow-up of 236 women with menorrhagia randomized to either the levonorgestrel IUD or hysterectomy found similar improvement in health-related quality of life in the two groups. Although 42% of women randomized to the IUD eventually had a hysterectomy, the costs in the IUD group remained substantially lower than in the hysterectomy group.<sup>48</sup>

The levonorgestrel IUD also is effective in treating menorrhagia in women with adenomyosis diagnosed by transvaginal ultrasound. Treatment resulted in resolution of menorrhagia in all 24 patients and a significant increase in hemoglobin at 3, 6, and 12 months of therapy.<sup>49</sup> In contrast, the levonorgestrel IUD is relatively ineffective in treating menorrhagia in women with leiomyomas and a uterine volume equivalent to 8 to 12 weeks of pregnancy but without intracavitary abnormalities, with 14 of 19 women having persistent menorrhagia after 12 months of therapy.<sup>50</sup>

Randomized trials have shown that NSAIDs reduce menstrual blood loss by 20% to 50% in women with objectively verified menorrhagia and are well tolerated when given for about

5 days.<sup>51</sup> Mefenamic acid 500 mg three times a day is the most studied drug. However, both ibuprofen 400 mg three times a day and naproxen 250 mg four times a day are efficacious. Limited data do not suggest a difference in efficacy among the NSAIDs.

Danazol 200 mg daily for 3 months reduces menstrual blood loss by 80%.<sup>52</sup> Small clinical trials have found that danazol is more effective than the oral contraceptive pill or mefenamic acid in treating menorrhagia.<sup>53</sup> Its usefulness is limited by daily administration and the need for adequate contraception owing the risk of masculinization of a female fetus exposed to danazol between 8 and 18 weeks' gestation. Other androgenic side effects of danazol include weight gain, acne, hirsutism, and hoarseness. Thus, danazol is effective but rarely used to treat menorrhagia because of side effect and safety concerns.

Tranexamic acid is a plasminogen activator inhibitor approved in the United States for treatment of acute episodes of bleeding in hemophilia. It reduces menstrual blood loss by 50% in women with objectively proved essential menorrhagia.<sup>54</sup> The usual dose is 1 g four times a day during days 1 through 5 of the menstrual cycle. Tranexamic acid is more effective than NSAIDs but has not been compared with hormonal treatments for menorrhagia. The major concern about use of tranexamic acid is the risk of thrombosis. Long-term studies in Sweden show that the rate of thrombosis in women treated with tranexamic acid is comparable with the rate in untreated women. However, there have been at least three cases of intracranial arterial thrombosis in women using antithrombolytics for menorrhagia.<sup>6</sup>

GnRH agonists have been investigated in patients with essential menorrhagia and adenomyosis. There are case reports of pregnancy following GnRH agonist therapy of severe adenomyosis.<sup>55,56</sup> A GnRH agonist given with cyclic hormone replacement therapy reduced menstrual blood loss by 43% in women with objectively proved essential menorrhagia.<sup>57</sup> Because of their expense, GnRH agonists should be reserved for use in women with essential menorrhagia or adenomyosis who are unresponsive to other medical therapy and who wish to preserve childbearing.

Surgical therapy of essential menorrhagia is discussed in detail in Section 6 of this text but is briefly considered here, particularly in comparison to medical therapy. Hysterectomy and endometrial ablation are the two general categories of surgical treatment for essential menorrhagia. First-generation endometrial ablation techniques include endometrial resection, rollerball, and laser ablation. Second-generation ablative techniques include inflatable balloons inserted into the endometrial cavity through which heated water is circulated, hot water instillation systems, endometrial cryoablation, and intrauterine diode laser fiber arrays.<sup>58</sup> The goal of these second-generation techniques is to achieve effectiveness similar to that of first-generation techniques but with greater patient safety and ease of operator use. Most second-generation techniques give similar results. Generally, there is about a 30% to 50% prevalence of amenorrhea and 80% to 90% satisfaction rate 6 months after second-generation treatments.<sup>58</sup>

After 6 months to 2 years of treatment or follow-up, both hysterectomy and endometrial ablation are superior to oral medical therapy with regard to control of bleeding, patient satisfaction, and side effects as determined in randomized trials.<sup>58-60</sup>

As noted previously, the levonorgestrel IUD is somewhat less effective than endometrial ablation or hysterectomy but remains a reasonable alternative.

When surgical techniques are compared, patient satisfaction rates are slightly but significantly higher after hysterectomy than after first-generation endometrial ablation techniques. Within 5 years of ablation, about 15% of women will have a second ablation and about 20% will undergo hysterectomy.<sup>58</sup>

If deep adenomyosis is present, hysterectomy, not ablation, is probably a more appropriate therapy. Adenomyosis is a frequent finding in hysterectomy specimens from patients whose ablation treatment has failed.<sup>61,62</sup>

### Dysfunctional Uterine Bleeding

When dysfunctional uterine bleeding is due to hyperprolactinemia, a dopamine agonist, such as cabergoline or bromocriptine, is effective in restoring ovulatory function. Cabergoline is more effective and better tolerated than bromocriptine, but only bromocriptine is approved for ovulation induction in women desiring pregnancy.<sup>63</sup> The oral contraceptive pill may also be used to control abnormal bleeding in hyperprolactinemic patients, although there is some concern that it could result in growth of a prolactin-secreting microadenoma.<sup>64</sup> Patients with dysfunctional uterine bleeding and hypothyroidism respond quickly to thyroid hormone replacement therapy, as noted above.

In other patients with dysfunctional uterine bleeding, periodic progestin administration is probably effective in restoring a normal bleeding pattern (see Table 8-3). A progestin, such as medroxyprogesterone acetate, is given by mouth 5 mg daily for the first 14 days of each month. There are some objective data that either cyclic medroxyprogesterone acetate or norethindrone acetate given for 14 days of each month results in a significant decrease in blood loss and duration of bleeding in women with dysfunctional uterine bleeding.<sup>65</sup> The oral contraceptive pill is often used and widely accepted as effective treatment in patients with dysfunctional uterine bleeding, although objective data are scarce. A randomized, double-blind, multi-center trial found a triphasic norgestimate-ethynodiol oral contraceptive pill superior to placebo in treating anovulatory dysfunctional uterine bleeding. Subjects treated with the oral contraceptive pill were nearly twice as likely to note improvement in their bleeding pattern than were women treated with placebo (87% vs 45%), and 47% of treated subjects developed regular bleeding patterns in the relatively brief three study cycles.<sup>66</sup>

Metformin, usually in dosages of 1500 to 1700 mg/day, results in ovulation in 50% or more of women with polycystic ovary syndrome.<sup>67</sup> However, it has not been investigated as a treatment for dysfunctional uterine bleeding in this disorder.

The levonorgestrel IUD is a reasonable next option in women who do not respond to therapy with progestins or the oral contraceptive pill, although there are no data on its efficacy in this subgroup. As with essential dysmenorrhea, the last resort of medical therapy in women desiring more children is a GnRH agonist with add-back therapy.

Occasionally, patients with dysfunctional uterine bleeding have acute episodes of extremely heavy bleeding that require immediate therapy. An effective outpatient therapy is to give

any low-dose oral contraceptive pill, one or two pills twice daily for 5 to 7 days. Patients usually stop bleeding within 12 to 24 hours, but therapy should be continued for the full 7 days. Upon completion of therapy, the patient will have a self-limited episode of bleeding, which may be heavy. Five days after discontinuing the initial dosage, the birth control pill can be restarted, one tablet daily as for contraception.<sup>68</sup> In patients with significant anemia, the withdrawal bleed may be postponed by continuing the oral contraceptive until the hemoglobin is adequate to allow it. In women requiring inpatient observation and therapy, intravenous Premarin, 25 mg every 3 to 4 hours for up to three doses, is effective in the treatment of dysfunctional uterine bleeding.<sup>69</sup> After the acute episode of bleeding is treated, it is important to give the patient chronic intermittent progestin therapy or the oral contraceptive pill to prevent further episodes.

Endometrial ablation is not the ideal therapy for patients with dysfunctional uterine bleeding, because chronic anovulation and unopposed ovarian estrogen production continue despite ablation. Since the endometrium may not be completely destroyed by endometrial ablation, there is continued need for progestin therapy to prevent endometrial carcinoma in the residual islands. Endometrial carcinoma has been reported in a variety of circumstances following endometrial ablation, including in two perimenopausal patients 3 and 5 years after endometrial ablation for dysfunctional uterine bleeding.<sup>70,71</sup> In the author's opinion, hysterectomy may be a more appropriate surgical choice for patients who cannot tolerate or do not respond to medical therapy for dysfunctional uterine bleeding.

**KEY POINTS**

- Preventive medicine involves a spectrum of interventions, including primary, secondary, and tertiary prevention.
- Screening tests should not be utilized or interpreted in the same way as diagnostic tests.
- A basic knowledge of epidemiology is important for understanding preventive health care and implementing preventive evaluations and interventions.
- Many different preventive recommendations or guidelines are offered by various professional medical, research, and epidemiologic societies.
- Important preventive health topics include tobacco use, alcohol misuse, unintentional injury, seat belt use, depression, hyperlipidemia, hypertension, and obesity. Physicians can make a difference in these areas with appropriate screening and counseling.
- As health care resources become more scarce and practitioners become busier, it is important to use only those interventions that have been proven to change outcomes.

**INTRODUCTION**

The advent of health care maintenance organizations and the concept of primary care physicians as gatekeepers have brought preventive medicine to the forefront as the key to better use of health care resources. The purpose of preventive medicine is to detect disease before its onset or in its early stages in order to implement early treatment. Preventive counseling can empower a patient to take appropriate measures to eliminate risks and to adopt healthful behaviors to prevent disease.

Although many diseases present clear potential for prevention, many interventions have not been proved to prevent disease. It is paramount that clinicians know which tests, types of counseling, and treatments actually work as demonstrated by rigorous research. Unfortunately, screening of the asymptomatic individual is time consuming and is often unwelcomed by the patient and not reimbursed by third-party payers.

While screening for disease seems only beneficial, there are potential harms. There certainly is harm if screening is performed incorrectly. But even when performed correctly, screening has downfalls. Screening inevitably produces a certain number of false-positive results. Subsequent testing, particularly if invasive, can increase morbidity and mortality. The patient can experience anxiety and stress induced by the diagnostic limbo created by a positive screening test. Patients who are incorrectly screened

can be mislabeled. False-negative screens, on the other hand, can give a false sense of security.

Additionally, clinicians need to be knowledgeable about the appropriate interpretation of screening tests. The possible outcomes of screening should be reviewed with patients before the test and then more specifically reviewed after test results are returned. The imprecise role of screening for diagnosis should be clarified for patients.

Preventive medicine is inherently different from the classical curative model of the physician's role.<sup>1</sup> Historically, patients come to physicians with complaints. Preventive medicine requires the physician to be proactive—the instigator of questions, screening, and treatment. A physician's skills as an educator are paramount for a successful preventive practice. The physician must be able to assess a nondiseased patient's risks, offer applicable screening for diseases, determine the most appropriate preventive interventions, counsel the patient about these interventions, and then educate the patient about the potential results and necessary follow-up plans. The physician has to be able to motivate the unmotivated patient and to change patient behavior and compliance—and to be able to do all of this in the setting of a busy ambulatory practice!

**DEFINITIONS**

*Primary prevention* is preventing the onset of disease. It should be applied to all patients. Common examples include obesity counseling and immunizations. *Secondary prevention* is diagnosing disease in its asymptomatic state. It is often applied to a more narrow population, perhaps those at risk for a specific disease. For instance, the Papanicolaou (Pap) smear is a screening test for early dysplastic changes that can be treated, preventing progression to cervical cancer. *Tertiary prevention* is preventing serious sequelae from previously diagnosed disease. An example is anticoagulation in patients with known coagulopathy in order to prevent deep vein thrombosis and subsequent pulmonary embolus.

To evaluate a screening test, it is important to be familiar with some basic epidemiologic concepts and link them to important clinical questions. *Sensitivity* is the proportion of the population with disease who have a positive test. (What percentage of people who actually have the disease will test positive?) *Specificity* is the proportion of the population without disease who have a negative test. (What percentage of people who do not have the disease will test negative?) *Positive predictive value* is the proportion of the population with a positive test who have the disease. (What is the chance that you have the disease if your test is positive?) *Negative predictive value* is the proportion of the population with a negative test who do not have the disease.

## Ambulatory Office Practice

(What is the chance that you really do *not* have the disease if your test is negative?)

Additional concepts that are important to be familiar with include the following. *Incidence* is the number of new cases of disease in a certain period of time. *Prevalence* is the total number of existing cases. This is a particularly important concept because a disease with low prevalence decreases positive predictive value, highlighting the point that certain screening tests are inappropriate in certain populations. *Reliability* is a test's ability to produce the same result time after time. *Validity* is the ability of a test to measure what it claims to measure.

In general very few tests have good sensitivity and good specificity. Most involve trade-offs between the two. Experts have tried to develop different measures of validity to help clinicians understand and gauge which tests are appropriate. One example is diagnostic accuracy, which is defined as the sum of true positives and true negatives divided by the number of all those tested.<sup>2</sup> Others suggest that the definition of a "good" screening test is one in which the sum of the sensitivity and specificity is greater than or equal to 1.5. A "very good" test has a sum of at least 1.8.

A good screening test is sensitive but often not specific. Screening tests should be designed to detect a significant majority of those affected, sometimes at the cost of falsely detecting some who are not. Screening protocols, constructed with a series of tests, correct for this by further evaluating those who are screen positive. These tests usually proceed in a step-wise fashion, becoming progressively more invasive, more diagnostically accurate, and more expensive in order to maximally utilize resources. It is possible also to screen by performing two tests simultaneously, thus often improving sensitivity.

Though many health care dollars are spent researching and implementing screening strategies, screening is only appropriate if the following criteria are met.<sup>3</sup> (1) The disease being screened for is a significant public health problem. What is the burden of disease compared with the burden of prevention? What are the long-term outcomes of this disease? What is the severity of the disease? What is the prevalence of the disease? (2) The disease can be detected in the asymptomatic state. In other words, there is a definable period prior to the onset of disease that can be identified. Various methods of screening include questionnaires and history-taking, laboratory results, and physical examination findings. (3) The disease can be treated in the early stages. There is no point to screen for disease if no intervention will improve outcomes.

To make the situation even more confusing, many governing bodies offer different recommendations colored by their organizational biases and based on different data. Sometimes their recommendations even conflict! Examples of such organizations are the American Cancer Society (ACS), the American College of Obstetricians and Gynecologists (ACOG), the World Health Organization (WHO), the Centers for Disease Control and Prevention (CDC), the American Academy of Family Physicians (AAFP), the American Heart Association (AHA), the National Institutes of Health (NIH), the American College of Physicians (ACP), the American Medical Association (AMA), the United States Preventive Services Task Force (USPSTF), and the American College of Preventive Medicine (ACPM).

The best strategy is to examine all the data with a critical eye; however, in light of the plethora of literature, not to mention clinical responsibilities, this is impossible for most practitioners. All these organizations strive to summarize the data, but their conclusions can differ. USPSTF and its Canadian equivalent, the Canadian Task Force, adhere to rigorous standards in their evaluation of preventive care data. Their recommendations offer solid guidelines based on objective review of the best data available.

## TOPICS FOR PREVENTIVE MEDICINE

The following discussion does not address preventive issues that are discussed elsewhere in this text, such as osteoporosis, cancer prevention, preventive health in pregnancy, domestic violence, screening in the pediatric patient, preconceptional screening, contraception screening, and sexually transmitted infection screening. The following discussions occur in no particular order.

### Skin Cancer

Skin cancer is the most common cancer in the United States. There are three major types: melanoma, basal cell carcinoma, and squamous cell carcinoma. Basal cell carcinoma is the most common; melanoma is the most lethal, accounting for 75% of deaths from skin cancer. The incidence of melanoma is increasing from 5.7/100,000 in 1973 to 17.7/100,000 in 2000. The overall mortality also is increasing from 1.6/100,000 to 2.4/100,000 in the same time period. Melanoma is the sixth most common cancer-causing death, with 44,000 new cases diagnosed in 1999. The 5-year survival from melanoma is 89.6%, increased from previous years.<sup>4</sup>

It is important to distinguish between melanoma and non-melanoma (basal cell and squamous cell) skin cancers. Basal cell and squamous cell carcinoma treatments are almost always curative. Most screening protocols are directed at melanoma because of its increased morbidity and mortality.

A successful screening program with early treatment has the potential in theory to prevent some of the morbidity associated with advanced skin cancer treatments including disfigurement, anxiety, and complications of treatment. Screening techniques that have been studied in this area include full-body skin examination, questionnaires identifying risk, and education about sun avoidance, including wearing sun block and staying out of the sun during times of highest ultraviolet ray exposure. The morbidity associated with these techniques is limited to inconvenience to the patient, embarrassment from full-body skin examination, possible skin reactions from sun block, and misdiagnosis.

The official recommendation of USPSTF is that the evidence is insufficient to recommend for or against performing full-body examination for early detection of skin cancer.<sup>5</sup> The benefit is unproved even in patients at high risk for melanoma, including fair-skinned men and women older than 65 years of age, individuals with atypical moles, and those with more than 50 moles. Of course, suspicious lesions, specifically those with asymmetry, variable coloring, irregular borders, or a diameter greater than 6 mm should be sampled for biopsy.

No randomized-controlled trials have examined whether skin cancer screening of the general population results in a difference

in skin-cancer deaths. In populations that were self-selected secondary to interest in free screening or that had lesions requiring examination, dermatologic specialists were able to identify cancerous lesions with greater sensitivity and specificity than were general practitioners. These results cannot be extrapolated to a general population for screening. General screening does not seem to increase the detection rate compared with partial examination or lesion-focused examination.<sup>6</sup>

One case-control study examined the effect of self-examination on morbidity and mortality from melanoma.<sup>7</sup> Berwick and colleagues studied 650 Caucasians with primary melanoma and matched them to 549 Caucasians from the general population. They followed both groups for 5 years and queried them about whether they performed skin examinations of any kind. They found that self-skin examination was associated with a decreased incidence of melanoma (OR 0.66, 95% CI 0.44–0.99) in the control group and a decreased incidence of lethal melanoma (OR 0.37, 95% CI 0.16–0.84) in those who already had the diagnosis.

It is important to remember that self-examination is not the same intervention as routine screening by a primary care physician. Self-examination usually occurs at more frequent intervals and thus can detect changes in lesions more effectively. However, one benefit of physician total-body examination is increased self-skin examination. Screening has been shown to increase biopsies.

USPSTF also has concluded that the evidence is insufficient to recommend routine counseling to change behaviors as a means to prevent long-term morbidity and mortality associated with skin cancer.<sup>8</sup> These behaviors include wearing sunscreen with UVA and UVB protection, avoiding tanning beds, avoiding sun from 10 AM to 4 PM, wearing protective clothing and accessories, and self-examining of the skin. Intense exposure, fair complexion, severe sunburn, and intermittent (as opposed to chronic) sun exposure all have been shown to increase risk for melanoma.

Wearing sunscreen decreases squamous cell carcinoma, but the results concerning preventing melanoma are mixed. Several descriptive studies show increased melanoma in those using sunscreen. Perhaps those using sunscreen are more likely to be at risk for other reasons and spend more hours in the sun when wearing sunscreen. The effect of tanning beds on melanoma incidence is mixed as well. There is no decreased vitamin D level in those using sunscreen.<sup>9</sup> One study has shown that youths are more likely to use sunscreen if their parents do. Thus, one benefit of changing adult behavior is to potentially alter the behavior of their children<sup>10</sup> (Table 9-1).

### **Physical Activity**

All evidence points to the benefits of physical activity in preventing many common chronic illnesses: obesity, hypertension, osteoporosis, cardiovascular disease, diabetes, and depression to name a few. This benefit is seen at even modest increases in activity or moderate activity for 30 minutes on most days of the week, with a dose-response effect. Despite these commonly known benefits, only 20% to 30% of adults achieve this activity level, with no appreciable change from 1990 to 1998.<sup>11</sup> At this writing, tobacco is the number one preventable cause of death, but obesity is predicted to soon surpass it. Epidemiologists who

**Table 9-1**  
**Skin Cancer Screening Recommendations**

Organization	Recommendation
<b>U.S. Preventive Services Task Force</b>	<b>Insufficient evidence for or against routine screening examination</b>
Canadian Task Force	No routine screening Regular total-body skin examination in high-risk individuals
American Cancer Society	Monthly skin self-examination Total-body skin examination every 3 years between ages 20 and 39, every year after age 40
National Institutes of Health American Academy of Dermatology	Annual total-body skin examination
American College of Preventive Medicine American Academy of Family Physicians American College of Obstetricians and Gynecologists	No routine screening Interval total-body skin examination in high-risk individuals

study obesity have found that most obese people do not eat significantly more than nonobese people but are much less active. A sedentary lifestyle is more and more common in U.S. culture. Watching television is an independent risk factor for obesity.<sup>12</sup>

USPSTF states that the evidence is insufficient to recommend for or against routine counseling for increased physical activity.<sup>13</sup> Many organizations recommend this routine counseling, but it is based on the obvious benefit of exercise rather than the true impact counseling might have. Although it is clear patients would be healthier if they exercised more, it is unclear whether clinicians can have a meaningful impact on their activity levels.

Possible interventions include brief counseling, written exercise prescriptions, specific physical activity goal setting, mail or phone follow-up, and individualized exercise regimens. Trials that compare physical activity counseling with routine primary care have mixed results in both the short term (<6 months) and the long term (>6 months), with a majority finding no difference. There are six controlled trials comparing intervention versus usual care or no intervention and two trials comparing two or more different interventions. All these trials demonstrate mixed results.<sup>14</sup> One trial showed that patients who received a written prescription in addition to advice about exercise were more active at 6-week follow-up.<sup>15</sup> Another trial comparing increasingly intensive counseling ranging from 18 minutes over 2 years to 9 hours over 2 years did not show a difference in physical activity up to 24 months later.<sup>16</sup>

Adverse effects of physical activity counseling potentially include increased injury to deconditioned patients attempting exercise. Presently, there is no convincing evidence to support this, and in fact there is evidence to demonstrate decreased falls in elderly community-dwelling patients after participating in exercise programs<sup>17</sup> (Table 9-2).

### **Dietary Activity**

Many dietary habits are associated with diseases including coronary arterial disease, osteoporosis, obesity, diabetes, and

**Table 9-2**  
**Physical Activity Counseling Recommendations**

Organization	Recommendation
<b>U.S. Preventive Services Task Force</b> Canadian Task Force	<b>Insufficient evidence for or against routine counseling</b>
Department of Health and Human Services Centers for Disease Control and Prevention American Academy of Family Physicians American Heart Association American College of Obstetricians and Gynecologists	Routine counseling for increased physical activity

some neoplasia. The evidence is convincing that a diet low in saturated fat and cholesterol and high in fruits, vegetables, and whole-grain products helps prevent and treat these diseases as well as the associated morbidity and mortality. The Dietary Guidelines for Americans recommend daily consumption of 2 to 4 servings of fruit or fruit juice, 3 to 5 servings of vegetables or vegetable juices, 2 to 3 servings of protein, 2 to 3 servings of dairy products, and 6 to 11 servings of grains. They also recommend limiting total daily fat intake to less than 30% of total calories, total cholesterol to less than 300 mg/day, and total saturated fat intake to less than 10% of total calories.<sup>18</sup> Fewer than 20% of Americans follow these guidelines.

USPSTF performed a large meta-analysis to determine if counseling in patients results in dietary changes. They examined randomized-controlled trials performed in patients without chronic disease, though some had risk factors for chronic disease. They included only trials involving counseling as the intervention with dietary change as the endpoint and compared net change in consumption. For various nutrients, they determined standards for “small,” “medium,” and “large” net effects, and they standardized definitions for “low,” “medium,” and “high” intensity counseling. Low intensity was defined as one counseling session lasting 30 minutes or less. This is similar to what most primary care providers can achieve in a single office visit. High intensity was defined as six or more counseling sessions of 30 minutes or more. Medium intensity included all interventions that fell in between. When these studies were examined in this systematic way, overall counseling did produce dietary change with regard to fruit and vegetable intake, fiber intake, and fat intake. Low intensity counseling produced minimal positive change in diet; more intense counseling was associated with greater changes. Larger changes were also produced in those with risk factors for disease and those who were counseled in a research clinic versus a primary care setting. Goal setting, involving family and social support, dietary assessment, individualized and personalized interventions, and group counseling, also seemed to increase dietary change. There are no studies to prove that these specific interventions ultimately produced change in disease status.<sup>19</sup>

USPSTF states that there is insufficient evidence to promote or discourage routine dietary counseling.<sup>20</sup> There is good evidence that medium to high intensity counseling should be offered to patients at risk for chronic disease associated with diet deficiencies. If counseling is to be offered, a validated dietary

survey can be used for assessment of dietary deficiencies, keeping in mind that patients are notorious at underreporting unhealthful behaviors. There seem to be no significant adverse effects of this type of counseling (Table 9-3).

### Tobacco

Smoking is the most reversible cause of disease in the United States, responsible for one in five deaths. The burden of disease is oppressive, with smoking being linked to not only oropharyngeal and pulmonary neoplasia but also pancreatic, renal, and cervical neoplasia. Smoking promotes atherosclerosis and increases the risk for myocardial infarction, ischemic stroke, and other vascular disease. Smoking is a key factor in the development of chronic obstructive pulmonary disease. It exacerbates asthma and can lead to pneumonia.

The effects extend beyond smokers to those in their environment. Fetuses carried by pregnant smokers are at risk for decreased birth weight, perinatal death, and preterm delivery and potentially for sudden infant death syndrome. Passive smoking in children increases the incidence of upper respiratory infections and otitis and exacerbates asthma. In adults, passive smoking can be linked to 3000 deaths per year from lung cancer! Cigarettes are responsible for 25% of deaths from residential fires.<sup>21</sup> Despite the well-known dangers of smoking, millions of people continue to smoke, and 2000 adolescents daily become regular smokers. However, it is encouraging to note that 50% of ever-smokers have successfully quit.

The evidence for the benefit of smoking cessation is compelling. After 1 year of smoking cessation, the risk of myocardial infarction or myocardial death is halved. After 5 years of smoking cessation, the risk for oropharyngeal neoplasia is halved. After 10 years of abstinence, the risk for lung cancer is halved. After 15 years of abstinence, the risks for myocardial infarction and stroke are almost equivalent to those of nonsmokers. A pregnant smoker who has quit by as late as her 30th week of gestation can increase her infant's birth weight relative to infants of women who smoke during their entire pregnancy.<sup>21</sup>

USPSTF makes it clear that screening for and education about tobacco use is beneficial.<sup>22</sup> They make a strong recommendation for screening adults. Benefits can be inferred in light of the evidence for strong association with cardiovascular disease,

pulmonary disease, and neoplasia. Short counseling sessions (3 minutes) as well as pharmacotherapy increase rates of smoking cessation with an effect lasting at least a year. More intensive counseling, setting a goal “stop date,” and scheduling follow-up visits to address smoking cessation are associated with a longer lasting effect. The highest relapse rate is in the first 2 weeks; intense follow-up should be directed at this clinical window.<sup>21</sup>

The recommendation for pregnant women is similar but emphasizes that slightly lengthier counseling, 5 to 15 minutes, is necessary as is distribution of literature specifically addressing smoking in pregnancy and fetal effects. There is direct evidence of increased abstinence rates and increased birth weight with these interventions.<sup>21</sup> The evidence is insufficient to support routine screening in children and adolescents.

There are several Food and Drug Administration (FDA)-approved pharmacotherapies for smoking cessation. Nicotine substitution or replacement methods include gum and patch, which are available over the counter, and prescription inhaler and nasal spray. All have been shown to be safe and effective, with an 18% to 31% abstinence rate as compared with 10% to 17% in those who do not use these products.<sup>21,23</sup> The nicotine patch is effective regardless of the level of smoker. The nicotine gum, specifically the 4 mg dose, is more effective for treating heavy smokers. The inhaler and nasal spray have not been studied extensively. Combinations of the above methods are more effective than single therapy alone. If these therapies are used while a person is still smoking, there is a risk for nicotine toxicity.

Other therapies that have demonstrated increased cessation rates when compared with placebo include sustained-release bupropion, clonidine, and nortriptyline. Bupropion is the only one of the three having FDA approval for this indication.

The safety and efficacy of these interventions in pregnant individuals, adolescents, and children are not well studied; therefore, specific recommendations cannot be made (Table 9-4).

## Alcohol

USPSTF defines alcohol misuse by defining a range of alcohol consumption and consequences. “Risky” or “hazardous” drinking means drinking more than seven drinks per week or more than three per occasion for women, and more than 14 per week or more than four per occasion for men. “Harmful” drinking is drinking to the point of causing physical, social, or psychological

consequences, but not to the point of meeting the criteria for true alcohol dependence. Patients who meet the criteria for alcohol dependence, as defined by the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition, should be referred for treatment.<sup>24</sup> This discussion is limited to discovering alcohol misuse prior to the development of alcohol dependence in the primary care setting.

Excessive alcohol use can cause neurologic, hepatic, pancreatic, and cardiac insult. It increases risk for various neoplasms including those of the liver, breast, digestive tract, and oropharynx and is responsible for both intentional and unintentional injury. Alcoholism is also at the root of many social problems including divorce, unemployment, decreased productivity, increased risky behavior, and domestic violence. It is responsible for the fetal effects of mental and growth retardation in the pregnant patient. Moderate levels of alcohol consumption, defined as two or fewer drinks per day for men and one or fewer drinks per day for women, are associated with health benefits. No drinks are considered safe for pregnant patients.

The USPSTF recommends that all patients be screened for alcohol abuse via standardized methods and counseled if found to be misusing alcohol.<sup>24</sup> Pregnant women should be counseled to discontinue alcohol use. All patients should be cautioned against driving while consuming alcohol. Practical screening tests include the Alcohol Use Disorders Identification Test (AUDIT), with a sensitivity of 51% to 97% and specificity of 78% to 96%, and the CAGE (cut back, annoyed by criticism, guilty, eye-opener) questionnaire, with a sensitivity of 43% to 94% and specificity of 70% to 97%.<sup>24</sup> The TWEAK [tolerance, worried, eye-opener, amnesia, k (for cut down)] and T-ACE (tolerance, angry or annoyed, cut down, eye-opener) are designed for pregnant patients, who are at risk at lower levels of alcohol consumption. Laboratory data are not effective for screening for alcohol abuse.<sup>25</sup>

Multiple studies have demonstrated the benefit of counseling to decrease alcohol abuse. A meta-analysis of 12 controlled studies examined the effect of counseling in those who were screened and found to have risky or harmful levels of alcohol consumption.<sup>26</sup> The counseling was stratified as “very brief” (one 5-minute session or less), “brief” (one 15-minute session or less), or “brief multicontact” (initial 15-minute session with follow-up contacts). The brief, multicontact sessions decreased weekly drinking, decreased risk from drinking, and had a questionable effect on binge drinking. Shorter counseling produced less significant results. One study with extensive follow-up showed decreased mortality in heavy drinkers. Studies in pregnant women show that many women reduce alcohol consumption during pregnancy, but this reduction has not been linked with counseling or interventions<sup>25</sup> (Table 9-5).

## Drug Abuse

Drug abuse and drug use are a source of not only medical morbidity and mortality but also severe social consequences, including criminal activity and violence. In the United States, marijuana accounts for the most drug use and abuse, with more than 5 million Americans using it at least weekly. Other major drugs used include illicit drugs, such as cocaine and heroin, legal but unprescribed drugs such as barbiturates and amphetamines, and inhalants such as gasoline and glue.

**Table 9-4**  
Tobacco Counseling Recommendations

**Table 9-5**  
**Alcohol Misuse Screening and Counseling**

Organization	Recommendation
<b>U.S. Preventive Services Task Force</b> American Medical Association American Academy of Family Physicians Canadian Task Force American College of Obstetricians and Gynecologists	<b>Screen in all patients, including pregnant women, using standardized tools; counsel those misusing alcohol</b>

Morbidity and mortality can stem from both acute and chronic effects, and occasional and regular use. Cocaine is associated with acute cardiac compromise from arrhythmia or infarction. Infectious complications can result from use of all intravenously injected drugs including the spread of human immunodeficiency virus (HIV). Chronic use or abuse of many substances decreases work productivity and increases insomnia. Drug use in pregnancy clearly has effects on the fetus including abruptio, low birth weight, preterm delivery, and withdrawal in the neonate. Drug use is involved in a significant portion of motor vehicle accidents and other recreational injury.

Screening can be performed by taking a detailed history, including type of drug used, amount, duration, and frequency, as well as noting any social disruption caused by drug use. There are no validated screening questionnaires for drug use. Other screening might involve obtaining objective laboratory data. Drug screens are sensitive but depend on the timing of the drug use and the timing of the laboratory test. Marijuana can be detected up to 14 days after use, but cocaine, opiates, amphetamines, and barbiturates can be detected only 2 to 4 days after use. These limits can be manipulated if the patient alters the urine sample or purposely uses diuretics. Positive tests are of course not indicative of drug abuse but only of recent drug use. Patient consent should be obtained prior to drug testing, and results should be reviewed with patients.

USPSTF recommends taking a substance abuse history. There is insufficient evidence to recommend for or against laboratory screening.<sup>27</sup> Clinicians should note signs or symptoms of drug abuse or addiction. Drug use should be discouraged and drug abuse should be addressed with intensive therapy or other appropriate treatment plans. There is little evidence that treating the asymptomatic drug user or abuser impacts outcome. These

recommendations are based on the potential for preventing addiction and the subsequent medical and social consequences. The asymptomatic user is commonly less motivated to make lifestyle changes (Table 9-6).

### Household and Recreational Injuries

Unintentional injuries, half of which are household and recreational injuries, are the fifth leading cause of death in the United States. The most common types of accidents in order of frequency are motor vehicle accidents, falls, and poisonings. Others include fires, drowning, strangulation, aspiration, firearm injury, and injury resulting from use of recreational vehicles including bicycles, motorcycles, boats, and all-terrain vehicles.<sup>28</sup>

The prevention of injuries in children is not discussed here, but an important risk factor for injuries in adolescents and young adults is substance abuse. Alcohol abuse has been implicated in 25% to 40% of fatal unintentional injuries in this age group and provides another reason for alcohol abuse screening and counseling. Drug abuse contributes to the incidence of overdose. Cigarette smoking is a common cause of residential fires.

Many recreational injuries are preventable by use of common sense. Swimming lessons, flotation devices, and close supervision of beginners all are associated with decreased fatal swimming or boating accidents. Careful handling of firearms and careful supervision of young firearm handlers can prevent some of these injuries. Again, it is unclear whether physician counseling can change recreational behavior.<sup>28</sup> It is hypothesized that this type of counseling may induce an adolescent to increase risk-taking behavior and thus may cause additional morbidity and mortality, but this hypothesis is not supported by any data.

In the elderly, the most common cause of household injury is falls. The elderly population is at risk secondary to decreased muscle strength, decreased balance and flexibility, and possible mild impairment secondary to multiple medication use and poor vision. Those with osteoporosis, syncope, or dementia are more likely to be injured after a fall. Possible interventions to minimize these risks include exercise, mobility therapy, careful monitoring of medications, close monitoring of bone density, protection against hard surfaces, and correction of environmental obstacles such as slippery floors and poor lighting. These have had variable success in preventing falls. Exercise programs, which target improved balance, have been associated with fewer falls. External hip protectors have been shown to decrease injury from falls but are not FDA approved for this purpose.

The most effective measures to decrease unintentional injury are passive. Examples are childproof packaging on poisonous household materials and smoke detection devices. Some measures must be instituted at a community or legislative level rather than a clinical level. Individual behavior modification with regard to recreational behavior or household routine has been shown to be ineffective; thus, physician counseling is ineffective. A more promising approach is to counsel specifically with regard to substance abuse to prevent injury. In the elderly, interventions that decrease falls include home health visits or visits with medical educators, assessment of home environment, assessment of risk factors for falls, medication review, and exercise.

USPSTF recommends periodic counseling of children, adolescents, those using alcohol or illicit drugs, and elderly patients based on the risk for recreational and household

injury.<sup>28</sup> Counseling should be individualized. Though not supported by the data to date, it might be justified owing to the emotional devastation caused by an unintentional death secondary to injury. Keep in mind that patients underreport the level of safety measures taken at home<sup>29</sup> (Table 9-7).

### Motor Vehicle Accidents

The two most important risk factors for a motor vehicle accident are failure to wear a seat belt and alcohol use. Interventions for alcohol abuse are described earlier in this chapter, and the evidence overwhelmingly shows that alcohol intoxication is associated not only with increased motor vehicle accidents but also with increased mortality, increased serious injury, longer hospitalization, and increased neurologic impairment following motor vehicle accidents.<sup>30</sup>

The evidence is clear that seat belts, when used appropriately, decrease injury and death associated with motor vehicle collision by up to 50%. Use of seat belts also decreases the severity of injury, the likelihood of hospital admission, and the cost of hospitalization.<sup>31</sup> Seat belt laws increase the use of seat belts. In model year 1998, driver- and passenger-side air bags became a requirement for passenger vehicles. These have further reduced injury and mortality.

Most studies examining the effectiveness of physician seat belt counseling involve counseling the parent of a pediatric patient. Studies in pregnant women who were counseled several times during their prenatal care showed increased proper car seat use, suggesting that counseling can potentially change behavior with regard to safety restraints. Most studies looking at personal seat belt use found some improvement in self-reported seat belt use, although in some studies this increase was not sustained. One study suggests that a brief reminder by physicians increases seat belt use,<sup>32</sup> but this study was neither controlled nor randomized. It is important to remember that self-reported seat belt use is not necessarily correlated with true seat belt use.

USPSTF recommends that clinicians remind patients to wear seat belts and inform them that air bags are effective in further reducing motor vehicle injuries.<sup>33</sup> Doctors should not neglect to remind patients that driving under the influence of alcohol or recreational drugs is dangerous. The appropriate interval for counseling is undetermined. Counseling is most important for

high-risk groups including adolescents, young adults, and those with substance use or abuse problems. This recommendation is not based on direct evidence that counseling will change outcomes but on the potential benefit of changing patient behavior with regard to motor vehicle safety and on the low morbidity and mortality associated with counseling (Table 9-8).

### Suicide and Depression

Depression is common and has a prevalence of 5% to 8% in the primary care setting. Detection and subsequent treatment can decrease not only associated morbidity but also the irreversible endpoint of suicide. Risk factors for depression include a family history of mental illness, unemployment, and chronic illness. Risk factors for suicide include mental illness, substance abuse, living alone, recent grieving, access to firearms, personal or family history of suicide attempt or suicide completion, divorce, separation, or unemployment. Women are more likely to be depressed and more likely to attempt suicide. Men over the age of 65 years are the most common suicide completers.

USPSTF recommends screening for depression in care settings where accurate diagnosis, treatment, and follow-up are feasible.<sup>34</sup> The evidence is insufficient to recommend for or against suicide risk screening.<sup>35</sup> There are many standardized tools for depression screening. Asking the two questions, "Over the past 2 weeks, have you felt down, depressed, or hopeless?" and "Over the past 2 weeks, have you felt little interest or pleasure in doing things?" may be as effective as some more elaborate screening tools.<sup>36</sup> Most depression screening tools have good sensitivity and fair specificity. The obvious potential adverse effect is misdiagnosis and associated stigma. Positive screening should be followed by more specific diagnostic evaluation.

Fourteen randomized-controlled trials, comparing outcomes in patients who were screened for depression and those who were not screened, were examined in a meta-analysis.<sup>37</sup> Some studies examined the effect of feedback of screening results to practitioners. Detection rates of depression increased when feedback, either positive or negative screening results, was given to practitioners, but treatment rates did not change. Other studies examined outcomes when usual care was compared with a screening and treatment protocol; patients who were screened demonstrated clinical improvement. This result suggests that clinics which can follow positive screening with more specific diagnosis and appropriate treatment can change outcomes in depression.

American College of Obstetricians and Gynecologists	Be aware of symptoms; inquire about social stressors and family history of depression at routine examination
American Medical Association	Screen for depression in adolescents at risk

Studies on suicide are difficult to perform because it is a relatively rare event. All subjects who succeed in committing suicide are not available to compare with those who survive. Information on those who attempt suicide and fail cannot necessarily be extrapolated to those who attempt and succeed. Though it seems intuitively reasonable that identifying a patient who will attempt suicide allows for timely intervention, there is no solid evidence that intervention is effective. Treatment of psychiatric disease and substance abuse may potentially prevent suicide. Removal of firearms may prevent suicide. Neither of these interventions has been clearly demonstrated to reduce suicide rates (Table 9-9).

### Anemia

Anemia is defined by the World Health Organization as hemoglobin of less than 13 g/dL in men and less than 12 g/dL in menstruating women as determined by venous blood sampling. The prevalence in reproductive age women is below 2%, and the burden of disease is minimal. Severe anemia can certainly cause decreased activity, decreased exercise tolerance, fatigue, and cardiorespiratory difficulty, but mild anemia or asymptomatic anemia is associated with little morbidity and mortality. Additionally, iron supplementation in the mildly anemic produces little significant change in symptoms or sense of well-being, despite improvement by laboratory evidence.

USPSTF recommends screening for anemia in pregnant women and high-risk infants. There is insufficient evidence to recommend for or against screening in asymptomatic adults.<sup>38</sup> Militating against screening are the cost of the test, the adverse effects of iron therapy, and the low prevalence of the disease. For anyone who is found to be anemic, the type of anemia should be determined and the patient treated appropriately. Routine iron supplementation in nonanemic pregnant or nonpregnant adults is not supported.

### Lipid Disorders

There is little debate that an abnormal lipid profile signifies increased risk for coronary heart disease, the leading cause of

morbidity, mortality, and disability in the United States. The lifetime risk of coronary heart disease is 49% for men by the age of 40 years and 32% for women. USPSTF recommends routine screening for men aged 35 and older and women aged 45 and older. Abnormal results should be treated. Men aged 20 to 35 and women aged 20 to 45 should be screened if they have risk factors for coronary heart disease, specifically diabetes, a family history consistent with familial hyperlipidemia, multiple other coronary risk factors, or a family history of cardiovascular disease at a young age. There is no recommendation for adults younger than age 20. All patients should be counseled about a diet low in saturated fat and high in fiber.<sup>39</sup>

The screening tests of choice are total cholesterol and high-density lipoprotein (HDL) cholesterol.<sup>40</sup> These tests are reliable, have acceptable variability, and can be performed on nonfasting venous blood. Two measurements should be made on two separate occasions to ensure accuracy. The addition of triglycerides and low-density lipoprotein (LDL) cholesterol necessitates a fasting sample. In general, patients are open to screening for lipid disorders, and the test is feasible and convenient for most physicians. Other possibilities for screening include sequential protocols based on stratified risk assessment and varying levels and ratios of the different cholesterol measurements. These are more time consuming and require more physician counseling time.

The evidence is clear that dietary manipulation can decrease total cholesterol and improve the lipid profile on average from 2% to 6% to 10% to 20%.<sup>41</sup> These changes translate to decreased cardiac risk, but studies have not linked dietary changes to decreased cardiac events. Medications such as HMG-CoA inhibitors and gemfibrozil, when taken for 5 to 7 years, improve the lipid profile; a meta-analysis of the main drug therapy trials also demonstrates a 30% decrease in cardiac events in patients with moderate to high cholesterol levels<sup>42</sup> and a 20% reduction in strokes in patients with known coronary heart disease.<sup>43</sup> These benefits should be weighed against the side effects of these medications including but not limited to myopathy and liver enzyme abnormalities. It is unclear whether drug therapy has any effect on overall mortality after the first 5 to 7 years of therapy, particularly in the lower risk patient (Table 9-10).

### Thyroid Disorders

Subclinical thyroid disease affects 3% to 5% of adults, with increasing prevalence in older individuals, females, and white individuals. In women over age 75 years, it is estimated to be 17.4%. It is defined as an abnormal thyroid stimulating hormone (TSH) level with normal thyroid hormones in an asymptomatic individual. The population at risk for thyroid disease includes elderly and postpartum patients, those with Down syndrome, and those who have a history of high-level radiation exposure.

Subclinical hyperthyroidism is much less common than subclinical hypothyroidism. Both entities, if untreated, can lead to overt disease or at least some of the same morbidity associated with overt disease. Subclinical hyperthyroidism is associated in some studies with atrial fibrillation, osteoporosis, and dementia; untreated hyperthyroidism is associated with those findings as well as congestive heart failure. Subclinical hypothyroidism is associated in some studies with dyslipidemia and atherosclerosis; untreated hypothyroidism can lead to fatigue, weight gain, heart failure, and elevated lipid levels.<sup>44</sup> It is important to note that

Table 9-10 Cholesterol Screening Recommendations	
Organization	Recommendation
U.S. Preventive Services Task Force	Screen routinely in men at least 35 years of age and in women at least 45 years of age; screen in men 20–35 years of age and in men and women 20–45 years of age if they have coronary risk factors
American Heart Association	Screen all adults over age 20 every 5 years
American College of Obstetricians and Gynecologists	Screen all women over age 45 every 5 years
American College of Physicians American Academy of Family Physicians	Screen men aged 35–65 and women aged 45–65 periodically
American Diabetes Association	Screen in all patients with diabetes annually

the associations with subclinical disease are merely that, associations, often not reaching statistical significance, often not studied with appropriate controls, and often not measured by true clinical outcomes but by physiologic endpoints or laboratory data.

It would seem reasonable to screen patients to prevent this morbidity and mortality; however, it is estimated that only a small number of cases of subclinical thyroid disease discovered by mass screening progress to true thyroid disease with clinically relevant outcomes. There are no controlled studies examining whether screening, and thus early detection, of thyroid disease changes long-term morbidity and mortality.<sup>44</sup> Screening does *not* mean testing a patient who comes in with complaints consistent with thyroid disease. In a referral population tested in a specialty clinic, the sensitivity and specificity of TSH are 92% and 98%, respectively.<sup>44</sup> When used for confirmatory reasons, TSH is very useful. In a primary care population, however, the positive predictive value of the same TSH test ranges from 0.06 to 0.24.<sup>45</sup>

This potential benefit has to be balanced with the adverse effects associated with treatment and the possibility of false-positive results. Overtreatment of hypothyroidism has been associated with a small risk of atrial fibrillation. Thus, USPSTF can make no recommendation for or against routine screening<sup>46</sup> (Table 9-11).

## Diabetes

Various tests are used to help diagnose diabetes in the symptomatic or high-risk patient. The American Diabetes Association recommends using the fasting plasma glucose at a cut-off of greater than 126 mg/dL. Compared with hemoglobin A<sub>1</sub>C, random glucose testing, and the 2-hour glucose load test, fasting plasma glucose is faster, easier, more reproducible, more convenient, more reliable, and less expensive. It also correlates with development of microvascular complications. An abnormal test must be corroborated by a second abnormal screen on a separate day.

Studies show that lifestyle interventions in patients with impaired glucose tolerance by various criteria can prevent

development of diabetes.<sup>47</sup> We know these patients are at higher risk of developing diabetes in the future. However, diabetes is preceded by an asymptomatic phase whose length has yet to be determined. It is estimated that up to a third of individuals with laboratory criteria for diabetes have not yet received a diagnosis.<sup>48</sup> There are no randomized-controlled trials studying screening for diabetes or the effectiveness of intervention during the asymptomatic phase.

A wealth of research demonstrates that treatment for diabetes decreases microvascular and macrovascular complications that can develop 10 to 15 years after clinical diagnosis. These include retinopathy, nephropathy, cardiovascular disease, stroke, and amputation. Possible treatments include blood pressure control, glycemic control, angiotensin-converting enzyme (ACE) inhibitors, foot-care programs, aspirin, and dyslipidemia treatment. Do these interventions work better if started in the asymptomatic phase?

One way to tackle this question is to see whether these treatments improve outcomes differently in diabetic and nondiabetic patients. Because the risk for cardiovascular disease in the asymptomatic diabetic patient is significant, there is interest in interventions geared toward cardiovascular risk reduction. There is evidence that treatment of hypertension and dyslipidemia in diabetics decreases cardiovascular risk more than in nondiabetics. On the other hand, foot-care programs, diet and activity counseling, and smoking cessation do not offer added benefit or effectiveness in the diabetic patient.<sup>49</sup>

USPSTF does not recommend for or against routine screening for diabetes or any form of glucose intolerance. USPSTF does, however, recommend screening for diabetes in patients with hypertension or dyslipidemia.<sup>50</sup> Potential harms of screening include the anxiety and stress caused by labeling with the diagnosis of diabetes and the stigma attached when applying for insurance policies. Risk associated with treatment includes hypoglycemia and side effects of medications (Table 9-12).

Table 9-11 Thyroid Disease Screening Recommendations	
Organization	Recommendation
U.S. Preventive Services Task Force	Insufficient evidence for or against routine screening
American Thyroid Association	Measure thyroid function every 5 years after age 35 years
Canadian Task Force	Use clinical suspicion to determine appropriate screening, particularly in the perimenopausal and postmenopausal woman
American College of Physicians	Screen in women > 50 years of age with one or more symptoms
American Association of Clinical Endocrinologists American Academy of Family Physicians	Screen in all women > 50 years of age
American College of Obstetricians and Gynecologists	Use clinical suspicion to determine appropriate screening, particularly in the postpartum period

**Table 9-12**  
**Diabetes Screening Recommendations**

Organization	Recommendation
<b>U.S. Preventive Services Task Force</b>	<b>Insufficient evidence for or against routine screening</b>
American Diabetic Association	Consider screening with fasting plasma glucose at 45 years of age, or younger in the high-risk patient
American College of Obstetricians and Gynecologists	Screen routinely every 3 years in women aged 45 and older
American Heart Association	Consider screening with fasting plasma glucose at age 20 years and older based on risk

### Hypertension

Hypertension is systolic blood pressure 140 mm Hg or higher and diastolic blood pressure 90 mm Hg or higher on two occasions at least 1 week apart. Complications of untreated hypertension include congestive heart failure, myocardial infarction, chronic renal failure, retinopathy, stroke, and aortic aneurysm. The risks of these endpoints depend on the level of blood pressure elevation as well as various risk factors such as concomitant dyslipidemia, smoking, diabetes, age, and sex.

Hypertension can be treated with a wide variety of interventions including the lifestyle changes of decreasing sodium intake, adding potassium to the diet, decreasing alcohol intake, increasing exercise, reducing weight, and managing stress. Though these lifestyle changes have been shown to lower blood pressure, no trials have demonstrated a decrease in cardiovascular events as a result. Antihypertensive medications decrease cardiovascular events, stroke, myocardial infarction, and congestive heart failure, some more significantly than others. Though no studies directly measure the benefit of screening, most patients are found by screening in the asymptomatic state.<sup>51</sup>

USPSTF strongly recommends blood pressure screening for adults aged 18 and older. The evidence is insufficient to recommend for or against screening those younger than age 18.<sup>52</sup> There are no studies evaluating whether all patients should be screened or only those with risk factors. Possible harms from screening include the risks of the various treatments. Studies evaluating quality of life and well-being showed mixed results with regard to absenteeism from work but found no psychological burden caused by the diagnosis of hypertension (Table 9-13).

### Obesity

Obesity is the accumulation of an excessive amount of a body fat and is most universally defined as a body mass index (BMI) greater than 30, with the precursor of obesity, overweight, defined as a BMI of 25 to 29.9. Morbid obesity is defined as BMI greater than 35. Other methods of measuring body fat include skinfold measurements, which are notoriously unreliable owing to high inter- and intra-observer variability. Waist-to-hip ratio has been used to measure obesity and more specifically to link it to cardiovascular outcomes and those diseases associated with visceral adiposity. Other less practical, more invasive, and more accurate measurement tools include hydrostatic weighing and

bioelectric impedance. BMI calculation is simple, is linked most broadly with various outcomes, and is the most appropriate screening tool, with a 0.7 to 0.8 correlation with true body fat content.

Obesity is linked to a host of diseases including cardiovascular disease, hyperlipidemias, diabetes, disorders of glucose metabolism, many types of neoplasia including endometrial, breast, ovarian, and colon cancer, and sleep apnea. Much morbidity and mortality is associated with obesity including perioperative and postoperative complications and pregnancy-related complications. There are social and cultural stigmas against obesity, causing difficulties with quality of life secondary to physical limitations and potential discrimination in professional and social settings. Obesity will soon become the leading preventable cause of death, surpassing tobacco use, in the United States.

The reasons to screen for obesity are many. First, the yield of screening should be high, secondary to its high prevalence. It is important to prevent those who are not obese from becoming obese, and to prevent morbidity and mortality in those who already are obese by helping them lose weight. There are no randomized-controlled trials examining mass screening for obesity and its implications for long-term outcomes, but there is evidence that addressing obesity at preventive health care visits can improve weight loss. Weight loss, specifically lower BMI, is associated with lower overall morbidity and mortality.<sup>53</sup>

USPSTF recommends that all patients be screened by means of BMI for obesity or overweight. Those who are obese should undergo intensive counseling and behavior modification to initiate and sustain weight loss.<sup>54</sup> Fair-to-good evidence shows that those with a BMI greater than 30, with the help of intense counseling including behavioral modification, diet, and exercise, can sustain weight loss in the range of 3 to 5 kg over the course of a year. Intense counseling is defined as counseling at intervals greater than monthly. The ideal setting for this counseling is not clear. Randomized-controlled trials demonstrate that counseling that stresses diet modification, specifically caloric restriction, produces weight loss. Counseling that stresses increased physical activity also produces weight loss. Counseling that includes elements of both types produces even greater weight loss.<sup>53</sup> Behavioral modification was also an important component of this counseling. The 5-A framework (*assess, advise, agree, assist, and arrange*) has been used for behavior modification with

**Table 9-13**  
**Hypertension Screening Recommendations**

Organization	Recommendation
<b>U.S. Preventive Services Task Force</b>	<b>Screen in all adults 18 years of age and older</b>
American Heart Association	Screen at least once every 2 years in adults over age 20
American Academy of Family Physicians	Screen periodically in adults over age 21
American College of Obstetricians and Gynecologists	Screen annually in adults over age 13

regard to tobacco use and may be useful in this scenario. Long-term success depends on continued counseling. There are no identified harms in weight loss counseling except possible embarrassment about obesity. Counseling that is less intense, defined as containing fewer components or occurring less than or equal to once a month, has not been effective. It is unclear whether counseling in those who are overweight but not obese is beneficial.

Another aspect of obesity screening and treatment includes pharmacotherapy. Only two medications are FDA-approved for the long-term treatment of obesity: sibutramine, which is a centrally acting appetite suppressant, and orlistat, a lipase inhibitor that prevents absorption of fat in the gastrointestinal tract. They should be used in patients with a BMI greater than 30 or with a BMI greater than 27 with risk factors. Multiple randomized-controlled trials have shown significant weight loss in the short term with these therapies when compared with placebo, with average weight loss of 5% to 10% of body weight.<sup>53</sup> Those who continued to use these medications had more successful weight loss maintenance up to 2 years when compared with those who took placebo. Obviously, the possible side effects of these medications must be considered. Orlistat can cause headache, oily discharge, flatus, diarrhea, or fecal urgency. Sibutramine can cause headache, insomnia, gastrointestinal upset, agitation, constipation, and other symptoms. Other medications that have been studied include metformin, phentermine, fluoxetine, and diethylpropion. These treatments did not show consistent benefit and are not approved for long-term use. They are best used in the context of a regimented diet and exercise plan.

Surgical intervention is a consideration for patients with BMI greater than 40 or BMI greater than 35 with risk factors. There are several options, both laparoscopic and open, but all induce a malabsorptive state by bypassing portions of the gastrointestinal tract or restricting gastric storage capacity and thus oral intake. The quality of evidence is limited by ethical concerns and the lack of blinded subjects, but randomized trials demonstrated significant weight loss on the order of 30 to 50 kg, with an average of 20 kg of weight loss maintenance after 8 years. Again, the risks of these surgical procedures must be weighed against the benefit of weight loss for these patients (Table 9-14).

**Table 9-14**  
**Obesity Screening Recommendations**

Organization	Recommendation
<b>U.S. Preventive Services Task Force</b> American Academy of Family Physicians American Diabetes Association American College of Preventive Medicine American College of Obstetricians and Gynecologists	<b>Take periodic height and weight measurements in all patients; offer intensive counseling for weight loss in those who are overweight or obese</b>
Canadian Task Force	Insufficient evidence to recommend for or against periodic body mass index measurements

## CONCLUSION

Preventive care is an area that is wide open for more research to clarify the issues that can determine a patient's future health or illness. As health care resources become more and more scarce and as practitioners become more and more busy, it is important to use only those interventions that have been proven to change outcomes.

## KEY POINTS

- Preconception counseling and anticipation of genetic or medical problems is superior to postconception discovery and management.
- Genetic counseling and screening can be initiated before conception.
- Folic acid begun before conception reduces the risk for a child with a neural tube defect and should be prescribed for every woman anticipating pregnancy.

Most physicians would agree that preventive care and anticipation of potential medical problems is likely to result in a superior outcome as compared to secondary intervention. Unfortunately, almost half of all pregnancies are “unintended.” Therefore, by the time of the first prenatal visit, the opportunity for prevention of harm to the mother and the fetus may have been lost. For example, pregnancy may be contraindicated by a maternal medical condition, required medications, or use of illicit substances. In many cases, recognition by the care provider of the possibility of conception would allow modification of the medication schedule, recommendation to postpone pregnancy until a chronic disease is in remission, or advice to change the patient’s lifestyle before undertaking a pregnancy. Knowing that a pregnancy may adversely affect her own health or that she is at high risk for an abnormal fetus may result in a woman’s firmer commitment to reliable contraception. Optimally, then, physicians seeing reproductive-age women would briefly explore with them their desire for pregnancy in the near future and their personal and family medical histories. Those patients expressing an interest in conception should have an appointment scheduled for fuller exploration of these issues.

In the case of a familial disorder, addressing potential problems before conception will allow adequate time to explore all of the reproductive options, possibilities for prenatal diagnosis, and the patient’s feelings about intervention in an abnormal pregnancy. These issues can be much more calmly and thoughtfully dealt with when the pregnancy is anticipated rather than a fact.

## GENETIC HISTORY

The most important part of a genetic evaluation is asking the right questions. Many patients are ignorant of which disorders are genetic and therefore will not volunteer any information when asked if there is a genetic disease in the family. Therefore,

one must be specific and ask the patient her age, ethnic background, outcome of all prior pregnancies, as well as information on chronic illness or death of a child, sibling, or parent. An initial screening questionnaire may be useful, but the information must be reviewed verbally with the patient to ensure that she has understood the questions. The health of the prospective parents, their parents and grandparents, aunts and uncles, siblings, nieces, and nephews should all be queried. Consanguinity (descent from a common ancestor) should be routinely sought. Details regarding prior pregnancy losses and anomalous fetuses or infants should be explored and relevant medical records obtained if possible. The records should be studied to verify the diagnosis, to determine how the diagnosis of a genetic condition was made, and whether other diagnoses were appropriately excluded. Consideration of whether the condition is sporadic or familial, alternative patterns of inheritance, and the risk to the consultant’s offspring are all relevant. In many cases the latter issues are complex and referral to a genetic specialist is appropriate (Table 10-1). Sufficient time to obtain old records and to evaluate the level of risk and the patient’s options is available if counseling is initiated prior to conception.

## PARENTAL AGE

A common concern for the preconception patient is the effect of her and her partner’s age on the health of their offspring. Risk for chromosome abnormalities in offspring increases with maternal age<sup>1</sup> (Table 10-2). Many gynecologists are familiar with the risks associated with advancing maternal age and are comfortable advising their patients of these risks and the routine ways of addressing them (i.e., first-trimester or second-trimester screening or diagnosis). Educational brochures from the American College of Obstetricians and Gynecologists are available for patients to read and consider.

Advanced paternal age (45 years or older) does not increase the risk for chromosome abnormalities but does confer increased risk for a child with a new dominant mutation (e.g., neurofibromatosis, achondroplasia) and for cardiac defects.<sup>2</sup> Although elevated severalfold compared to that of younger men, the risk for a new dominant mutation in the child of a father older than age 40 is still less than 1%. Because a new dominant mutation can be for any of a variety of disorders, prenatal diagnosis cannot exclude the possibility of a new mutation. However, we advise pregnant partners of men older than age 45 to have a detailed ultrasound examination at 18 to 20 weeks’ gestation because a skeletal disorder will occasionally be detected. Because cardiac defects are also more common in the offspring of older men, we may also suggest a fetal echocardiogram.

**Table 10-1**  
**Indications for Considering Genetic Referral**

Personal or family history of child (or fetus) with congenital anomaly, chromosome abnormality, genetic disorder, early neonatal death  
Multiple pregnancy losses  
Advanced maternal age  
Personal or family history of individual(s) with mental retardation  
Personal or family history of genetic disorder  
Couple both heterozygous for the same genetic condition  
Potential exposure to teratogen

**Table 10-2**  
**Risk of Having a Live-Born Child with Down Syndrome or Other Chromosomal Abnormality**

Maternal Age	Risk of Down Syndrome	Total Risk for All Chromosomal Abnormality*
20	1/1667	1/526
21	1/1667	1/526
22	1/1429	1/500
23	1/1429	1/500
24	1/1250	1/476
25	1/1250	1/476
26	1/1176	1/476
27	1/1111	1/455
28	1/1053	1/435
29	1/1000	1/417
30	1/952	1/384
31	1/909	1/384
32	1/769	1/322
33	1/625	1/317
34	1/500	1/260
35	1/385	1/204
36	1/294	1/164
37	1/227	1/130
38	1/175	1/103
39	1/137	1/82
40	1/106	1/65
41	1/82	1/51
42	1/64	1/40
43	1/50	1/32
44	1/38	1/25
45	1/30	1/20
46	1/23	1/15
47	1/18	1/12
48	1/14	1/10
49	1/11	1/7

Because sample size for some intervals is relatively small, 95% confidence limits are sometimes relatively large. Nonetheless, these figures are suitable for genetic counseling.

\*47,XXX excluded for ages 20–32 (data not available).

## GENETIC DISORDERS

In couples with a history of a prior chromosomally abnormal fetus or liveborn, or with a history of a chromosomal rearrangement in one of the parents, we advise formal genetic counseling to confirm the diagnosis, assess risk, and consider reproductive options. In many cases the additional risk based on this history is not great, yet the anxiety level in the potential parents can be enormous.

Families that have had a child with an X-linked recessive, autosomal dominant, or autosomal recessive genetic syndrome are frequently at high risk for recurrence. In addition, if one of the parents has an autosomal dominant genetic disorder (e.g., achondroplasia or neurofibromatosis), each fetus is at 50% risk for inheriting the mutant parental allele. If the father has an X-linked disorder, none of his sons will inherit the gene, but all of his daughters will inherit the gene and eventually be at high risk for affected offspring. Pregnancy may also exacerbate certain maternal genetic conditions (e.g., Marfan syndrome), with implications for maternal life and health. Therefore, identifying the high-risk patient, obtaining records to confirm the diagnosis, and counseling or referring the patient to the appropriate medical specialist before conception is crucial.

Multifactorial conditions, including isolated structural defects, usually recur in 2% to 5% of siblings or offspring. Some of these conditions (e.g., neural tube defects [NTDs]) can be detected during pregnancy; others, such as pyloric stenosis, will not be apparent prenatally. In families that have previously had a child or fetus with an NTD the opportunity exists to decrease the risk of recurrence by starting high-dose (4 mg/day) folic acid supplementation before conception and continuing through the period of embryogenesis.

### Ethnic and Racial Background

Ethnic background is important to ascertain because members of different ethnic and racial groups are at increased risk for specific disorders. Because almost all of these disorders are autosomal recessive in inheritance, prospective parents can be screened for the appropriate conditions once their ethnic/racial backgrounds are known. If both parents are heterozygous (carriers) for the same condition, options are available prior to conception (e.g., adoption, donor gametes, preimplantation diagnosis) that will not be available once a pregnancy is in progress. Although it is not possible to describe in detail each disorder for which screening is available, following is an example of the kind of information we provide verbally and in take-home pamphlets to our patients, prior to their deciding on screening.

### African Background

Sickle cell disease (which includes SS disease, SC disease, and sickle cell-thalassemia disease) occurs in 1 in 500 African Americans. Children and adults with sickle cell disease have painful crises, which may occur frequently or rarely. They are also at risk for poor growth and for childhood death due to infections. Strokes or kidney failure may occur at a young age. Carrier frequency is 1 in 12.

### Ashkenazi Jewish Background

Several conditions are more common in the Ashkenazi Jewish population. If one member of the couple is Jewish and the other is not, the Jewish parent can be tested first. If he or she is positive for a trait, the non-Jewish parent can then be tested. For some of these conditions, testing a non-Jewish individual is less reliable.

Tay-Sachs disease causes mental and physical deterioration of the child, with death usually by age 5. The carrier frequency is 1 in 30, and 1 in 3600 Jewish children are affected. The Tay-Sachs gene is also more common among French Canadians from eastern Quebec and Cajuns in southern Louisiana. Canavan disease causes symptoms similar to Tay-Sachs disease. One in 40 Ashkenazi Jews carries this trait, and 1 in 6400 children is affected.

Familial dysautonomia is a neurologic disorder. Children with familial dysautonomia have trouble regulating their temperature, blood pressure, and digestive systems. About half of affected individuals live to age 30. The carrier frequency is 1 in 30, and 1 in 3700 children is affected.

Niemann-Pick disease type A causes an enlarged liver and spleen, poor growth, and progressive physical and mental deterioration, with death by age 4. The carrier rate is 1 in 90, with 1 in 32,000 Jewish children affected.

Children with Fanconi anemia type C have anemia, short stature, learning disabilities, or mental retardation. Birth defects of the limbs, heart, or kidneys may also be present. The risk for leukemia and early death is increased. The carrier rate is 1 in 89 Jewish individuals, and 1 in 31,000 Jewish children is affected.

Bloom syndrome results in poor growth and poor resistance to infection. There is a high rate of cancer, from which individuals usually die before age 30. One in 100 Jewish individuals carries this trait, and 1 in 46,000 children is affected.

Gaucher disease type 1 can be very mild or severe. Children and adults may have nosebleeds, anemia, an enlarged liver and spleen, bone pain, and easily broken bones. Because the severity is so variable, decisions about testing are difficult. The carrier frequency is 1 in 12, and 1 in 600 children is affected.

Mucolipidosis IV is a disorder of motor and mental retardation beginning in the first year of life. The carrier frequency is 1 in 100.

### Northern European Background

Cystic fibrosis (CF) is common among whites, particularly those of northern European origin. The disease causes lung infections, difficulty breathing, and problems with bowel function, weight gain, and growth. Children frequently need to be hospitalized, have physical therapy, and take several medications. The average life span is 30 years. One in 2500 white newborns has cystic fibrosis, and 1 in 25 whites carries the CF trait. CF is also found in the Ashkenazi Jewish population.

### Mediterranean Background (also Southeast Asian, African)

Beta-thalassemia causes severe anemia in children, requiring frequent blood transfusion. Children may grow poorly, have bone deformities or fractures, and develop heart failure from their disease. Carrier frequency varies with ethnic group.

**Table 10-3**  
Heterozygote Screening

Disorder	Screening Test
Alpha-thalassemia	MCV
Beta-thalassemia	MCV
Sickle cell anemia	Hemoglobin electrophoresis
Cystic fibrosis	Mutation analysis
Tay-Sachs	Hexosaminidase assay and mutation analysis
Canavan	Mutation analysis
Familial dysautonomia	Mutation analysis
Gaucher type 1	Mutation analysis
Fanconi anemia type C	Mutation analysis
Bloom syndrome	Mutation analysis
Niemann-Pick type A	Mutation analysis
Mucolipidosis IV	Mutation analysis

MCV, mean corpuscular volume.

### Southeast Asian Background

Alpha-thalassemia is a blood disease that results in severe anemia and, in some forms, death of the fetus or newborn. Carrier frequency varies but may be as high as 1 in 20.

Carrier testing for some of the conditions described is possible using routine blood tests. However, for other conditions specialized testing is needed to determine whether an individual is a carrier (Table 10-3). Carrier tests cannot entirely eliminate the possibility of being a carrier, but a negative test makes the chance very low.

If the patient is interested in carrier testing, this may be arranged through the primary care provider, alternatively, a genetic counseling appointment can be made to discuss the most appropriate testing, the accuracy of test results, which laboratories do the testing, and the cost.

## CONSANGUINITY

Consanguinity is occasionally the reason couples will present for preconception counseling. If one of the members of the couple is the result of a consanguineous union or has a close relative who is, there is no concern as long as the individual in question is phenotypically normal and does not have a genetic disorder. However, if the couple itself is consanguineous, the exact degree of relatedness must be sought. Offspring of first-cousin unions have a twofold increase in risk for perinatal and childhood death, malformation, or mental retardation, as compared to the general population risk.<sup>3</sup> This assumes that both parents are phenotypically normal and there is no family history of a recessive disorder. If the family does have an autosomal recessive disorder, or if the ethnic background warrants, heterozygote testing should be offered to the couple.

As the degree of relatedness decreases, the likelihood of carrying identical mutant genes decreases sharply. Therefore the risk to offspring of second and third cousins is not increased as compared to the general population.<sup>3</sup> Obviously if a known genetic disorder exists in the family, specific counseling should be offered.

## MEDICAL ISSUES

### Nutritional Status

As part of the preconception counseling process, a complete medical history should be obtained. This must include information on the patient's nutritional status (i.e., whether she has an eating disorder or unusual diet, whether she is underweight or overweight, and whether she takes dietary supplements or weight loss products). A history of bulimia or anorexia should be explored to determine the patient's current eating practices.

Underweight women are at increased risk for preterm delivery and a low-birth-weight infant or fetus with intrauterine growth restriction (IUGR).<sup>4</sup> Overweight women have an increased likelihood of developing hypertension, preeclampsia, gestational diabetes, thrombophlebitis, preterm or post-term delivery, abnormal labor, and delivery by cesarean section with increased postoperative complications.<sup>5</sup> Offspring of obese women are at greater risk of late fetal demise, macrosomia, birth trauma, and congenital malformations (e.g., spina bifida).<sup>5,6</sup> In addition, obese women (body mass index > 27) have a greater risk of anovulatory infertility.

Women deficient in iron have an increased chance of preterm delivery and low-birth-weight infants. Pica, or the ingestion of nonfood substances, can result in lead poisoning or iron deficiency. Vegetarian diets may be satisfactory for pregnancy as long as there is adequate protein intake.

Ocean fish (e.g., shark, king mackerel, swordfish) are known to be contaminated with methyl mercury; however, the level of contamination varies with type of fish and geographic origin. Women with high ingestion of heavily contaminated fish have had children with microcephaly, cerebral atrophy, mental retardation, and seizures.<sup>7</sup> On the other hand, ingestion of fish with a lower mercury concentration has not been demonstrated to cause these defects.<sup>8</sup> Nonetheless, the U.S. Food and Drug Administration (FDA) and the Environmental Protection Agency (EPA) have recommended that pregnant women avoid eating any shark, swordfish, king mackerel, or tilefish and that they limit other small ocean fish, canned tuna, and shellfish to less than 12 ounces per week, with no more than one serving of any one type of fish per week. Local freshwater fish will also vary in their level of contamination. The EPA can be contacted to obtain advice on specific locales.<sup>9</sup>

Supplementation with 0.4 mg of folic acid/day in low-risk women (4 mg/day in women who have previously had a child with an NTD) has been shown to substantially reduce the risk for an open NTD when started at least 1 month prior to conception and continued through the first trimester.<sup>10</sup> Because so many pregnancies are unplanned, folic acid supplementation should be recommended to all women of childbearing age. Although the FDA has mandated folic acid fortification of food, intake is inadequate in most women to meet the required dose without further supplementation. Multivitamins containing folic

acid have also been associated with decreased risk for neuroblastoma, genitourinary anomalies, and facial clefts.<sup>11,12</sup> Low maternal levels of zinc, most likely to be found in women who exercise strenuously or who are vegans, have been associated with occurrence of NTD.<sup>13</sup> Therefore, a multivitamin containing folic acid and zinc should be recommended to all potentially pregnant women. Additional folic acid supplementation must be prescribed to women at high risk for NTD.

Oversupplementation with vitamin A (retinol) has been reported to be associated with a variety of congenital anomalies, including cardiac, central nervous system, and urinary tract defects, as well as IUGR. Although these reports have been contested,<sup>14</sup> it is safest for patients not to take supplements with more than 10,000 IU retinol/day. Most prenatal vitamin supplements are currently formulated to have 8000 IU or less. The beta-carotene form of vitamin A has not been associated with birth defects, even when ingested in large doses.

### Chronic Medical Conditions

Pregnancy may have a deleterious effect on some chronic medical conditions; conversely, medical conditions and medications can affect the outcome of pregnancy. Therefore, before conception, each woman should be queried as to the medical conditions she has been or is currently being treated for and all of the medications and over-the-counter substances she is ingesting. The primary care provider may not be familiar with the effect of the disorder, or drug, on pregnancy and may elect to refer the patient to a specialist who can assess whether a disease is in good control, help plan the timing of a pregnancy, and consider the potential teratogenicity of required medications and the alternatives (Table 10-4).

There are, however, a few disorders that are sufficiently common to warrant familiarity of the primary physician caring for the preconception patient. For example, carbohydrate intolerance affects 1.5 million women of reproductive age in the United States. Although maternal and fetal mortality associated with diabetes in pregnancy has decreased, congenital malformations still occur 2 to 3 times more commonly in offspring of diabetics than in offspring of women with normal carbohydrate metabolism.<sup>15</sup> Cardiac, renal, and neural tube defects are especially common. Although they occur infrequently, holoprosencephaly and sacral agenesis are much more common among offspring of diabetic than nondiabetic mothers.

**Table 10-4**  
**Medications Contraindicated During Pregnancy**

ACE inhibitors and angiotensin II receptor antagonists
Alkylating agents
Amiodarone
Androgens
Diphenhydantoin
Etretinate
Isotretinoin
Leflunomide
Tetracycline
Trimethoprim
Valproic acid
Warfarin

Poorly controlled diabetics have a higher pregnancy loss rate and a higher fetal malformation rate than do well-controlled diabetics.<sup>15</sup> However, because most embryologic development occurs before 10 weeks' gestational age, good control must be achieved before conception and must be continued through the phase of organogenesis to impact the morbidity and mortality rates. Control starting after the first prenatal visit, although it may have other beneficial effects on maternal health and fetal growth, is usually too late to reduce the risk of malformation. Other complications in diabetic women and their fetuses are maternal hypertension and preeclampsia, increased need for cesarean section, macrosomia and associated birth trauma, and IUGR; complications in the neonate include hypoglycemia, respiratory distress syndrome, hypocalcemia, polycythemia, and hyperbilirubinemia. If the maternal diabetes is of long standing, diabetic nephropathy may be present, increasing the likelihood of preterm birth, hypertensive complications, and the need for maternal dialysis or transplantation in the near future, while her child is very young.<sup>16</sup> Progression of diabetic retinopathy, again requiring aggressive treatment and possible permanent morbidity, is more common in pregnant women with poor control than in pregnant women with good control.<sup>17</sup>

Ideally, the patient's renal, cardiac, and retinal function would be assessed prior to conception. Glycosylated hemoglobin levels can be used to assess the level of control for the previous 3 months. Tight control may require changing from an oral hypoglycemic agent to several injections of insulin each day. The patient will have to manage her disease intensively, measuring her blood sugar frequently at home, and plan for frequent medical visits both in the early and late stages of pregnancy. Discussing these issues before conception allows the patient the opportunity to think about whether she is prepared to make this commitment to preconception control and prenatal care. If not, she may want to consider a very effective method of contraception or sterilization.

Hypertension, likewise, is a common disorder in the general population. Although this condition can usually be satisfactorily managed without complication during pregnancy, women with hypertension are at increased risk for cerebrovascular accident, renal failure, preeclampsia, gestational diabetes, placental abruption, IUGR, fetal demise, and preterm delivery.<sup>18</sup> The most severe complications occur in women over age 30 with evidence of end-organ disease (long-standing hypertension). Also, certain antihypertensive agents (e.g., angiotensin-converting enzyme inhibitors or angiotensin II receptor antagonists) are contraindicated in pregnancy for their fetopathic effect.<sup>19</sup> Atenolol has been associated with IUGR.<sup>20</sup> Hypertensive women should have their retinal, renal, and cardiac functions assessed prior to conception. If the patient requires an antihypertensive drug to maintain normal blood pressure, and the medication she is taking is not teratogenic, she should continue the medication during pregnancy. Alternatively, if the hypertension is mild and not complicated by renal disease or diabetes mellitus, a trial off medication with close monitoring is also reasonable.

An uncommon (1 in 14,000 women) disorder, but one that is extremely important to recognize prior to conception, is phenylketonuria (PKU). Women with PKU will report having been on a special diet throughout childhood and requiring multiple physician visits to monitor phenylketone levels. Women

who have adhered to this diet throughout childhood are usually of normal intelligence. However, many have stopped their phenylalanine-free diet on reaching adolescence. Although this may not be causing them any physical or mental harm, their phenylalanine levels will be very high on a normal diet. This in turn will have a teratogenic effect on their offspring (i.e., microcephaly, mental retardation, cardiac anomalies, and IUGR).<sup>21</sup> Therefore such women must be identified and aggressively treated with a phenylalanine-restricted diet prior to conception.

Seizure disorders are the most common neurologic problem in women who present for preconception counseling. Seizure frequency is unchanged or decreased in about half of pregnant women, and the other 50% report an increase in seizure frequency. Many women will have been on anticonvulsant medications for many years, and some will have a history of no recent seizures. In the latter case, it would be appropriate to arrange a consultation for the patient with her neurologist to see if a trial off anticonvulsants is reasonable. The usual guideline is that if no seizures have occurred for the preceding 2 years, and the seizure history does not include tonic-clonic seizures, then a trial off medication is warranted.<sup>22</sup> Even if such a trial proves successful, however, a patient with a history of idiopathic seizures must be advised of her twofold increased risk for a child with a non-specific birth defect.<sup>23</sup> The latter is true even if no anticonvulsant medication is taken during the pregnancy. The explanation for this empirical finding is that some individuals may have genetic syndromes characterized both by seizures and by increased risk for dysmorphogenesis.

Additionally, the patient who must continue her anticonvulsant medication during pregnancy should be advised that many anticonvulsants are known to have teratogenic effects. Both valproic acid and carbamazepine are associated with an increased risk for NTDs. Diphenhydantoin is associated with a pattern of dysmorphogenesis that includes growth restriction, microcephaly, mental retardation, and hypoplastic fingernails and toenails. Other anticonvulsants are also associated with similar dysmorphism. Some of the newer anticonvulsants (e.g., topiramate, gabapentin, lamotrigine) may ultimately prove safer, but only a minimal amount of data is currently available.<sup>23</sup> Folic acid may reduce the risk for a birth defect, and women taking valproic acid or carbamazepine are advised to take a dose of 4 mg/day starting before conception and continuing through the stage of neural tube closure (4 weeks' postconception). Anticonvulsant levels should be monitored serially throughout pregnancy to assure that they are at a therapeutic level. The required dose is likely to change during pregnancy, given the increased volume of distribution, decreased plasma protein levels, and change in liver metabolism and gastrointestinal absorption. Most important is the ability to manage the disorder with single rather than multiple drug therapy, the latter resulting in a higher malformation rate.

Once pregnancy occurs, maternal serum alpha-fetoprotein screening, amniocentesis, or detailed ultrasound examination at the appropriate gestational ages are available for screening and diagnosis of fetal NTDs. Ultrasound may also detect some cases with anticonvulsant-associated facial clefts or cardiac defects.

Patients may be receiving chronic anticoagulation for a number of reasons, including a history of antiphospholipid syndrome, thromboembolism, or prosthetic heart valve. First-

trimester exposure to Coumadin (warfarin sodium), an oral anticoagulant, is associated with fetal nasal hypoplasia. Second-trimester exposure infrequently results in optic nerve or cerebral damage.<sup>24</sup> Therefore, the safest option is for the patient to change to a form of heparin (regular or low molecular weight), which does not cross the placenta, prior to conception. Because heparin must be injected daily, this will obviously be a more difficult therapy for the patient, and requires discussion in the preconception period.

### Infections

The preconception period is ideal for screening for infectious disease and immunizing when appropriate. High-risk patients should be screened for tuberculosis. A rubella titer should be drawn. If no antibodies are present, the patient should be immunized and advised not to conceive for the next 3 months. The same is true for varicella in women who have no history of the infection. Patients without a history of hepatitis B can be immunized also if they fall into a high-risk group (e.g., health care worker, household contact, multiple sexual partners). Women with exposure to outdoor cats or raw meat should take precautions to avoid exposure to *Toxoplasma* unless they have a positive antibody titer. Childcare workers are at increased risk for cytomegalovirus and parvovirus. If they do not have antibodies they need to adopt appropriate precautions (e.g., wearing gloves when handling wet diapers). Testing for human immunodeficiency virus (HIV) and syphilis can be offered, as well as screening for other sexually transmitted diseases.

### Environmental Exposures

Other issues that should be raised in the course of preconception counseling include the patient's use of caffeine, tobacco, alcohol, and illicit drugs. Consumption of more than 2 cups of regular strength coffee (250 mg) a day has been associated with a slight decrease in fertility; more than 4 cups per day has been associated with pregnancy loss.<sup>25</sup> Causality, however, may be questioned on the grounds that women who drink such high levels of coffee in early pregnancy don't have the usual aversion and nausea commonly present in a healthy first-trimester pregnancy.

Approximately 15% of women smoke during pregnancy despite the known association with preterm delivery and low birth weight, placental abruption, placenta previa, and, more recently reported, facial clefting and clubfeet.<sup>26</sup> The odds ratio of delivering a small for gestational age infant in a smoker is 2.07 (95% confidence interval [CI], 1.69 to 2.53), with a direct dose-response association between number of cigarettes smoked and risk of growth restriction.<sup>27</sup> Because pregnancy is a powerful inducement to change, attempts to stop smoking in preparation for gestation may be more successful than at other times in a woman's life. Suggestions by the physician regarding use of nicotine replacement or other pharmacointerventions may be more positively received by the patient interested in her offspring's welfare. Because secondhand smoke exposure has also been associated with full-term low-birth-weight infants, the male partner should be encouraged to participate in these efforts. Cigarette smoking is associated with accelerated attrition of oocytes, decreased fertility, and earlier menopause, an issue for the older patient attempting pregnancy.<sup>28</sup>

**Table 10-5**  
**The T-ACE Questionnaire**

T	How many drinks does it take to make you feel "high" (can you hold)? (Tolerance: a positive response consists of two or more drinks)
A	Have people annoyed you by criticizing your drinking?
C	Have you ever felt you ought to cut down on your drinking?
E	Have you ever had a drink first thing in the morning to steady your nerves or to get rid of a hangover (eye-opener)?

Scoring: 2 points for the first question and 1 point each for the other three questions. A score of  $\geq 2$  is high risk.

Alcohol is a known teratogen and the leading preventable cause of mental retardation. There is a dose-response relationship between alcohol and congenital abnormalities and although low levels of exposure are not associated with the fetal alcohol syndrome, it cannot be assumed that even low-level exposure is without long-term subtle behavioral effects on the developing fetal brain. The preconception interview can include a few questions to screen for heavy alcohol use (e.g., the T-ACE questionnaire; Table 10-5).<sup>29</sup> Infertility secondary to anovulation is more common in women who consume alcohol, and heavy alcohol use by the male reduces spermatogenesis.<sup>30</sup>

Use of cocaine, heroin, or other illicit substances is known to confer increased risk for low birth weight and other obstetric complications. Referral to a detoxification program before conception would be beneficial to mother and child.

Domestic violence during pregnancy has been reported in at least 4% to 8% of women, most of whom are already suffering abuse prior to pregnancy. In fact, 59% of women abused prior to pregnancy have reported continuation of violence during pregnancy.<sup>31</sup> Counseling and resources should be made available to women in this situation.

Because there is data from animal studies indicating that hyperthermia during organogenesis is teratogenic, particularly for NTDs, use of hot tubs in very early pregnancy has been a concern. A study done by Milunsky and colleagues<sup>32</sup> showed that women who used a hot tub in the first 8 weeks of pregnancy had a 2.9 relative risk (95% CI, 1.4 to 6.3) of a child with an NTD. Although most women will not stay in a hot tub long enough to become hyperthermic, caution would suggest limiting exposure in the periconception period.

Although most workplaces are safe for pregnant women, an occupational history should be taken. If there is concern regarding exposure to excess physical stress, organic solvents, lead, mercury, or pesticides, which may be associated with pregnancy loss or teratogenesis, further investigation of the level of exposure, whether the patient is retaining toxic substances in her blood, and the need for a more protected work environment should be explored.

## KEY POINTS

- Cervical cancer is rare and almost always prevented through regular Pap tests.
- Most sexually active women will have a human papillomavirus (HPV) infection at some point, but very few will develop cervical cancer.
- Most HPV infections are temporary and regress spontaneously.
- Only an HPV infection that does not go away over a long time can lead to cervical cancer.
- Women over age 30 years may want to know their HPV status to help determine how often the health care provider will recommend a Pap test.
- A woman's HPV status is not a reliable indicator of her sexual behavior or that of her partner.

This chapter presents principles of cervical cancer screening and follow-up of abnormal Papanicolaou (Pap) test results that result in the histologic diagnosis of premalignant changes of the cervix. More detailed information about diagnostic follow-up of abnormal cervical cancer screening results by colposcopy and clinical features of cervical intraepithelial neoplasia and invasive cancer are discussed in Chapters 12 and 43, respectively. Issues related specifically to diagnosis and management of invasive cancer of the cervix are covered in Section 7.

In 1957, the United States Commission on Chronic Illness defined health screening as "the presumptive identification of unrecognized disease or defect by the application of tests, examinations or other procedures that can be applied rapidly."<sup>1</sup> Thus, health screening is the use of methods to detect unrecognized health risks or diseases in order to permit timely intervention.

Screening tests are usually applied on a large scale. They are used to distinguish apparently unaffected people from those who may have or may develop a disease. A screening test is not intended to be diagnostic. Screening procedures are generally easier to perform and cheaper than diagnostic procedures. Their results require confirmation through definitive diagnostic tests, or sometimes direct treatment is offered on the basis of a positive test. Even if the screening test is harmless, it can cause anxiety and the subsequent investigations and treatment may be hazardous. Ensuring the safety of screening is also important because large numbers of individuals will be screened, creating

a potential for greater numbers to be harmed by the screening process.<sup>2</sup>

Screening comprises three elements:

1. It is a preliminary process of selection to identify individuals at sufficiently high risk of a specific disorder to warrant further investigation or direct action.
2. It is offered to a largely healthy population not seeking attention for symptoms of the disease for which the screening is being conducted.
3. It is meant to benefit the individuals being screened.

These principles imply an ethical approach to participants in the screening process. In clinical practice, the special nature of the patient/provider relationship has resulted in the need to create a core of ethical principles to govern this relationship. An important distinction between screening and episodic care for medical diagnosis and treatment is that the screening encounter is not initiated by the subject but by the provider. This is true whether screening is offered in an organized way by governmental public health units or opportunistically by providers in a variety of ambulatory care settings. When a patient consults a health provider for diagnosis of, and hopefully relief of symptoms, or for treatment of an established condition, the provider exercises skills only to the extent that knowledge is currently available. In screening, however, those who participate are not patients in the sense that they are ill, and in the majority of situations, do not become patients in the traditional sense. The screener promotes the test based on evidence that as a result of screening, the overall health of the community will be better. This does not mean that the condition of every individual screened will be better, although in general, this should be so.<sup>3</sup> There is also an ethical responsibility of the provider community to (1) minimize the potential harms and anxiety that affect certain individuals being screened, (2) ensure that quality control of the screening tests is maintained and the effectiveness of proven, beneficial programs is continually monitored, and (3) guarantee that assurance is available that a useful course of management is available for all individuals identified as being truly test-positive.

Equity of access to screening services is another important consideration. Ideally, all who stand to gain from screening should have access to the procedure. Those who organize the service have an obligation to ensure that those who have not heard of the test/ procedure but who stand to benefit from it are adequately informed and are encouraged or invited to be screened. An additional issue concerns the extent to which the offer of screening in a community could divert resources from other important health care programs. This is of particular importance in low resource settings in which limited resources

\*All material in this chapter is in the public domain, with the exception of any borrowed figures or tables.

must be equitably distributed across the total community to obtain maximal benefit.

## EPIDEMILOGY, PATHOGENESIS, AND RISK FACTORS FOR CERVICAL INTRAEPITHELIAL NEOPLASIA

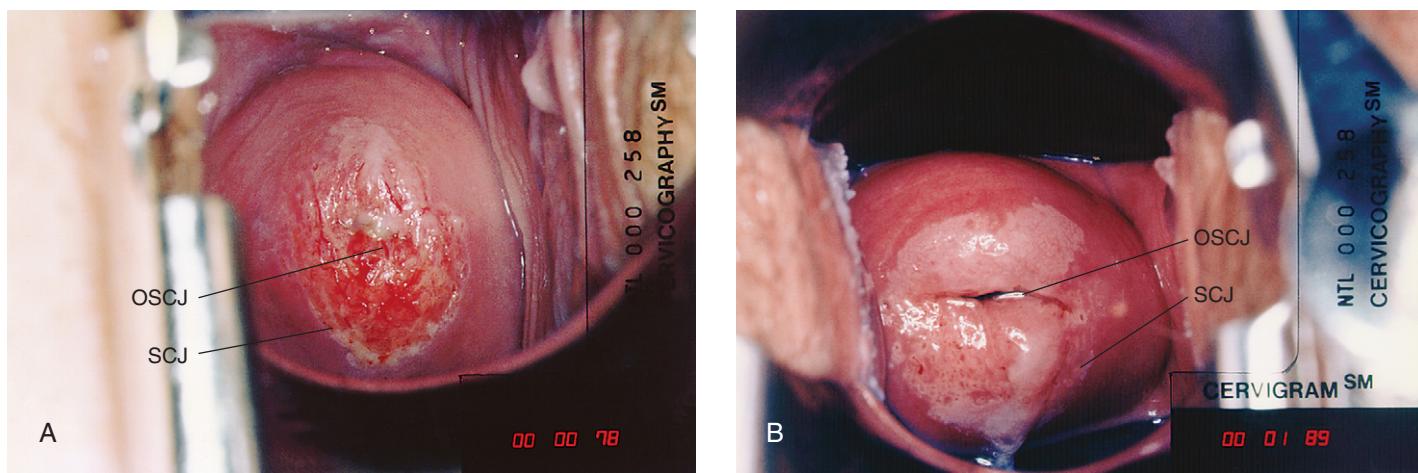

Persistence of DNA from a high-risk type of HPV is significantly associated with development of high-grade cervical intraepithelial neoplasia (CIN) or dysplasia and invasive cervical cancer.<sup>4,5</sup> CIN III and invasive cancer are most commonly found at the junction between the squamous and glandular cells of the uterine cervix, which is called the *squamocolumnar junction* (SCJ). This cervical *transformation zone*, an active area of squamous metaplasia, is especially vulnerable to HPV-induced cellular transformation (Fig. 11-1).

After infection with HPV, one of two clinical pathways may occur: (1) transient viral expression followed by clinical clearance, or (2) viral persistence. Most infections remain undetectable or produce transient cytologic changes that are missed by infrequent screening. Some infections cause detectable cytologic changes diagnostic of HPV infection, including a low-grade squamous intraepithelial lesion (LSIL) or high-grade squamous intraepithelial lesion (HSIL), or induce the shedding of cells that demonstrate only some, but not all, features of an HPV infection (e.g., atypical squamous cells of undetermined significance, or ASC-US). CIN is a tissue-based classification; i.e., it is based on reviewing the histopathology of biopsy specimens. The designation of CIN I, II, or III is based on the thickness of the epithelium showing abnormal cells, the degree of mitotic activity, and nuclear atypia<sup>6</sup> (Fig. 11-2). Since more than one naming system is used, it is important to note that CIN I and II correspond to mild and moderate dysplasia, respectively; CIN III is analogous to severe dysplasia, and this category includes carcinoma *in situ*. Pathologists often disagree about the interpretation of samples at the lower end of the cytologic and histologic spectra (ASC-

US and CIN I, respectively).<sup>7</sup> The disparity between the high rate of infection with HPV and the relatively low risk of cervical cancer reflects the fact that many women become infected with HPV but most infections spontaneously regress over time. Attempts to understand why the virus persists in some women have focused on variants of high-risk HPV types and cofactors such as smoking, other infectious agents (chlamydia, herpes, bacterial vaginosis), parity, use of oral contraceptives, and host immune factors. In the end, any important role played by HPV variants and cofactors is likely to be due to promotion of viral persistence because it is the most important factor in determining whether an HPV infection has the potential to progress to a precancerous lesion or cancer. The incidence of invasive cervical cancer reaches a plateau in women approximately 15 years later than the peak incidence of CIN III, suggesting a slow progression from CIN III to invasive carcinoma in most instances.<sup>8</sup> This prolonged period from development of CIN III to invasion probably reflects the long period of time required for the accumulation of mutations following viral integration and down-regulation of the apoptotic functions of certain tumor suppressor oncogenes (p53 tumor suppressor gene, or p53, and the retinoblastoma protein, or pRb). Inhibition of p53 and pRb leads to an increased cell proliferation rate and to genomic instability. The infected cell acquires more and more DNA damage that cannot be repaired, leading eventually to oncogenic transformation.

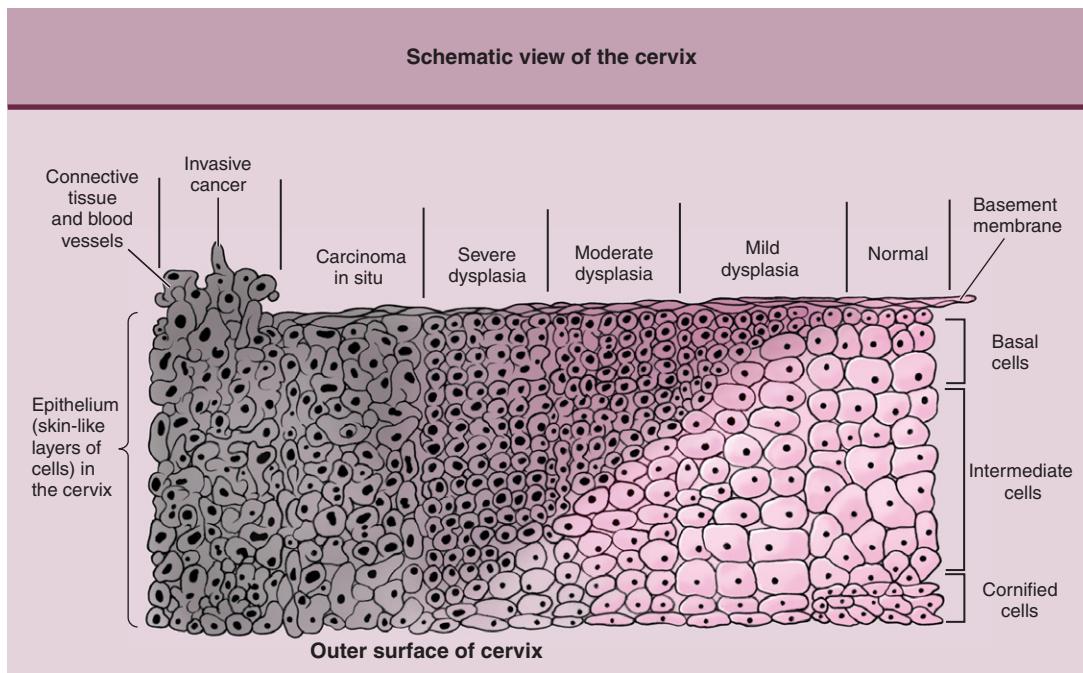

## NATURAL HISTORY OF HUMAN PAPILLOMAVIRUS

It is now clear that the natural history of cervical neoplasia and HPV are intimately related. The natural history of HPV begins with infection followed by a variable period of time during which disease expression is absent. Over time there may be an active growth phase and a finally a host-containment phase (Fig. 11-3). Most HPV infections do not result in signs or symptoms of disease.<sup>4,9,10</sup> If HPV infection is not controlled,

**Figure 11-1 Cervical transformation zone seen on cervigrams showing visual inspection with acetic acid (VIA).**

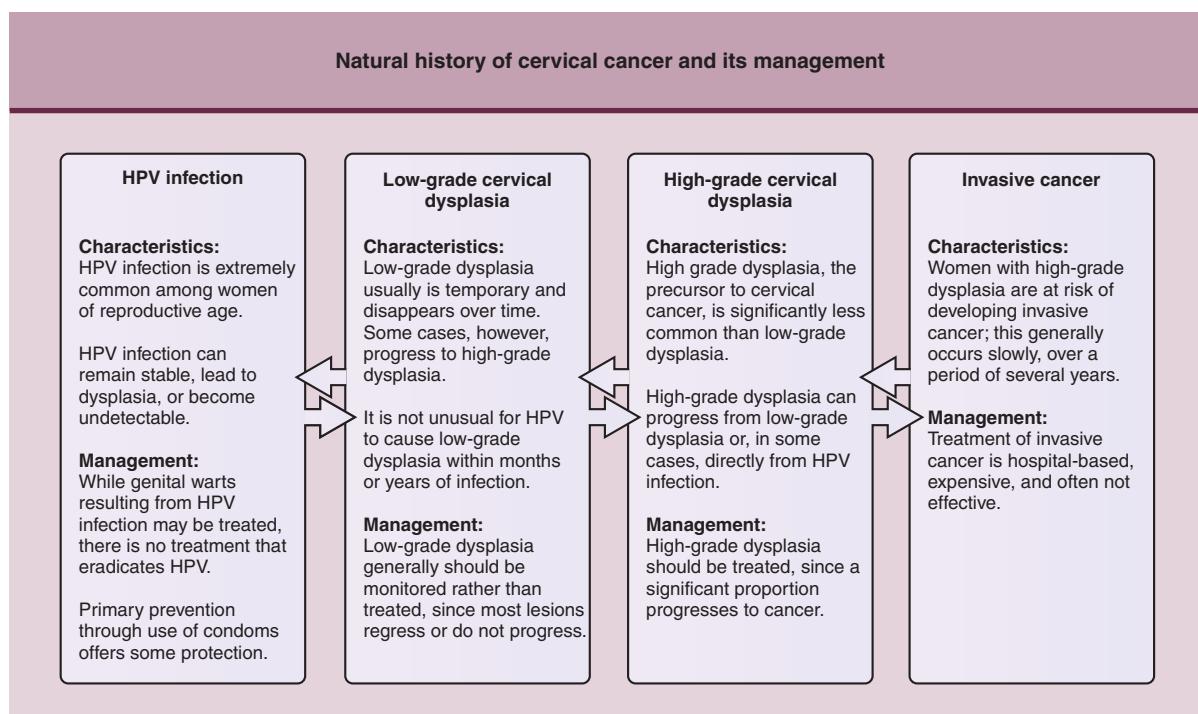

The transformation zone lies between the new squamocolumnar junction (SCJ) and the original squamocolumnar junction (OSCJ). The new squamocolumnar junction is defined by the leading edge of squamous cells as they abut the columnar epithelium. A, Small, flat, dull acetowhite lesion. B, Large, thick, shiny acetowhite lesion. Both are examples of high-grade squamous intraepithelial lesions (HSILs). (Courtesy of K. Dahlquist and J. Sellors, MD.)

**Figure 11-2 Schematic development of cervical cancer from normal and precursor lesions.** (Courtesy of V. Hanson, MD.)

owing to host, viral, or environmental factors, an active growth phase will be expressed as one or more morphologic changes such as abnormalities of cervical cytology, cutaneous warts, CIN, or invasive cervical cancer. For the majority of patients, a phase of host containment begins following immune recognition

of HPV presence. A successful immune response results in viral control or clearance. A minority of individuals do not develop adequate host control and are at risk for persistence of HPV. The persistence of high-risk HPV infection is a necessary step for the development of cervical cancer precursor lesions and

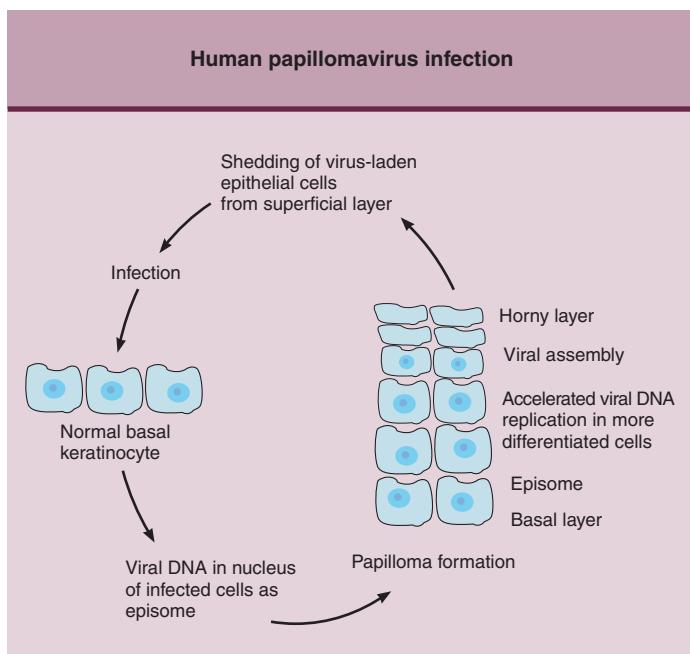

**Figure 11-3 Natural history of cervical cancer and program implications.** (From Sherris J, Herdman C: Preventing cervical cancer in low-resource settings. *Outlook* 2000;18:3. Used with permission of Program for Appropriate Technology in Health [PATH], Seattle, Wash.)

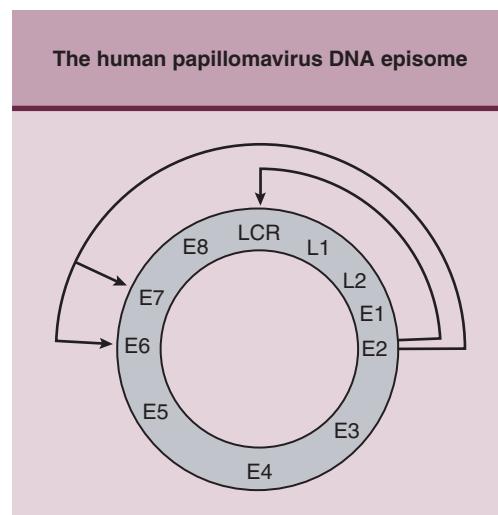

invasive cancer.<sup>11</sup> In summary, the basic segments of the natural history of transient HPV infection include viral entry, viral replication, productive viral infection, and host containment. The viral life cycle is depicted in Fig. 11-4.

HPV first enters the basal cells in the stratum germinativum of the epithelium.<sup>12</sup> The virus is most often transmitted by skin-to-skin contact and enters through sites of microtrauma, most commonly found in women at the introitus and perineum during or following sexual relations. Areas with increased vulnerability to HPV infection are the epithelial layers of immature squamous metaplasia located in the transformation zone of the cervix and anal verge.

HPV is a small, double-stranded DNA virus encased in a protein capsid. To enter the host cell, it must shed its protein capsid, injecting naked DNA into the cytoplasm of the cell. From the cytoplasm, the DNA travels to the cell nucleus. The viral genome usually exists in an episomal (circular) configuration that can be divided into three regions: the long control region (LCR), the early region (E), and the late region (L)<sup>12</sup> (Fig. 11-5). The LCR is responsible for regulation of viral replication and controls transcription of some sequences in the early region. The early region encodes mainly for proteins that are important in viral replication, occurring “early” in the viral life cycle. The late region encodes for viral structural proteins that are necessary for capsid production, which occurs “late” in the viral life cycle.<sup>12</sup> The early region has eight different regions that encode for proteins that play vital roles in the HPV life cycle. Two regions, designated E6 and E7, are crucial in the process of oncogenesis in high-risk types of HPV. The E6 protein binds to p53 and accelerates its destruction. The E7 protein binds to pRb, inhibiting its function.<sup>13</sup> The actions of the E6 and E7 proteins lead to cellular transformation.<sup>12</sup> Low-risk HPV types have a much lower capacity to induce malignant transformation in vitro

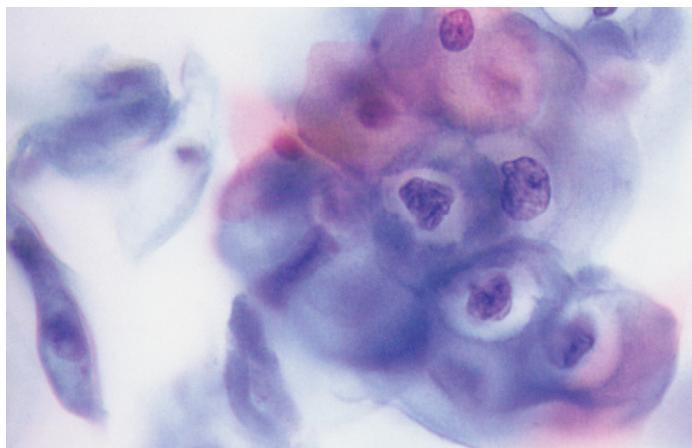

**Figure 11-4** The viral life cycle. (From Cox JT: Clinical Proceedings, Association of Reproductive Health Professionals, September 2003, p 5, with permission.)

**Figure 11-5** Human papillomavirus (HPV) DNA. Most HPV exists in episomal (circular) DNA. The important genomic sites are called open reading frames (ORFs). In the episomal state, E2 regulates both the long control region (LCR), which is responsible for regulation of viral transcription, and E6 and E7, the two sites most often responsible for malignant transformation. (From Cox JT: Clinical Proceedings, Association of Reproductive Health Professionals, September 2003, p 5, with permission.)

than high-risk HPV types because of functional differences between their E6 and E7 proteins.<sup>12</sup> For example, the E6 proteins of low-risk HPV types bind to the protein product of p53 poorly, and thus are less able to transform infected cells.<sup>12</sup> The two late regions, L1 and L2, encode for proteins involved in construction of the capsid of the infective HPV genome. In benign lesions associated with HPV, viral DNA exists as a circular extrachromosomal DNA in the nucleus. However, in cancerous cells and in some precancerous lesions associated with HPV, the viral DNA is integrated into the host genome. Generally, the integration of the viral DNA deletes or disrupts the E2 region, resulting in loss of normal E2 down-regulation of E6 and E7, which leads to increased expression of these two regions.

At some point, daughter cells of the infected basal cells may begin to carry transcriptionally active episomal HPV DNA. As these cells differentiate and mature, HPV replicates, making 50 to 100 replicated copies per cell. Activation of the L1 region of the HPV genome in the upper epithelial layers envelopes each episomal DNA in a protein capsid, recreating the infective unit. HPV induction of cytoplasmic proteins in some of the infected epithelial cells results in the hallmark cell of HPV infection, the koilocyte described by Koss in 1956.<sup>14</sup> Although described, it was not recognized as significant until 20 years later when Meisels and colleagues reported the changes in mild dysplasia.<sup>15</sup> Koilocytes are large, polygonal squamous cells with a wrinkled nucleus and a large perinuclear cavity<sup>13</sup> (Fig. 11-6). Shedding of the dead, surface squamous cells as part of the natural process of the cell cycle releases HPV virions to infect other cells or transmit the virus to another individual. In productive infection, viral replication is associated with proliferation of all layers except the basal layer.<sup>12</sup> In high-grade CIN, however, viral

**Figure 11-6 Low-grade squamous intraepithelial lesions (LSILs).** Classic koilocytes, as seen here, have a large cytoplasmic cavity with a sharply defined inner edge and are frequently binucleate. (Courtesy of ES Cibas, MD)

replication is associated with proliferation of the cells in the basal layer and with an increased number of mitoses, some of which are abnormal.<sup>12</sup> The exact factors that determine the transition from productive infection to persistent infection associated with high-grade lesions are unknown, but a complex interplay of host, viral, and environmental factors is most likely important.

Recognition of the presence of HPV by the immune system results in a T-cell response. T cells are the primary effectors of the cellular immune response, which is known to be of prime importance in limiting HPV infection.<sup>10</sup> The humoral immune system may also be involved with fighting HPV infection and preventing reinfection with the same HPV type. Antibodies against the viral capsid have been detected in individuals with cutaneous or urogenital warts.<sup>16-18</sup> In most cases, genital HPV infection appears to be transient. In one study of college women, the median duration of HPV detection by sensitive molecular tests was 8 months; this may be an underestimate because it was not possible to document when these infections began.<sup>19</sup> Other studies have documented a longer duration of detection of HPV that is type-specific, with a mean duration of 13.4 months for low-risk types and 16.3 months for high-risk types.<sup>20</sup> Ninety percent of HPV infections will be cleared or suppressed below the limits of detection by host defenses within 1 to 2 years.<sup>4</sup> Viral persistence is necessary for HPV-induced oncogenesis to occur. Persistent infection with high-risk HPV types correlates with age and high viral load and is associated with increased risk of CIN.<sup>19, 21, 22</sup> In a 2-year study, CIN lesions were 11 times more likely to develop in women with HPV type 16 or 18 infection at baseline than in women without HPV infection at baseline.<sup>23</sup>

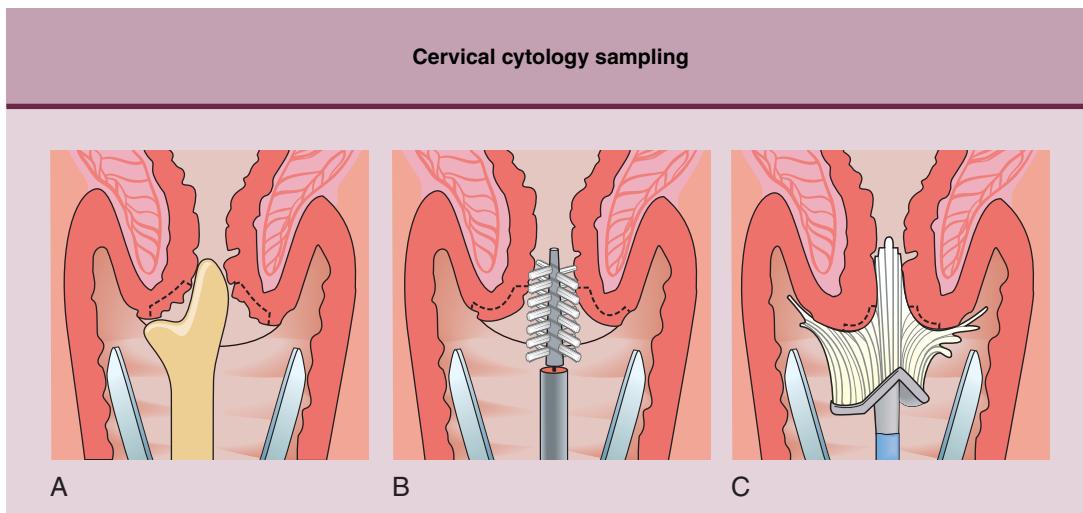

## CERVICAL CANCER SCREENING

Screening for cervical neoplasia to date primarily involves assessment of the cervical epithelium; the future of such screening may involve detection of high-risk HPV types.<sup>24</sup> More than 90% of lower genital tract neoplasia in women originates at the squamocolumnar junction of the cervix, where columnar and

nonkeratinizing squamous epithelia meet.<sup>25</sup> Under the influence of various factors, a variety of intraepithelial changes take place before invasive cancer develops, and these changes are confined to the squamous epithelium above the basement membrane—“cervical intraepithelial neoplasia” (see Fig. 11-2). Because the cervical transformation zone is large in adolescence and during a woman’s first pregnancy, early age at first sexual activity and at first pregnancy have been suggested as risk factors for cervical cancer. Given the progression of cytologic lesions of the cervix in some women, it is important to monitor those with persistent cytologic abnormalities to detect and treat high-grade intraepithelial lesions if they are detected. Screening and monitoring are done by the Pap test or possibly by HPV DNA testing.

For more than 50 years, the Pap test has been the primary screening tool for cervical disease. It is a cytologic screening test of a direct scraping or brushing of the uterine cervix and lower endocervical canal. In a conventional Pap test, the sample tissue is smeared onto a slide and fixed and stained. The slide is viewed under a microscope and a cytotechnologist or cytopathologist interprets the observed cellular changes. As noted earlier, this is a screening test and is not meant to be explicitly diagnostic. Patient preparation and appropriate provider technique help optimize collection of cellular material. In the conventional dry slide methodology, a single slide combining endocervical and ectocervical samples, or two separate slides for individual components, should be used. The most important consideration is rapid fixation of the samples to avoid air-drying artifacts. If liquid-based preparations are used, rapid immersion in liquid media is equally important.

In the past two decades, many refinements to techniques for collecting cervical cytology samples have been developed. In the 1980s, newer devices to enhance collection of exfoliated cells, such as nylon endocervical brushes and “broom” devices were created. These devices were responsible for improved collection of cellular material and of dysplastic cells from the transformation zone than was formerly possible with cotton swabs or the wooden Ayres spatula<sup>26,27</sup> (Figs. 11-7 and 11-8). In the 1990s, efforts to improve sampling turned to the development of liquid-based cytology methods and computer-based reading systems. In 1996, the first of two liquid-based systems currently available in the United States was approved by the U.S. Food and Drug Administration (FDA). The ThinPrep 2000 system was considered to be more effective in detecting LSILs and more severe lesions and to provide a better specimen than the conventional Pap test preparation<sup>28</sup> (Fig. 11-9). The basis of the liquid-based system is collection of a cervical cytology specimen using one of the new improved sampling devices and then suspending the sample in an alcohol-based preservative solution. Almost all the cells are transferred to the liquid preservative, with blood, mucus, and inflammatory cells generally filtered out or lysed. In the laboratory, a technician subsamples the cells, which are then deposited by an automatic device on to a slide. This technique thus removes much of the noncervical obscuring material from the sample, allowing for staining and screening of a uniform single-layer sample. The remaining sample can be stored for further testing if indicated (such as for HPV DNA testing). Even though the sampling may be improved, there still is no convincing evidence that thin-layer technology reduces morbidity or mortality from cervical cancer or its precursors.

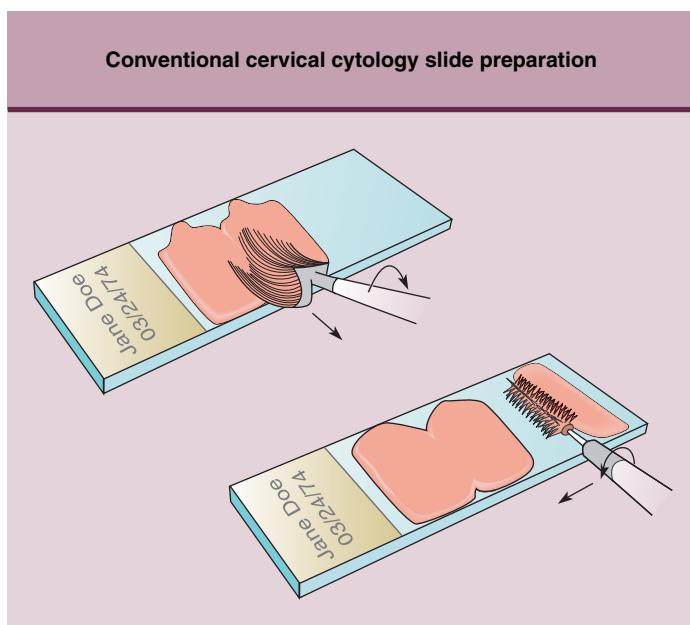

**Figure 11-7** Direct cervical cytology sampling using wooden Ayres spatula (A), Cytobrush (B), Cervex-Brush (C). (From ThinPrep Pap Test Quick Reference Guide. Courtesy of Cytac Corporation and Affiliates.)

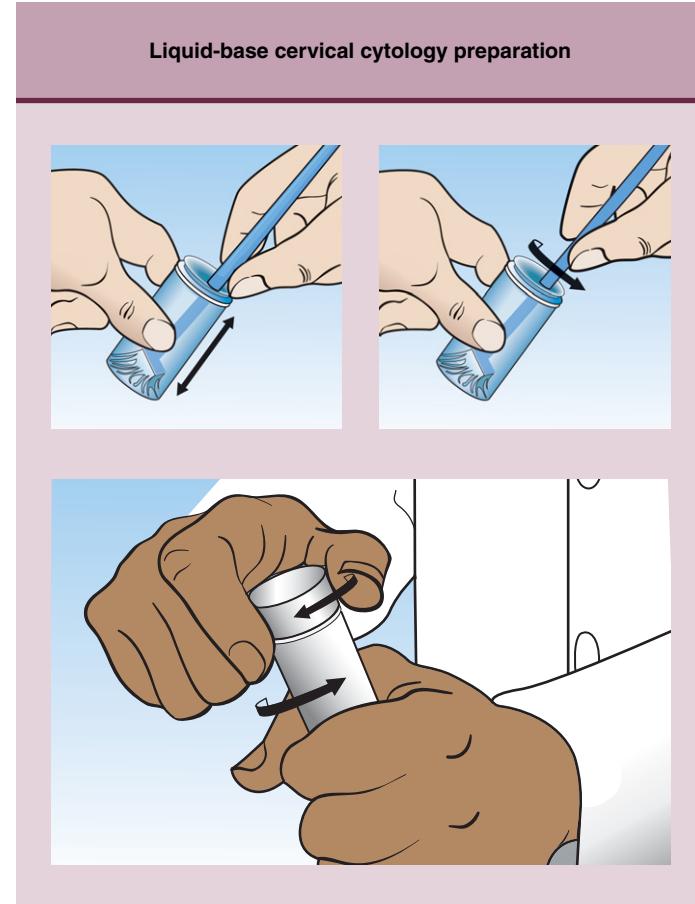

Moreover, increased detection of LSIL may not be of great importance as the majority serve as a proxy for the presence of an acute HPV infection, and in most women, HPV infections are cleared without consequence in less than 24 months. It is important to remember that little reduction in the burden of cervical cancer morbidity or mortality will be achieved without recruiting and screening women who are rarely or never screened.

In addition to new sampling devices and the liquid-based collection systems, automated computer-based technologies have been developed that use digitally scanned images and neural intelligence to facilitate primary cervical cancer screening and the Clinical Laboratory Improvement Amendments

(CLIA)-mandated 10% rescreening of cervical cytology tests that have negative results. The rationale for such systems involves the notion that false-negative readings may be secondary to human error and fatigue. While there is great potential benefit

**Figure 11-8** Applying specimen to slide in conventional cervical cytologic testing. (From ThinPrep Pap Test Quick Reference Guide. Courtesy of Cytac Corporation and Affiliates.)

**Figure 11-9** Preparation of specimen for liquid-based cytologic applications. (From ThinPrep Pap Test Quick Reference Guide. Courtesy of Cytac Corporation and Affiliates.)

of computerized screening devices to assist in identification of potentially abnormal cells or samples, using such devices will not compensate for specimens that are inadequately prepared or not representative of the cervical transformation zone, or result in interpretation errors when cytotechnologists and cytopathologists conduct secondary screenings.

One measure of screening effectiveness is knowing the population covered by the screening test. In the United States, where cervical cancer screening is entirely opportunistic (i.e., there is no organized system for inviting women to be screened at certain intervals as in some European countries), the only measure of coverage is based on self-reports by women enrolled in either the Behavioral Risk Factor Surveillance System (BRFSS), or the National Health Interview Survey (NHIS), both administered by the Centers for Disease Control and Prevention (CDC). BRFSS and NHIS show that more than 85% of women in the United States have had a previous cervical cancer screening test, and that approximately 80% have had one in the past 2 to 3 years.<sup>29,30</sup> Some variations exist by age, race/ethnicity, and availability of insurance coverage. Only one national program exists in the United States that covers women who are either uninsured or underinsured—the National Breast and Cervical Cancer Early Detection Program (NBCCEDP), administered by the CDC. This program was developed as a result of the U.S. Congress passing the Breast and Cervical Cancer Mortality Prevention Act in 1990.<sup>31</sup>

This comprehensive women's health initiative is implemented through cooperative agreements with qualifying health agencies, including state and U.S. territorial health departments and American Indian and Alaska Native tribes and tribal organizations. In addition to providing screening, participating programs conduct activities in a number of other critical areas: diagnostic tests; surveillance, tracking, and follow-up; case management; public education and outreach; professional education and training; quality assurance of screening tests; coalition and partnership development; and program evaluation. NBCCEDP-sponsored programs have initiated outreach efforts to serve women in high-priority groups, including older women, racial/ethnic minorities, foreign born women, women with disabilities, lesbians, and women living in rural or other hard-to-reach areas.

During the time period 1991 to 2003, 1.4 million women received approximately 2.5 million Pap tests through NBCCEDP-sponsored programs. During this time period, 14,000 women were found to have histologically confirmed CIN II or greater for a rate of 5.8 per 1000 Pap tests, and 929 women were diagnosed with invasive cervical cancer for a rate of 0.3 cervical cancers per 1000 Pap tests. Approximately 50% of the women served were members of racial and ethnic minorities. Tables 11-1 to 11-4 show more detailed NBCCEDP information on Pap test results and final diagnoses for the time period 1995 to 2002.<sup>32,33</sup>

In recent years, a large number of studies have updated information about cervical cancer screening and have been the basis for updating screening guidelines and recommendations by several U.S. professional organizations and government agencies from 2001 to 2004.<sup>34,35</sup> They are derived from clinical-based studies of cervical cytology and from mathematical modeling in situations where clinical data are not available. Issues covered

**Table 11-1**  
Characteristics of Women Receiving First Pap Tests in NBCCEDP

Characteristic	Number of Women (N = 750,591)	Percent Distribution
<b>Age (yr)</b>		
18–29	41,919	5.6
30–39	74,783	10.0
40–49	259,830	34.6
50–64	327,841	43.7

are age to initiate screening, frequency of rescreening and intervals between screening, and age to stop screening. Also covered is use of new screening technologies such as liquid-based cytology preparations and HPV DNA testing, as well as screening in special situations such as among postmenopausal women, pregnant women, women posthysterectomy, and immunocompromised women. While there are some differences in the recommendations of these groups, they all address the fact that certain high-risk HPV types are necessary in the chain of events leading up to the diagnosis of cervical cancer, that screening should begin for a woman by age 21, that a Pap test should be performed at least every 3 years, if prior tests were normal, and that screening may end by age 65 to 70 years depending on health status and confirmation that cervical screening tests in the prior 5 to 10 years were negative for malignant change. Less consistent are recommendations for use of liquid-based screening technologies and HPV testing because of concerns about test specificity and false-positive results. Included here is a summary of pertinent studies relating to these subjects, and a table comparing the various new U.S. professional organization screening recommendations<sup>34,35</sup> (Table 11-5).

### When to Initiate Screening

The natural history of cervical cancer is important in determining when to initiate screening, how often to screen, when to discontinue screening, and when to recommend treatment or follow-up evaluation (see Fig. 11-3). Cervical cancer most often develops in women after age 40 years, and high-grade CIN generally is detectable 10 to 15 years before cancer develops, with a peak high-grade CIN rate at about age 35. Therefore, where program resources are limited, screening initially should focus on women in their thirties and forties.

<sup>†</sup>Includes LSIL, HSIL, and SqCa.

<sup>‡</sup>Includes CIN II, III, CIS, or invasive cancer.

<sup>§</sup>All percentages and rates are age-adjusted to the 2000 NBCEDP population.

The incidence of invasive cervical carcinoma is low under the age of 20 but begins to climb from 20 to 24 years. In a cohort study from British Columbia, Canada, the incidence of carcinoma in situ at the ages of 20 to 24 was approximately 16 per 100,000.<sup>36-38</sup> This led to a National Workshop in Canada which recommended that screening begin at the age of 20.<sup>37</sup> Similar conclusions were derived by American Cancer Society in 2002, with the recommendation to begin screening no later than age 21.<sup>38</sup>

Other groups have taken a different view. In Europe, age to start screening varies widely, with Finland inviting women to their organized program from age 30.<sup>39</sup> Sasieni et al conducted a study designed to evaluate frequency of rescreening and recommended that women not be screened under the age of 25.<sup>40</sup> For developing countries, given the low incidence of cervical cancer below the age of 35 and with an objective of maximizing use of resources, it is generally recommended that screening start at age 35.<sup>41</sup>

### How Often to Screen

In most instances, cervical cancer develops slowly from precursor lesions; therefore, screening can take place relatively infrequently (less than annually) and still have a considerable

impact on morbidity and mortality. Screening every 3 years has almost as great an impact as screening every year or every 2 years (Table 11-6). Even screening every 10 years or once in a lifetime can have significant impact.<sup>41,42</sup> The emphasis of screening programs, therefore, should be on coverage of risk-appropriate women rather than on frequency.

Determining the frequency of screening is helped by knowledge about the natural history of the condition being screened for, including the duration of the asymptomatic or latent phase. Screening too frequently will result in a low number of cases per screen and thus a low predictive value for the test. The reason is that the prevalence of asymptomatic disease will be low in the population when the screening frequency is high. On the other hand, infrequent or no screening will leave much of the disease uncontrolled.<sup>43</sup>

The goal of screening programs is to maximally reduce incidence and mortality from disease given available resources. The optimal screening interval is one that provides the most favorable degree of disease control and cost of screening. The design of a screening program defines two key parameters for achieving these objectives: the target population and the screening interval. Adherence to these parameters is crucial in maintaining the effectiveness of the program, measuring

cost-effectiveness, and maximizing population coverage. Deviation from the recommended screening intervals or target populations may reduce program effectiveness either by using excessive resources as with annual rescreening for cervical cancer or by allowing the disease to “escape” the interval during which early intervention can lead to treatment of precursor lesions or cure of early-stage invasive disease. Modeling can facilitate decisions on the optimal frequency of screening.

An early evaluation of the British Columbia data using a Markov-Chain model supported a prolonged natural history of carcinoma in situ (an average sojourn time of at least 9 years) and concluded that women with a negative cytologic test should be rescreened every 5 years.<sup>44</sup> Nevertheless, the International Agency for Research on Cancer (IARC) report in 1986, based

on the best available data of the time, recommended cervical cancer screening every 3 years. This was based on a sojourn time of 5 to 8 years and predicted a cumulative reduction in incidence of approximately 90%<sup>42</sup> (see Table 11-6). Contrary to this recommendation, the cervical cancer screening program in Finland, utilizing screening every 5 years, achieved the level of success that the IARC model suggested would require triennial screening. As validation of the Finnish report, a reevaluation of British Columbia data using the Mican model developed in Rotterdam showed that although the median duration for progression from carcinoma in situ to invasive cancer in the IARC study was about 5 to 8 years, this was calculated by including women with screen-detected (prevalent) cancers, whose prognosis is excellent and who are affected by the lead time gained by screening.<sup>45</sup> Adjusting for screen-detected cancers lengthened the median sojourn time from CIS to invasive cancer to 15 years. The implication is that screening every 5 rather than 3 years will yield a 90% reduction in invasive cancer incidence and mortality.<sup>45</sup>

While Table 11-6 shows the expected impact on the cumulative incidence of invasive cancer of the cervix in optimally screened populations, it is important to emphasize that even in optimal circumstances, based on the presence of highly effective cytology screening programs, no realistic screening schedule will result in complete elimination of invasive cervical cancer. In most countries, including the United States, this failure to attain optimally reduced morbidity and mortality may involve any of the essential components of a program, occurring at the level of the woman, her provider, or the laboratory reviewing her Pap test.<sup>46</sup> Another reason may be the variability of the natural

**Table 11-6**  
**Percentage Reduction in Cumulative Rate of Invasive Cervical Cancer over Age Range of 35 to 64 with Different Frequencies of Screening**

Frequency of Screening (yr)	Percent Reduction in Cumulative Rate*	No. of Tests
1	93	30
2	93	15
3	91	10
5	84	6
10	64	3

Data from IARC, 1986.

history in different women. Models are based on averages of transition probabilities, each with a different distribution or range of time periods during which some lesions progress from one state to the next, while others regress to normal. Still others remain stable for long periods of time. Some lesions may progress so rapidly that they cannot be detected in a curable stage even with annual screening, and it seems unlikely that the majority of such lesions would be detected by more frequent screening. This does not mean that there are different types of cancers of the cervix, as suggested many years ago, but that the fast-growing lesions represent one extreme of the distribution of progression or sojourn times.<sup>47</sup>

Celentano et al conducted a case-control study that included 153 women with invasive cancer, 153 case-nominated controls, and 392 randomly selected controls.<sup>48</sup> Cases were much less likely to have been screened within 2 to 3 years than controls (Odds ratio [OR] 8.3, 95% confidence interval [CI] 3.4–19.9 compared with case-nominated controls, OR 4.6, 2.0–10.5 compared with randomly selected controls). Moreover, some degree of protection was seen among screened women for 4 to 6 years (OR 4.3, 1.5–12.7, and 3.6, 1.4–9.6, respectively) after adjusting for a number of confounding variables.

Herbert et al studied the incidence of cervical cancer in a region of the United Kingdom after the introduction of the UK computerized invitation and recall system.<sup>49</sup> The incidence of invasive cancer was significantly higher in those not screened in the previous 5 years than among those screened (relative risk [RR] 2.6, 95% CI 1.6–4.3]. RRs were even higher when screen-detected cancers were excluded. Based on their results, the authors concluded that a 5-year screening interval was too long.

Goldie et al modeled the natural history of cervical cancer using published data on transition and regression rates, and data from a study in South Africa.<sup>50</sup> They concluded that in developing countries, it would be more cost-effective if resources were available to screen three times in a lifetime, and that these tests should occur every 5 years from age 35 or 40, rather than every 10 years from age 35, as had been modeled by the IARC study.<sup>39</sup>

Miller et al conducted a case-control study within a U.S. health maintenance organization (Kaiser Permanente) between 1983 and 1995 of cases of invasive cancer diagnosed, and 934 controls, matched for length of membership in the HMO and race.<sup>51</sup> The ORs for different interval lengths between screens with 1-year interval as the referent are given in Table 11-7. The authors emphasized the low absolute risk of an abnormal cervical cancer screening test within 3 years of a prior negative test.

Sawaya et al studied the prevalence of biopsy-proved cervical neoplasia among 938,576 women less than 65 years of age in the NCCEDP.<sup>52</sup> The prevalence of all grades of CIN was highest in women below age 30 and higher in those with no previous negative cytology tests than in those with one or more tests. No invasive cervical cancers were detected in women with three or more previous negative tests. Using a Markov model and various rates of progression and regression from the literature, they estimated that for women aged 30 to 64 with three or more consecutive negative tests, extending the rescreening interval to every 3 years would result in an average excess risk of cancer of approximately 3 per 100,000.

Sasieni et al conducted a case-control study based on the screening histories of 1305 women aged 20 to 69 with stage 1B cancer of the cervix and 2532 age-matched controls from the records of the National Health Service in the UK.<sup>40</sup> The odds of cervical cancer occurrence increased with time from the last negative test, reaching 1.0 (no protection) at 3 years for women aged 20 to 39, approached 1.0 at 6 years for women aged 40 to 54, and remained approximately 0.5 at 6 years for women aged 55 to 69. The authors estimated the proportion of cancer of the cervix that could be prevented by using different schedules of rescreening, and based on their results, these proportions varied by age. For women aged 20 to 39, 30% could have been prevented by 5-year screening, 61% by triennial screening, and 76% by annual screening. The respective percentages for women aged 40 to 54 were 73%, 84%, and 88%, and for women aged 55 to 69, 83%, 87%, and 87%. The authors recommended triennial screening for women aged 25 to 49, a 5-year screening interval for women aged 50 to 64, and for women aged 65 or more, to only screen those who had not been screened since age 50. These

†Adjusted for ever having abnormal cervical cytology before the last negative Pap test, and for having at least one negative Pap test less than 36 months before last negative test.

## Ambulatory Office Practice

conclusions differed from those of the IARC Working Group on Cervical Cancer Screening, which recommended against different screening frequencies for different age groups.<sup>41</sup>

### When to Discontinue Screening

With the age-specific incidence of cervical cancer in all countries showing relatively high rates of invasive cancer in older women, there is a consensus that women over the age of 60 years who have never been screened or have not been screened for many years should be encouraged to have at least two tests over a period of a few years, and only if both are negative should they cease screening.<sup>37,39</sup>

Cecchini et al reviewed data for women aged 60 to 70 from the Florence screening program and the Tuscany Cancer Registry.<sup>53</sup> Only 5 of 242 women with invasive cervical cancer had two or more negative Pap tests between 50 and 60 years of age. However, of 11,342 women aged 58 to 60 with a negative test during 1980 to 1987 and followed to December 1990, only one invasive cancer was diagnosed, compared with the nearly 14 cases expected from age-specific incidence data from the cancer registry (OR 0.07, 95% CI 0.002–0.39). The authors recommended reconsideration of continuing screening after 60 to 64 years of age.

In North America, it is generally recommended that women actively screened and consistently negative could end screening at 70 years of age.<sup>37,38</sup> In Europe, guidelines recommend 64 as the upper age limit of the population to be actively invited for screening.<sup>54</sup>

It has been suggested that women without cytologic abnormalities who have been actively screened could end screening at even younger ages (e.g. 50 to 55).<sup>39</sup> No population-based studies to date have specifically addressed this issue.

## DIAGNOSIS

Exfoliative cytology is currently the most common means of screening for preinvasive disease. Other methods include screening colposcopy, visual inspection with acetic acid (VIA), visual inspection with Lugol's iodine (VILI), HPV DNA testing, and still largely experimental methods such as real-time imaging technology and tumor markers.

A recent revision of the Bethesda system (Table 11-8) of cervical cytologic classification includes prior terms used for high- and low-grade cervical cytology changes—low-grade squamous intraepithelial lesion (LSIL) and high-grade squamous intraepithelial lesion (HSIL). However, it subdivides the equivocal level of abnormalities—atypical squamous cells (ASC)—into two subcategories, namely, atypical squamous cells of undetermined significance (ASC-US), which lack certain expected cellular elements to more specifically categorize the test, and atypical squamous cells that cannot rule out a high-grade lesion (ASC-H), recognizing that some cytology specimens contain high-risk elements that may suggest a more serious endpoint (HSIL) and require immediate follow-up.<sup>55</sup> Management of abnormal Pap test results has been the subject of intense interest to researchers, providers, and the public. As noted earlier, a screening test result is of little value if there is no system of appropriate follow-up and management of abnormal results.

**Table 11-8**  
**The Bethesda System 2001 (Abridged)**

### Satisfactory for evaluation

A satisfactory squamous component must be present (see text)  
Note presence/absence of endocervical/transformation zone component  
Obscuring elements (inflammation, blood, drying artifact, other) may be mentioned if 50–75% of epithelial cells are obscured

### Unsatisfactory for evaluation

Specimen rejected/not processed because (specify reason). Reasons may include  

- Lack of patient identification
- Unacceptable specimen (e.g., slide broken beyond repair)

  
 Specimen processed and examined but unsatisfactory for evaluation of an epithelial abnormality because (specify reason). Reasons may include  

- Insufficient squamous component (see text)
- Obscuring elements cover more than 75% of epithelial cells

### General categorization (optional)

Negative intraepithelial lesion or malignancy  
Epithelial cell abnormality  
Other

### Interpretation/Results

#### **Negative for intraepithelial lesion or malignancy**

Organisms  
*Trichomonas vaginalis*  
 Fungal organisms morphologically consistent with *Candida* species  
 Shift in flora suggestive of bacterial vaginosis  
 Bacteria morphologically consistent with *Actinomyces* species  
 Cellular changes consistent with herpes simplex virus  
 Other non-neoplastic findings (Optional to report; list not comprehensive)  
 Reactive cellular changes associated with inflammation (includes typical repair), irradiation, intrauterine contraceptive device (IUD)  
 Glandular cells status posthysterectomy  
 Atrophy

#### **Epithelial cell abnormalities**

Squamous cell  
 Atypical squamous cells (ASC)  
 of undetermined significance (ASC-US)  
 cannot exclude HSIL (ASC-H)  
 Low-grade squamous intraepithelial lesion (LSIL)  
 encompassing: human papillomavirus (HPV)/mild dysplasia/cervical intraepithelial neoplasia (CIN) 1  
 High-grade squamous intraepithelial lesion (HSIL)  
 encompassing: moderate and severe dysplasia, carcinoma in situ; CIN 2 and CIN 3  
 Squamous cell carcinoma

Glandular cell  
 Atypical glandular cells (AGC) (specify endocervical, endometrial, or not otherwise specified)  
 Atypical glandular cells, favor neoplastic (specify endocervical or not otherwise specified)  
 Endocervical adenocarcinoma in situ (AIS)

Adenocarcinoma  
 Other (list not comprehensive)  
 Endometrial cells in a woman ≥40 years of age

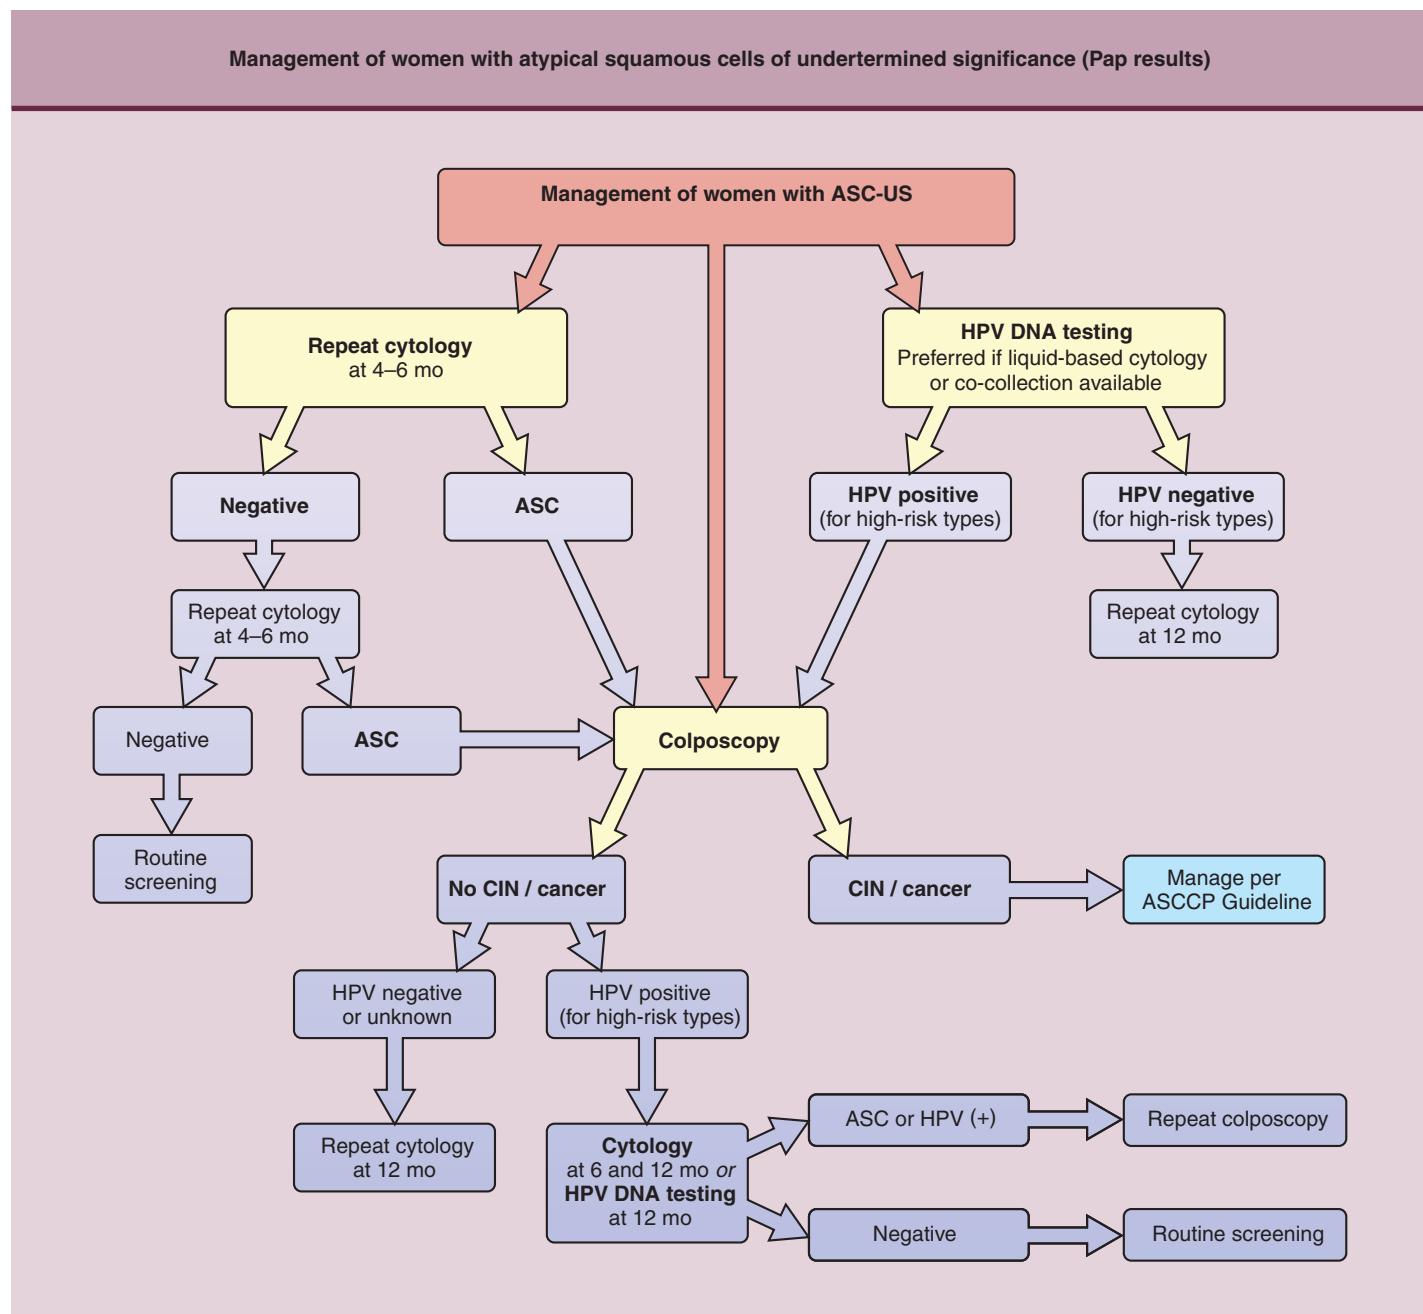

#### **Automated review and ancillary testing (include as appropriate)**

#### **Educational notes and suggestions (optional)**

In 2002, the American Society of Colposcopy and Cytopathology (ASCCP) published results of a consensus conference held in September 2001 that dealt with management and follow-up of abnormal Pap test results closely following the newly updated Bethesda system classification of cervical cytology

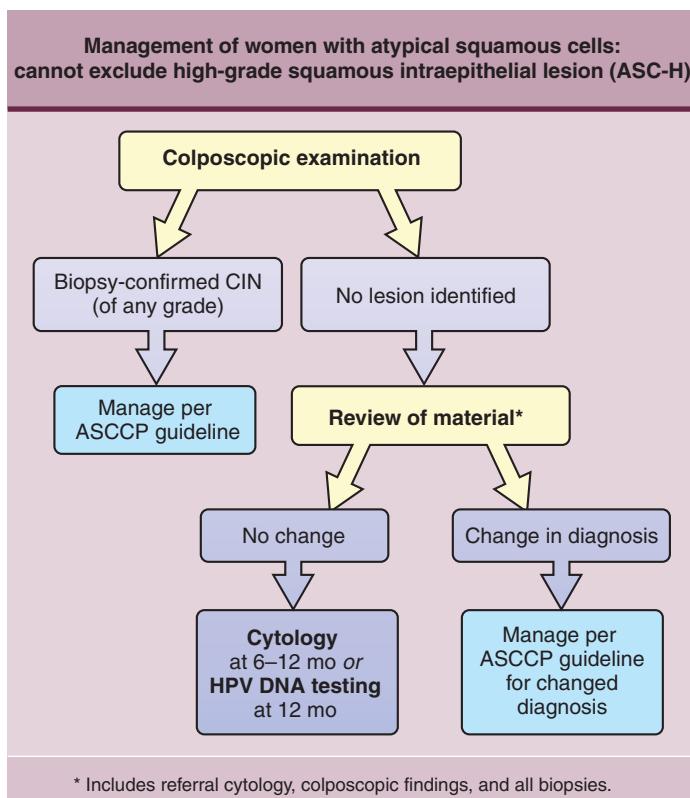

results<sup>56</sup> (Figs. 11-10 through 11-14). The process included an evidence-based review of pertinent published literature that was graded to assure that decisions could be based upon results of the most rigorous studies possible. A draft of the recommendations was then published on the ASCCP Web site ([www.asccp.org](http://www.asccp.org)), and all interested parties were invited to participate in a Web-based forum of the draft to recommend changes and additions to be most consistent with the science and clinical applications of the time. A revised draft document was developed and this document was discussed by those invited to participate in the 2001 consensus conference for final review and recommendations.

Atypical squamous cells (ASC) on Pap tests are associated with a risk of detecting high-grade CIN in 5% to 17% of cases.<sup>56</sup> The ASC-US/LSIL Triage Study (ALTS) confirmed that using HPV DNA testing was helpful in differentiating those women with ASC-US Pap test results at risk of having underlying high-grade histologic disease from those having little or no risk.<sup>7,55</sup> Women with negative tests for high-risk HPV types would be immediately excluded from further investigation, while those with positive results would be immediately referred for colposcopy and directed cervical biopsy if indicated. Alternatives to HPV testing include repeat Pap testing at 6-month intervals for up to 2 years, or immediate colposcopy. While all

three are considered to be of equal value in the follow-up process, reflex HPV testing using the Digene Hybrid Capture II test is recommended if the Pap test sample is obtained by means of a liquid-based system.<sup>56</sup>

In traditional cytology-based cervical cancer screening programs, it is usual to attempt to acquire a histologic diagnosis of the preinvasive lesion from either a colposcopically directed biopsy or an excisional procedure. In addition, some studies have shown cervicography to be as useful as colposcopy as a secondary means of assessing patients with abnormal Pap test results; however, the procedure has not gained wide acceptance for this use (Figs. 11-15 through 11-18).

If a woman has an LSIL, HSIL, or ASC-H Pap report, it is recommended that she undergo immediate colposcopy with endocervical assessment. The LSIL report is often equated with the presence of active HPV DNA in the cells demonstrated by the presence of koilocytes. As noted earlier, these vacuoles are now known to represent the presence of viral activity within the cell. In the ALTS trial, more than 70% of women with LSIL results were positive for HPV types.<sup>57</sup>

While immediate colposcopy is currently recommended for LSIL Pap results, it should be kept in mind that not all LSIL reports are due to high-risk HPV types. Any genital-tract HPV type can cause changes consistent with LSIL. Moreover, these changes may be transient, since the sample is likely being collected during an active HPV viral infection; most will clear spontaneously, leaving no persistent viral infection or residual

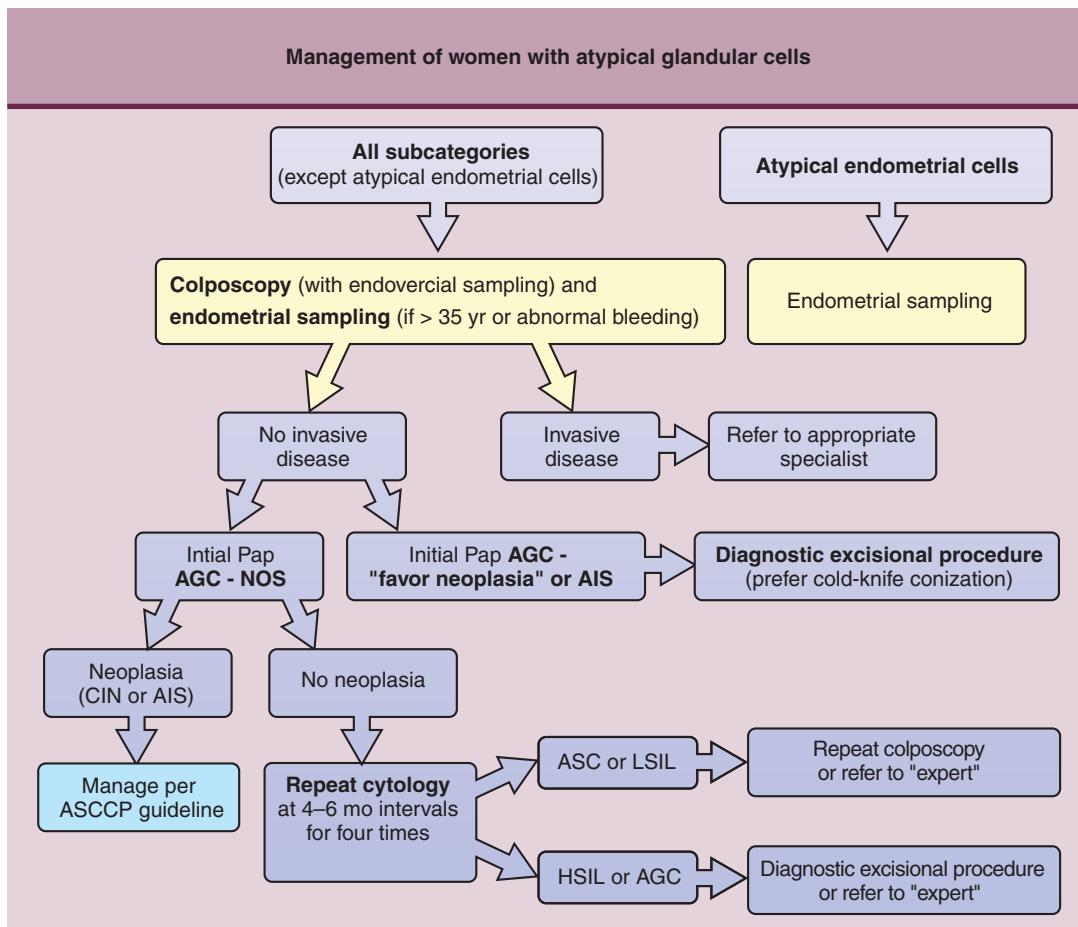

cervical cytologic changes. For reports of HSIL and ASC-H, the potential for identifying CIN II or CIN III is considerably higher than with LSIL results. Moreover, the interrater reliability for detecting HSIL and high-grade CIN is better than for detecting either ASC-US or LSIL. For ASC-H, cellular elements are absent that would otherwise allow the reviewer to report the test as HSIL, but the level of suspicion is high enough to warrant the slide being classified separately from other ASC slides. The histologic diagnosis of CIN based on colposcopically directed biopsies is similarly complicated. Not only might a large proportion of CIN lesions regress spontaneously, but analysis of data from the ALTS trial showed that 43% of biopsies originally classified as CIN I were reclassified downward in 40% of cases and upgraded to CIN II/III in 13% of cases.<sup>7</sup>

Whereas histologically confirmed CIN I lesions are associated with a low risk of progression to invasive cervical cancer, histologically confirmed CIN II lesions are associated with a risk of advancement to cancer of 20% and CIN III lesions with a risk of advancement to cancer of 30%.<sup>58–60</sup> Therefore, except in special circumstances as noted below, treatment needs to be initiated promptly for high-grade disease once histologic confirmation is available.

During pregnancy, regression of CIN II/III is reported to be minimal, however post partum; spontaneous regression is higher.<sup>61</sup> When a pregnant woman is found to have an LSIL or HSIL Pap result, immediate colposcopy is indicated; however, invasive evaluation of the endocervical canal is not. Although colposcopic examination in early pregnancy may be unsatisfactory, as the pregnancy progresses, repeat colposcopy will likely be satisfactory, since the transformation zone of the cervix may be more easily visualized. Biopsies of pregnant women should be reserved for situations in which there is high suspicion that invasive cancer is present. In certain circumstances, when there is a very high suspicion of invasive cancer, it is appropriate to consider performing a cold-knife conization of the cervix for definitive diagnosis.

Among postmenopausal women, special consideration needs to be given for most abnormal Pap test reports. If the result is ASC-US or LSIL and the woman has cytologic or clinical evidence of atrophic changes, a short course of intravaginal estrogen cream is indicated before repeating the test 1 week after completion of treatment. If the result is ASC-US or LSIL and no atrophy is present, it is satisfactory to repeat Pap tests at 6- and 12-month intervals or to perform an HPV DNA test at 12 months and refer for colposcopy if the Pap test result is ASC-US or greater or if the HPV test is positive.

For adolescents with LSIL, it is appropriate to postpone immediate colposcopy and biopsy in favor of a repeat Pap test at 6 and 12 months, using a threshold of ASC-US for colposcopy referral or performing an HPV-DNA test at 12 months and referring those adolescent women positive for high-risk HPV DNA for colposcopy. When biopsy-confirmed CIN II or III is not found in a young woman with confirmed HSIL cytology reports, observation with cytology and colposcopy at 4- to 6-month intervals is acceptable if colposcopic findings are satisfactory, endocervical sampling is negative, and the patient understands and accepts the risk of occult disease.<sup>56</sup> If progression is observed or HSIL Pap tests persist, consideration for invasive diagnostic excision (LEEP or cold-knife conization) is recommended.

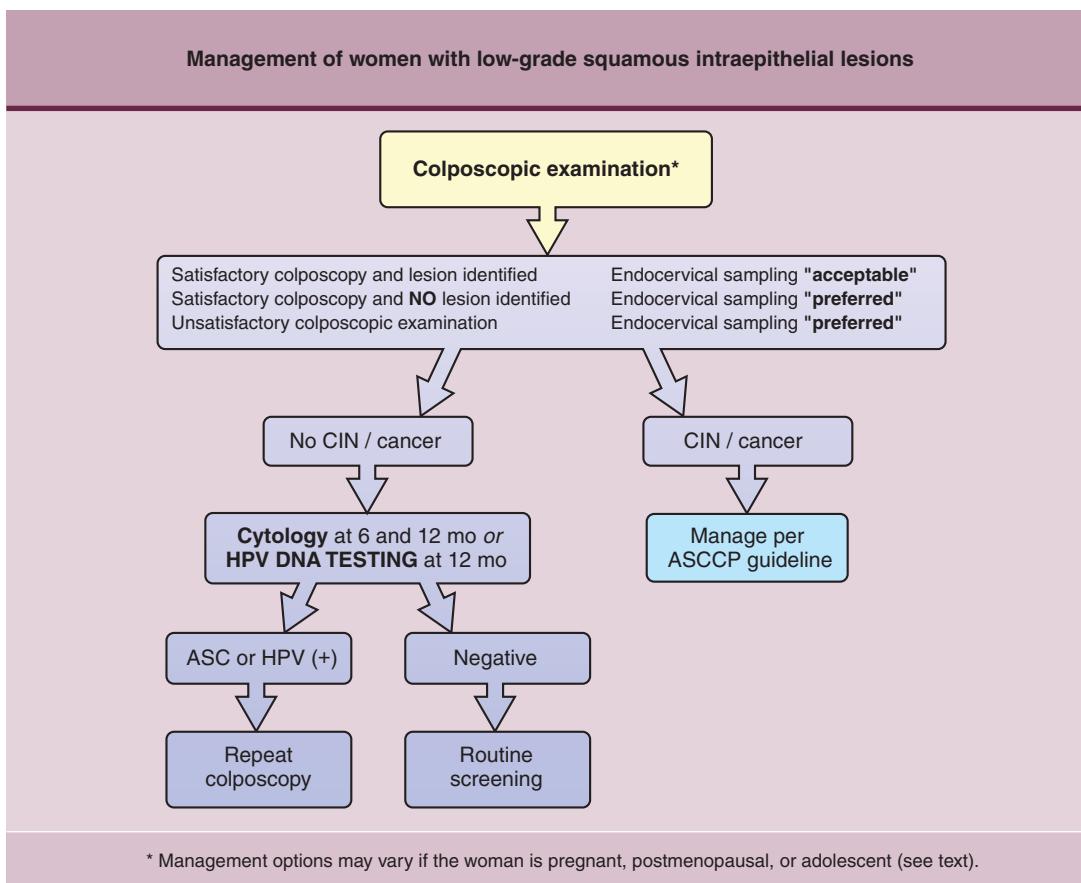

**Figure 11-12 Algorithm for management of atypical glandular cells (AGC).** (Reprinted from The Journal of Lower Genital Tract Disease Vol. 6 Issue 2, with the permission of ASCCP © American Society for Colposcopy and Cervical Pathology 2002.)

Immunosuppressed women have a higher incidence of persistent HPV infections and in turn higher incidence of all grades of abnormal Pap test results and cervical neoplasia.<sup>62</sup> Among HIV-positive women treated for histologically confirmed CIN II and III there is a high rate of recurrence and persistence of disease, with treatment failure rates approaching 25%.<sup>63</sup> For invasive cervical cancer, there is no clear picture about increased incidence among HIV-seropositive women; however, Selik and Rabkin in 1998 reported a relative risk of 5.5 for cervical cancer in HIV-positive women compared with seronegative women.<sup>64</sup> In 2000, Frisch et al, using data from the U.S. Cancer Match Registry for the period 1978 to 1996, showed an RR of 5.4 for invasive cervical cancer among HIV-positive women compared with the general U.S. population.<sup>65</sup> Careful adherence to CDC recommendations for cervical cancer screening of HIV-positive women is highly recommended.<sup>66</sup> Referral for colposcopy is recommended for all immunosuppressed women with ASC-US or abnormal Pap test results. This includes all women infected with HIV, regardless of CD4 count, HIV viral load, or antiretroviral therapy.<sup>66</sup>

The 2001 Bethesda system classified cervical glandular cell abnormalities less severe than adenocarcinoma into three categories: atypical glandular cells—either endocervical, endometrial, or “glandular cells” not otherwise specified (AGC

NOS); atypical glandular cells—either endocervical or “glandular cells” favoring neoplasia (“AGC neoplasia” category); and endocervical adenocarcinoma in situ (AIS).<sup>55</sup> The AGC category is associated with higher risk for cervical neoplasia than ASC or LSIL is. A number of studies show that 9% to 54% of women with AGC have at least biopsy-confirmed CIN.<sup>67–72</sup> These studies also suggest that there is a higher risk of high-grade lesions among women with “AGC favor neoplasia” than among women with AGC NOS. Biopsy-confirmed CIN II or III, AIS, or invasive cancer has been identified in 9% to 41% of women with AGC NOS compared with 27% to 96% of women with “AGC favor neoplasia.” The cytologic interpretation of AIS is associated with a high risk of either AIS—48% to 69%—or invasive cervical adenocarcinoma—38%.<sup>73,74</sup>

AIS is the only well-characterized preinvasive glandular lesion of the uterine cervix and is uncommon relative to squamous counterparts. The Surveillance Epidemiology and End Results (SEER) program from the U.S. National Cancer Institute during the time period 1973 to 1995 reported an estimated 121,793 cases of carcinoma in situ of the cervix.<sup>75</sup> Of these, only 1% were adenocarcinoma in situ. Although terminology has been proposed for intraepithelial glandular lesions with lesser degrees of nuclear atypia and mitotic activity than AIS, because of the rarity of biopsy-documented non-AIS preinvasive glandular

**Figure 11-13 Algorithm for management of low-grade squamous intraepithelial lesions (LSIL).** (Reprinted from The Journal of Lower Genital Tract Disease Vol. 6 Issue 2, with the permission of ASCCP © American Society for Colposcopy and Cervical Pathology 2002.)

lesions, their utility has not been established.<sup>56,76-78</sup> AIS coexists with preinvasive squamous lesions or invasive squamous cell carcinoma in nearly two-thirds of cases, and risk factors for AIS are similar to those for preinvasive squamous lesions.<sup>79,80</sup> Because no natural history studies for AIS have been published owing to its relative rarity, the evidence that AIS is the precursor lesion for invasive endocervical adenocarcinoma remains circumstantial.<sup>56</sup> Like high-grade squamous intraepithelial neoplasia, AIS is associated to a high degree with persistence of high-risk HPV types.<sup>81,82</sup>

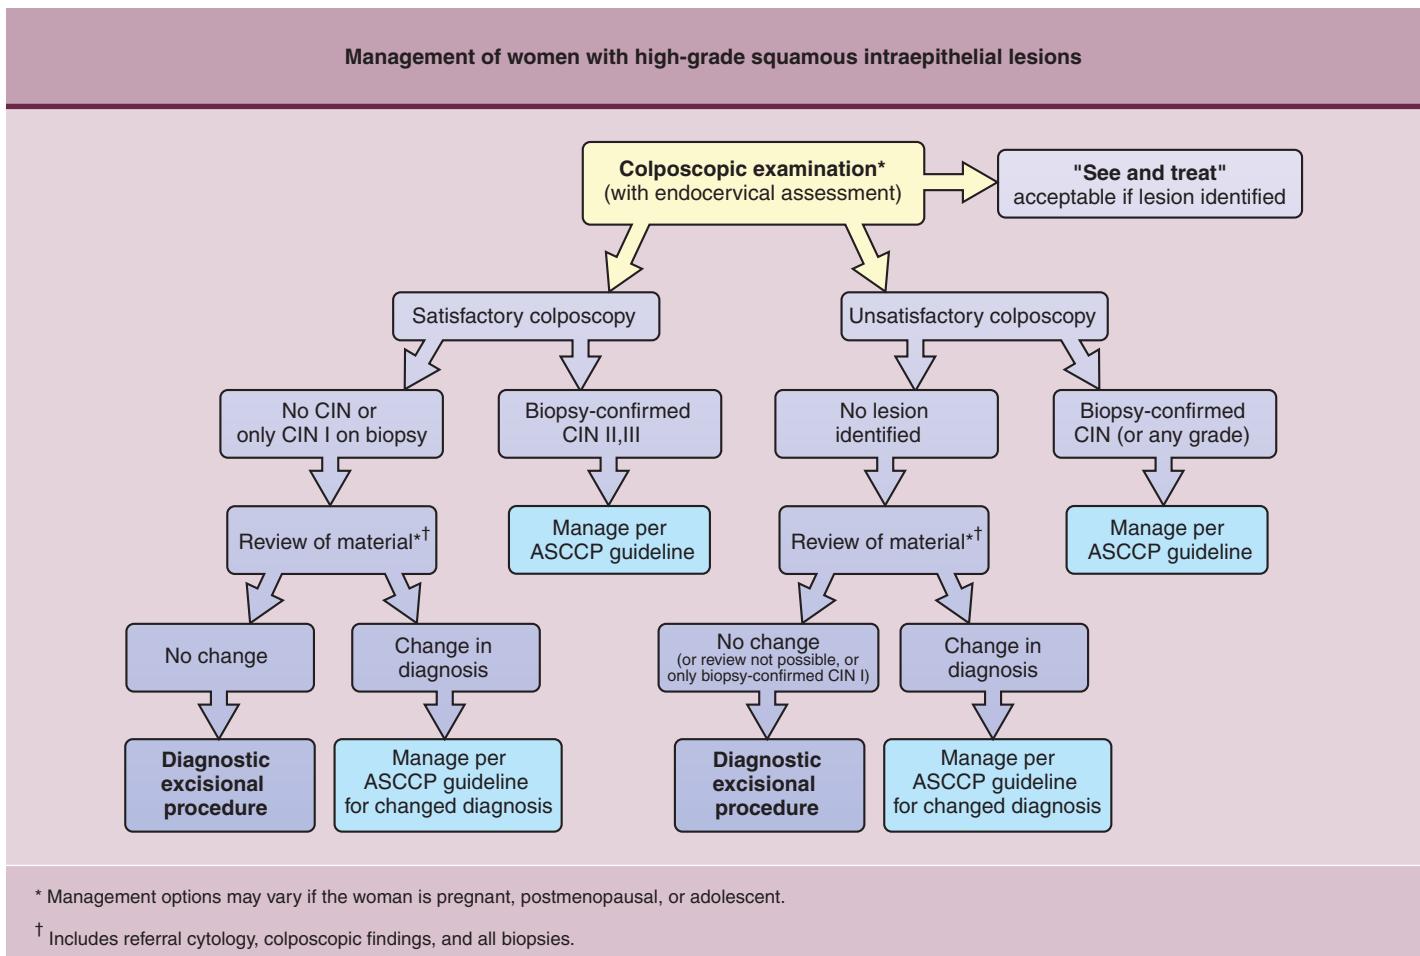

The value of traditional follow-up of AGC and AIS with repeat cytology, colposcopy, and endocervical sampling is limited. The sensitivity of all these modalities to detect either AIS or adenocarcinoma is low. Many cases of biopsy-confirmed AIS have no associated observed colposcopic abnormalities, and even combinations of cytologic testing and colposcopy can miss AIS and small endocervical adenocarcinomas localized in the endocervical canal. Nevertheless, colposcopy with endocervical sampling is recommended for women with all subcategories of AGC except those with atypical endometrial cells, who should initially be evaluated with endometrial sampling.<sup>56</sup> This should be done along with colposcopy in women older than age 35 with AGC, and among women under age 35 with AGC who have unexplained vaginal bleeding. Absence of sufficient data so far does not allow assessment of HPV DNA testing in management

of women with either AGC or AIS. Further follow-up depends on outcome of initial evaluation. If invasive disease is not identified, women with "AGC favor neoplasia" or endocervical AIS should undergo a diagnostic excision procedure. The preferred procedure is cold-knife conization. If invasive disease is not identified among women with AGC NOS, they should be followed using a program of repeat cervical cytology at 4- to 6-month intervals until four consecutive "negative for intraepithelial lesion or malignancy" results are obtained, after which they may return to routine screening. The ASCCP guidelines state that if a result of either ASC or LSIL is obtained on any of the follow-up Pap tests, acceptable options include repeat colposcopic examination or referral to a clinician experienced in the management of complex cytologic situations.<sup>56</sup>

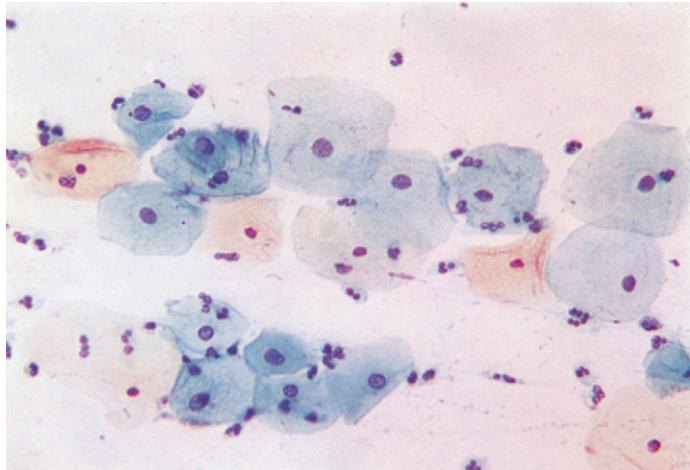

## TREATMENT

Whatever technique is employed to treat histologically confirmed preinvasive CIN, it must be effective in eradicating the lesion, as well as safe and associated with minimal patient morbidity. Two categories of treatment are available—destructive/ablative procedures and excisional procedures.

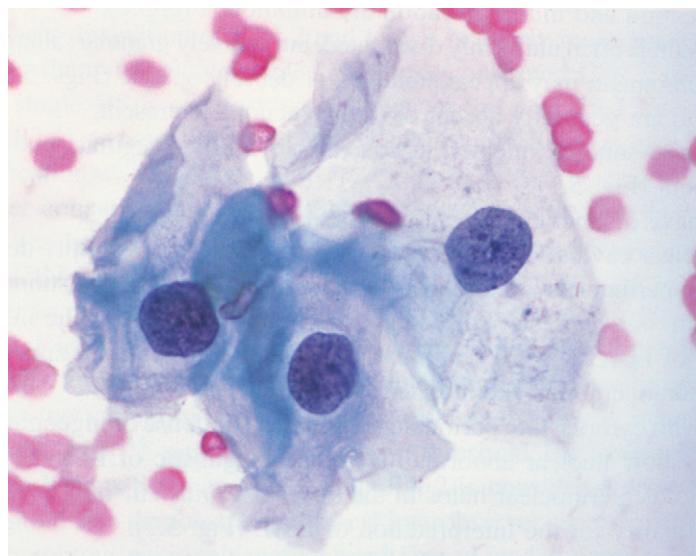

Techniques involving destruction or ablation of the abnormal transformation zone can be used only when strict criteria are available to ensure that for all practical purposes the presence of

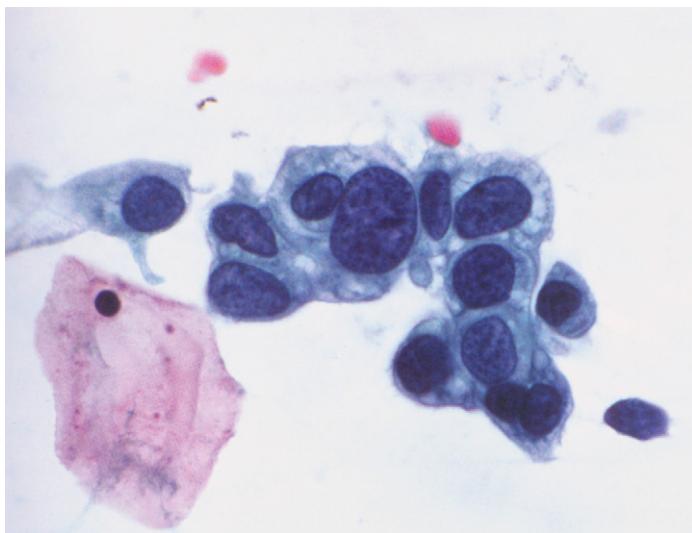

**Figure 11-14 Algorithm for management of high-grade squamous intraepithelial lesions (HSIL).** (Reprinted from The Journal of Lower Genital Tract Disease Vol. 6 Issue 2, with the permission of ASCCP © American Society for Colposcopy and Cervical Pathology 2002.)

**Figure 11-15 Superficial and intermediate squamous cells.** The mature squamous epithelium of the ectocervix in women of reproductive age is composed throughout most of its thickness by superficial and intermediate cells. (Courtesy of ES Cibas, MD.)

**Figure 11-16 “Nonkoilocytic” low-grade squamous intraepithelial lesions (LSIL).** Nuclei are significantly enlarged and show mild hyperchromasia and nuclear contour irregularity. No definite koilocytes are seen. (Courtesy of ES Cibas, MD.)

These squamous cells have scant cytoplasm and markedly hyperchromatic nuclei with highly irregular nuclear contours. (Courtesy of ES Cibas, MD.)

invasive cervical cancer has been excluded. Except where so-called “see and treat” modalities are used in developing countries, it is essential that treatment be preceded by a biopsy result that is concordant with other screening and diagnostic tests. The most common techniques are cryotherapy, CO<sub>2</sub> laser vaporization, and electrocautery. The last technique, although effective, is not used with great frequency. The level of tissue destruction is estimated to be approximately 3 to 7 mm based on information that crypt involvement by CIN extends on average to a depth of 3 mm.<sup>83</sup> All three have estimated success rates of about 90%.<sup>84</sup> Cure rates depend on size of lesion, endocervical gland involvement, and status of lesion margins.<sup>85,86</sup> Currently, cryotherapy is the most frequently used method of ablative treatment. The

**Figure 11-18 High-grade squamous intraepithelial lesions (HSIL).**

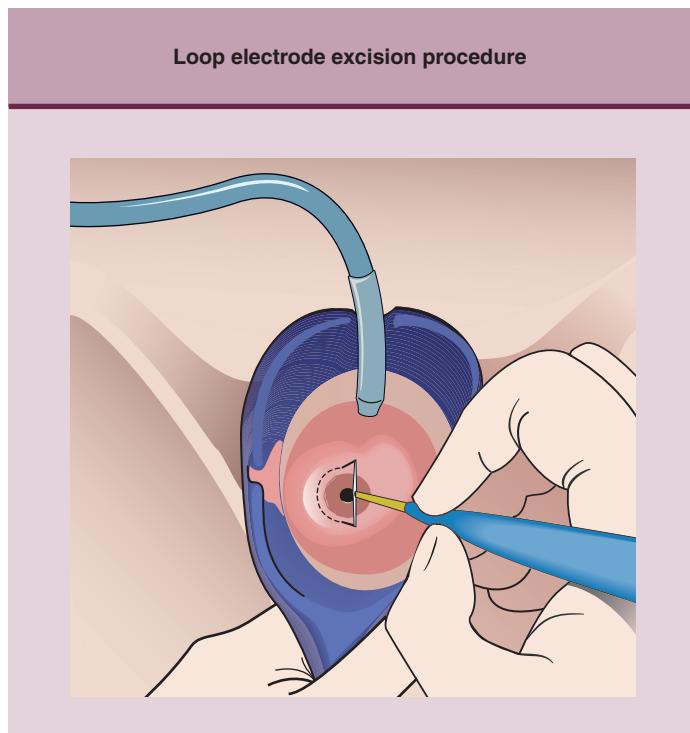

Cells with a moderate amount of cytoplasm, formerly called “moderate dysplasia” or “CIN II,” are included in the HSIL category. (Courtesy of ES Cibas, MD.)

equipment is relatively inexpensive; it requires nitrous oxide gas ( $-89^{\circ}\text{C}$ ) or carbon dioxide gas ( $-65^{\circ}\text{C}$ ), which achieve the temperatures necessary ( $-20^{\circ}\text{C}$  to  $-30^{\circ}\text{C}$ ) for effective cellular destruction and are readily available in many locations; the technique can be learned and applied with minimal instruction; it can be performed in most any ambulatory health care setting; and the discomforts and side effects are mild and complications rare. Cryotherapy instruments designed with probes specifically intended for treatment of cervical lesions facilitate the ease with which the technique can be applied. Cryotherapy destroys the surface epithelium of the cervix by crystallizing the intracellular water, resulting in eventual destruction of the cell. The most effective technique seems to be a freeze-thaw-freeze method in which an ice ball is achieved 5 mm beyond the edge of the probe. The time required for the procedure depends on the pressure of the gas; the higher the gas pressure, the more rapidly the ice ball forms.

CO<sub>2</sub> laser vaporization, on the other hand, requires considerable outlays for the equipment, electric power source, training in the form of a laser course or a preceptorship, and experience to become adept at applying the technique correctly and safely. The operator must be familiar with the physics of the procedure and thoroughly understand the safety precautions. For these reasons, in recent years, less attention has been paid to this technique as a means of cervical ablation therapy. However, laser vaporization is particularly suited for treating large lesions that the cryo-probe cannot adequately cover, for treating an irregular cervix with a “fish mouth” appearance and deep clefts, for treating disease extending to the vagina, and for treating lesions with extensive glandular involvement to reach the deepest gland clefts.

Excisional methods include the loop electrode excision procedure (LEEP), CO<sub>2</sub> laser excision, cold-knife conization, and total hysterectomy and trachelectomy (removal of the cervical stump). Traditionally, cold-knife conization of the cervix has been the gold standard for obtaining an adequate tissue specimen to assure maximal opportunity to eliminate the presence of preinvasive disease, and also for obtaining the best specimen for histologic review. Prior to the availability of colposcopy, conization was the standard method of evaluating an abnormal Pap test result. It can be either diagnostic or therapeutic. Today, the disadvantages of this procedure are that it requires hospitalization, anesthesia, and considerable training; is expensive; and is associated with a moderate amount of both short- and long-term morbidity. Nevertheless, the procedure is indicated when the limits of the lesion cannot be visualized with colposcopy or the SCJ is not seen, if endocervical curettage is histologically CIN II or III, if there is a lack of correlation between various study results, and if either microinvasion or more advanced disease cannot be ruled out.

In many western countries, LEEP is currently the most popular technique. In some centers, extended uses of the procedure have replaced cold-knife conization. The advantages of this procedure are that, although it depends on the availability of an electrosurgical unit and a source of electricity, it can be performed in an ambulatory setting with local anesthesia and requires less intensive training to master the technique and apply it effectively and safely. This electrosurgical unit produces a constant low voltage flow of energy with the ability to blend

**Figure 11-19 Loop electrode excision procedure (LEEP).** (Used with permission of Cooper Companies, Lake Forest, Ca.)

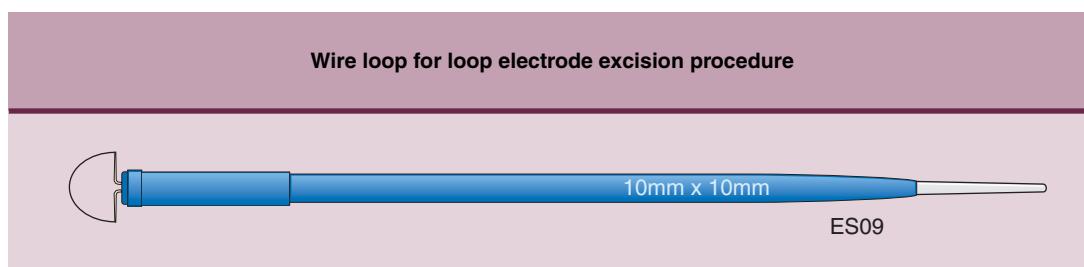

and mold both cutting and coagulation characteristics of current. It should be used primarily for management of CIN II and III lesions. It must be performed after a comprehensive colposcopic examination and is intended to remove the entire transformation zone with an adequate margin of normal squamous epithelium surrounding the abnormal area and with minimal artifactual damage to the excised specimen.<sup>87</sup> Descriptions of the technique can be found in modern textbooks of operative gynecology, but basically it is important to assess the size of the transformation zone, location of the squamocolumnar junction, size of the lesion in question, and amount of tissue necessary to excise. The tissue effect of electricity depends on the concentration of electrons, the power, and the water content of the tissue. Low power settings may cause extensive thermal damage to the tissue. Higher power settings when a small wire loop is used will result in an electrosurgical effect with little thermal damage. The actual cutting is the result of a steam envelope developing at the interface between the wire

loop and the water-laden tissue. This envelope is then pushed through the tissue, separating it from surrounding structures.

To obtain a specimen with clear margins, an appropriate-sized wire loop should be selected and the depth gauge set to achieve the best specimen possible. It is important to use a grounding pad on the patient's thigh and nonconductive instruments in the vagina, to have a vacuum source to exhaust any smoke created from the procedure, and to use local anesthesia with epinephrine. Performing colposcopy prior to the procedure may help delineate the lesion and determine endocervical involvement. The electrosurgical generator should use a blend of cutting and coagulation current and should be set to 35 to 55 watts. Using a continuous motion, beginning either on the posterior lip or the lateral aspect of the cervix, allowing for a margin of normal tissue, the operator moves the loop electrode perpendicularly to the limit of the depth guide and then either upward or transversely to a point on either the anterior lip or the opposite side of the cervix, allowing for a margin of normal tissue, and then draws the loop out of the cervix toward herself or himself (Figs. 11-19 and 11-20). Although removing the specimen in one piece is encouraged, it is satisfactory to remove the specimen in two parts depending on its size. After the specimen is removed, the base should be coagulated using a ball electrode at 50 watts of power. Application of Monsel's solution for additional chemical coagulation is optional.

A meta-analysis of 28 trials of various treatments for CIN showed that while there was no considerable difference overall between ablative and excisional techniques, LEEP behaved as an ideal method for treating CIN because it produced the least morbidity and the most favorable surgical specimen for histologic assessment.<sup>84</sup>

The effectiveness of LEEP was analyzed by Flannelly et al in studies in 1997 and 2001.<sup>88,89</sup> Women less than 50 years of age with clear margins in excised specimens had a 92% chance of normal Pap tests on subsequent examinations, while those without clear margins had an 86% chance of normal Pap tests. Among women over 50 years of age who had margin involvement, only 57% had normal Pap tests on follow-up examination. Although the latter group comprised only a small proportion of those treated, this group appears to be at higher risk of recurrence and possibly should be more intensely followed by cytology and colposcopy than the younger age cohort. Other studies confirm the low failure rate of LEEP. The finding overall of CIN in specimen margins did not translate to a high risk of recurrence at 1 year posttreatment.<sup>88</sup> Moreover, the finding of microinvasive carcinoma in the excised specimen did not seem

**Figure 11-20 Example of wire used in loop electrode excision procedure (LEEP).** (Used with permission of Cooper Companies, Lake Forest, Ca.)

## Ambulatory Office Practice

to increase the efficacy of an excisional technique over that of a destructive procedure.<sup>88</sup>

Laser excisional conization can be used similarly to LEEP or cold-knife conization with equivalent therapeutic effectiveness. Local anesthetic with epinephrine should be injected directly into the cervical stroma to assist with hemostasis during and after the procedure. The laser beam is adjusted to a watt size of 0.2 to 0.5 mm in diameter and set at 20 to 30 watts to outline the peripheral margins of the area to be removed. The incision is deepened circumferentially by passing the laser beam across tissue, and traction instruments are used on the cone specimen to facilitate visualization of the underlying stroma as the procedure extends deep enough to remove all abnormal tissue. Once appropriate depth is reached, the tissue at the endocervical margin can be sharply removed with laser, scissors, or scalpel. Deep or large cone defects are at greater risk of bleeding and postoperative discharge, but only rarely is additional hemostatic medication necessary.<sup>90</sup>

Hysterectomy and trachelectomy are not currently considered as primary treatment for CIN. The risk of significant morbidity with these procedures is higher than with the other described modalities of treatment. Nevertheless, there are some indications for which hysterectomy is a valid treatment option for CIN: (1) conization specimen margins positive for CIN, especially in women who have completed childbearing or who are expected to adhere poorly to follow-up recommendations; (2) presence of coexisting gynecologic conditions requiring hysterectomy; and (3) request by patient with CIN III or carcinoma in situ who cannot be persuaded otherwise based on informed decision making (cancer phobia).

## CLINICAL COURSE AND PROGRESSION

Inherent in the above discussions about the natural history of HPV infection and cervical neoplasia is that HPV infections and low-grade cervical neoplasia regress to a high degree without intervention, and although there is no actual treatment for HPV infections, the various methods of treating CIN result in cures in approximately 90% of cases. The most important issues are to screen women for cervical cancer, to follow up abnormal results adequately and in a timely manner, to apply therapy appropriately, and to insure long-term follow-up. Along with appropriate follow-up is the need for culturally appropriate patient education and reassurance to enhance adherence to a program of continued surveillance if necessary. Overall, an estimated 93% of cervical cancers can be prevented by screening and appropriate management of abnormal results. The most difficult task may be encouraging, recruiting, and inviting those women who for a variety of reasons do not come in for screening.

For cryotherapy, grade of lesion is of great importance to recurrence of disease; CIN III has the greatest chance of failure. Size of lesion is most important. Large lesions are associated with recurrence or progression rates of 42%, whereas there is only a 7% rate of recurrence when lesions are 1 cm or less.<sup>91</sup> Moreover, finding a positive endocervical curettage specimen can ultimately reduce the usefulness of this technique at the time of colposcopy as it is associated with recurrence or progression rates of 27% versus 9% among women without positive endocervical curettage.<sup>83</sup>

Laser therapy has highly varied results. In properly selected patients, cure rates of 95% or higher can be achieved. Probably the most important lesson learned over time is that treating the entire transformation zone rather than just localized lesions is necessary to effect appropriate levels of cure.<sup>92,93</sup>

LEEP is effective in reducing the proportion of recurrences if performed correctly. In a review of several studies including almost 2500 women, only 97, or 4%, of lesions recurred following treatment.<sup>94</sup> For cold-knife conization of the cervix, recurrence of disease is most closely associated with having positive margins or gland involvement.<sup>86</sup>

## PITFALLS AND CONTROVERSIES

Most controversy in cervical cancer screening currently relates to new technologies and the frequency with which women are screened in largely opportunistic clinical settings. Information is available on a variety of technologies such as aided visualization (VIA, VILI), cervicography, computer-assisted screening devices, optical probe devices, self-collected vaginal samples for HPV DNA testing, and spectroscopy/electronic detection devices but not enough to provide satisfactory evidence of their efficacy and effectiveness in clinical practice settings.

Much current interest on new technologies focuses on how liquid-based testing and HPV-DNA testing enhance the accuracy of cervical cancer screening. For evaluating and comparing the utility of the technologies, several points need to be emphasized.<sup>37</sup> For the most part, data on sensitivity of testing are derived from research settings with optimized testing conditions. The same results may not be achievable in actual practice. Certain research designs by their nature may over- or underestimate test sensitivity. Test sensitivity must be distinguished from program sensitivity. Test sensitivity is the probability that a single test performed at a specified time will detect the presence of underlying disease. Program sensitivity is the probability that tests repeated at specified intervals will detect underlying disease over a period of time. Repeat screening at regular intervals therefore compensates somewhat for limitations in the sensitivity of a technique. For any test, sensitivity for detection of disease can be improved by lowering the test threshold for a "positive" result but only with concomitant loss in specificity, resulting in more false-positive results. When screening a population for a disease of very low prevalence, even a small percentage change in specificity affects a large number of women because the vast majority of women screened do not have disease. For example, if disease prevalence is 10% and test specificity 95%, then a 5% decrement of specificity for 50 million screening tests represents an increase of approximately 2.5 million women (from 2.2 million to 4.5 million) who will receive a "false-positive" result and may in turn have unnecessary diagnostic tests performed with potentially harmful effects.<sup>37</sup> With regard to liquid-based testing, the reader is directed to the literature on the subject most of which has come from studies supported by industry. Taken as a whole, the available evidence supports the conclusion that LBP is an acceptable option for cervical cancer screening, that LBP is somewhat more sensitive but less specific for high-grade lesions, and that it may increase the number of ASC-US referrals and possibly the proportion of samples lacking an endocervical component. Any

decision for its use should be based on looking at all the evidence as well as the additional costs involved and determining whether the end result is in the interest of all patients served. A similar decision should be made about HPV-DNA testing for all currently recommended uses.

Since the mid-1990s there has been interest in the use of HPV DNA testing as a cervical cancer screening tool based on the premise that standardized molecular testing of exfoliated cervical cells for the causative agent of cervical cancer could demonstrate acceptable diagnostic performance while being more reproducible and more easily adapted for clinical practice than conventional cytology. Several studies have assessed the relative utility of both a cytology test and HPV DNA testing compared with the cytology test alone as a primary cervical cancer screening tool. Most of these studies indicate that women with a concurrent normal cytology test and a negative HPV-DNA result have little risk of a high-grade lesion being found on colposcopy relative to those for whom the only screening information is a normal conventional cytology result. On the other hand, a positive high-risk HPV result is not an absolute indicator that high-grade lesions exist or will develop; the prognostic value of a positive test result, especially in the absence of a cytologic abnormality, has not been fully evaluated in prospective studies. While definitive evidence of efficacy is still needed from long-term follow-up studies with CIN II/III as an outcome and from randomized controlled trials, evidence supports consideration of the use of HPV DNA testing (high-risk HPV types only) as an adjunct to cervical cytology with a screening interval no more frequent than every 3 years if both tests are negative. More frequent screening would not significantly improve sensitivity but would likely result in over-evaluation and possible overtreatment of many women with transient HPV infections.<sup>95</sup>

Pervailing management paradigms, medicolegal issues, economic factors, and societal expectations all are factors in determining the balance between sensitivity and specificity for screening programs. Risk perception, understanding, and acceptability vary among individual patients, care providers, and policy makers.<sup>96–99</sup> In recent years, the public has been bombarded with direct-to-consumer advertising for all categories of goods and services including many drugs, medical treatment modalities, and screening tests. Vast improvement in public health education is necessary to enable individuals to understand these complex issues well enough to make informed decisions about the effectiveness of new technologies and the impact they might have on their individual needs and health status.

Lengthening the cervical cancer screening interval remains a controversial issue in the United States. While the evidence supports the conclusion that conventional cytology can be safely performed at 2- to 3-year intervals, many women and providers in the United States may be more comfortable with annual screening. A key factor is the limited sensitivity of the conventional Pap test. A significant proportion of false-negative conventional cytology results are due to inadequate sampling; improvement in the ability to obtain an adequate sample would increase the sensitivity and effectiveness of cytology, either conventional or liquid-based. Some improved sensitivity and cost-effectiveness of screening may be realized by utilizing new technologies but at longer intervals. If the new technologies are

used as frequently as annually, they would greatly increase the number of women referred for colposcopy unnecessarily, increasing health care costs and potential harms to patients, with little or no benefit. The greatest gain in reducing cervical cancer incidence and mortality would be achieved by increasing screening rates among women who have not been screened or who have not been screened regularly. Missed opportunities for screening abound, particularly among unscreened older women, foreign-born women, women of low income or low education, and women who are uninsured or underinsured. Clinicians, hospitals, health plans, and public health officials should seek to identify and screen these women and to ensure continued screening at regular intervals.

## KEY POINTS

- Human papillomavirus (HPV) infection in young women is generally transient, and the majority of women with HPV infection will not develop squamous intraepithelial lesions (SIL).
- Risk factors for development of SIL and progression of low-grade squamous intraepithelial lesions (LSIL) to high-grade squamous intraepithelial lesions (HSIL) are persistence of HPV infection and presence of high-risk oncogenic subtypes.
- Additional risk factors for progression to high-grade squamous intraepithelial lesions (HSIL) are cigarette smoking, multiple pregnancies, multiple sexual partners, long-term contraceptive use, and immunosuppression.
- The role of colposcopy is to locate and describe cervical abnormalities detected by cytologic screening in order to rule out invasive disease.
- Consistent and frequent use of colposcopic assessment systems such as Reid colposcopic index (RCI) and Rubin and Barbo during colposcopy assist in characterizing and identifying the most abnormal lesions for focused sampling and confirmation of the most severe disease.
- For colposcopy to be satisfactory or adequate, the entire lesion, squamocolumnar junction (SCJ), and transformation zone (TZ) must be visualized.
- Important colposcopic features to assess are color, margin, surface contour, vessels, and iodine coloration of the lesion.
- The role of colposcopy in pregnancy is to rule out invasive disease.
- Cervical sampling is generally not needed in pregnancy unless concern for microinvasive disease is present.
- Indications for conization are an unsatisfactory colposcopy, microinvasive disease, positive endocervical curettage, discrepancy between Pap test and biopsy, and adenocarcinoma in situ.
- Colposcopic findings of concern for microinvasive disease are atypical vessels, spontaneous areas of bleeding (lakes and pools), and ulcerations.
- A short course of intravaginal estrogen can assist with the atrophic cervix and vagina in evaluation of the postmenopausal patient.
- In the diethylstilbestrol (DES) patient, complete evaluation of the lower genital tract, particularly palpation of the upper vagina, is necessary to ensure no evidence of cancer.

Since the early 1900s colposcopy has been the clinician's instrument for identifying cellular abnormalities detected by the Papanicolaou (Pap) test or for evaluating gross lesions suspicious

for cancer. The main purpose of colposcopy is to identify the most abnormal lesions within the lower genital tract for directed sampling and confirmation of grade of disease. Of the approximately 50 million Pap tests performed each year in the United States, 10% will show some cytologic abnormality and 5% will reveal a LSIL or higher.<sup>1</sup> These cellular abnormalities will require evaluation with colposcopy, and the ability to accurately detect disease will depend on the experience and expertise of the colposcopist.

## ACCURACY OF COLPOSCOPY

Several studies have evaluated the efficacy and accuracy of colposcopy as a tool for identification of dysplasia and invasive disease of the cervix. Clearly, the ability to accurately grade the level of disease in the lower genital tract is dependent on the experience of the examiner, and there is variation in sensitivity and specificity among studies. However, in a meta-analysis by Mitchell et al<sup>2</sup> of over 80 articles, the sensitivity of diagnostic colposcopy ranged between 87% and 99% with a positive predictive value of 53% to 96%. Its specificity was variable at 23% to 87%. In general, colposcopy is a predictive tool for the determination of disease, and even in pregnancy, when most biopsies are not performed until after delivery, the colposcopic impression is typically within one grade of level of disease as compared with pathologic results from biopsy specimens taken after delivery.

## INDICATIONS FOR COLPOSCOPY

The Pap smear is the primary screening test for referral of patients to colposcopy. Abnormalities detected by the cytopathologist suggesting premalignant or malignant changes on the cervix or lower genital tract are based on certain morphologic cellular characteristics distinguishing LSIL from HSIL.

There are several indications for referral to colposcopy:

1. Cellular abnormalities suggesting LSIL on a Pap test
2. Cellular abnormalities suggesting HSIL on a Pap test
3. Cellular abnormalities suggesting atypical squamous cells of high-grade disease (ASC-H) on a Pap test
4. Cellular abnormalities suggesting atypical squamous cells of undetermined significance (ASC-US) on two consecutive occasions within a 1-year time period
5. Atypical squamous cells of undetermined significance (ASC-US) with concurrent high-risk HPV
6. Glandular abnormalities such as atypical glandular cells (AGCs) or adenocarcinoma in situ (AIS)

**Figure 12-1** Several areas representative of leukoplakia with elevated white plaques present prior to application of 3% to 5% acetic acid.

This finding may be secondary to intraepithelial neoplasia, cancer, trauma, or infection.

7. Any Pap test or suspicious cervical lesion seen on pelvic examination suggestive of invasive cancer
8. Repetitive unsatisfactory Pap tests
9. Persistent clinical impression of cervicitis and bloody vaginal discharge with no evidence of cervical infection (negative cervical cultures)
10. Evidence of HPV infection (condyloma) in other areas of the lower genital tract such as the vagina and vulva
11. History of DES exposure with no prior evaluation

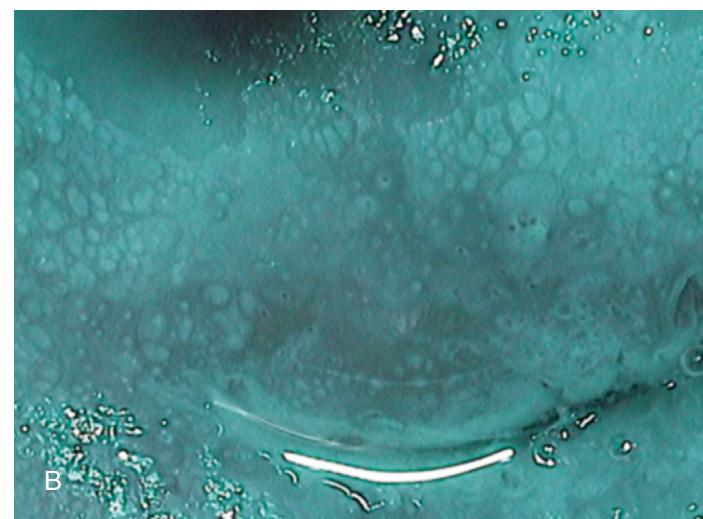

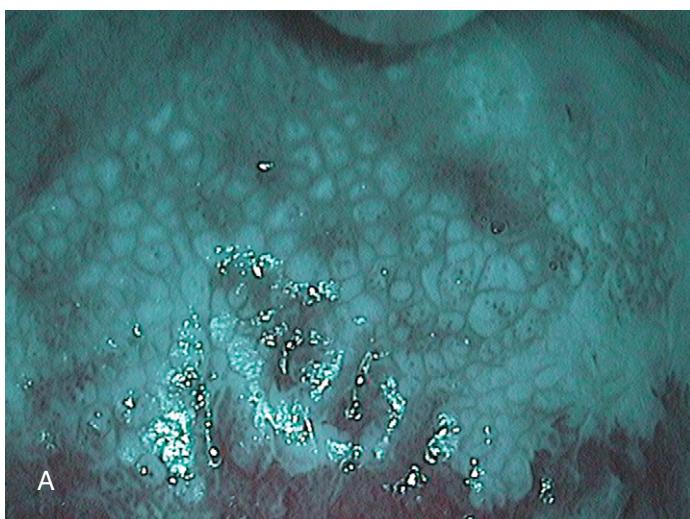

These indications justify a thorough colposcopic assessment of the lower genital tract, with particular focus on the cervix. Components of the colposcopic evaluation allow for proper

management and treatment in the follow-up period. The colposcopic report should include the indication for colposcopy, whether the examination was satisfactory or adequate, description of all lesions seen, and impression of level of disease.

## COLPOSCOPIC PROCEDURE

During the colposcopic examination, the patient is placed in a modified lithotomy position and the external genitalia are completely evaluated for any physical evidence of HPV infection (condyloma) or abnormally pigmented (e.g., hyperpigmented areas) areas requiring biopsy. The vaginal speculum is placed into the vagina until the cervix is located and in complete view of the colposcopist. The vagina and cervix are inspected for suspicious lesions or leukoplakia (white patches suggestive of keratinization due to dysplasia, cancer, or trauma; Fig. 12-1). The colposcope is a microscope using illuminated magnification to allow for visualization of lesions with 6- to 40-fold magnification. The Pap test may be repeated if indicated and normal saline applied to allow for visualization of the subepithelial capillary network. Typically a green filter is used to accentuate vessels by deepening the red color to identify any abnormal vascular patterns (Figs. 12-2A and 12-2B).

Next, 3% to 5% acetic acid is applied to the cervix and vagina to assist with visualization of dysplastic lesions. When acetic acid is applied to the epithelium of the cervix, it rapidly penetrates the tissue, creating a hyperosmotic environment that causes transient contraction of the cytoplasmic volume, thus increasing the nuclear cytoplasmic ratio in cervical cells. An additional effect is interaction of acetic acid with the nucleoproteins, causing precipitation of these nucleoproteins. Dysplastic cells have a higher nuclear density and contain more nucleoprotein compared with normal cells. The elevated nucleoprotein level obscures the underlying vessels, and when light is reflected from the colposcope, the epithelium appears white, thus, acetowhite epithelium (Fig. 12-3). In normal squamous

**Figure 12-2** A and B, The green filter accentuates coarse mosaic tiles bordered by vessels within the field of acetowhite epithelium.

**Figure 12-3** After application of 3% to 5% acetic acid to the cervical epithelium, a dense white color change occurs in areas suspicious for intraepithelial neoplasia.

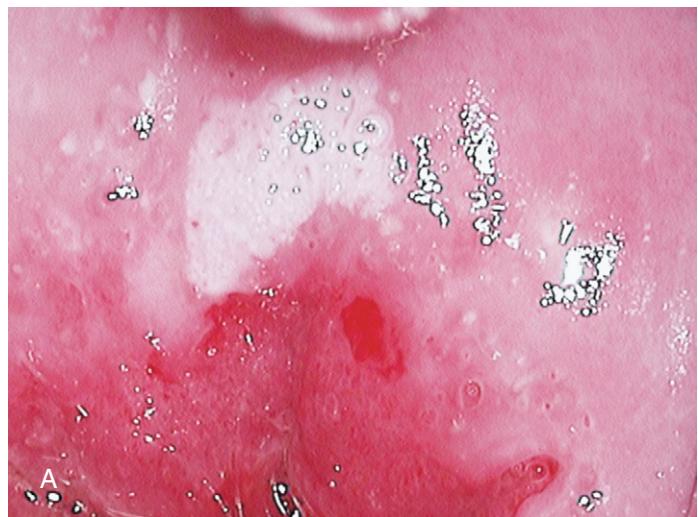

epithelial cells acetic acid produces little precipitation, and the pink color from the underlying stroma with its network of subepithelial vessels is predominantly seen. Therefore, in low-grade lesions the onset of white is delayed and transient, since the nuclear to cytoplasmic ratio (N/C) is not so pronounced as in high-grade disease in which the acetowhite effect occurs rapidly (Figs. 12-4A and 12-4B). Acetowhiting of the epithelium can occur in other instances in which the N/C ratio is increased such as metaplasia, healing regenerating epithelium, and presence of viruses. The effect is reversible and typically lasts for 50 to 60 seconds.

Another diagnostic tool is Lugol's solution or Schiller's test. Lugol's solution is  $\frac{1}{4}$  iodine to  $\frac{3}{4}$  water, and it stains normal squamous epithelium brown secondary to the large amount of glycogen in the cytoplasm of normal cells. In abnormal epithelium, application of Lugol's will demonstrate various levels of staining based on the amount of glycogen and the severity of disease (Figs. 12-5A and 12-5B).

#### Satisfactory or Adequate Colposcopy

The term satisfactory or adequate colposcopy indicates to the clinician that the area most at risk for disease—the present SCJ or TZ—and the margin of any visible abnormal lesion were completely visualized by the colposcopist. The SCJ is the junction of the squamous epithelium and columnar (glandular) epithelium usually located near the external cervical os (opening of the cervix; Fig. 12-6). Visualization of the SCJ may require use of an endocervical speculum to evaluate the endocervical canal for the presence of neoplasia. The transformation zone is the area undergoing active metaplastic change and the likely region for abnormal colposcopic findings. It lies between the original SCJ and the “new” or present SCJ.

If the examination is determined to be unsatisfactory for either reason, a diagnostic excisional procedure (conization) of the cervix may have to be performed to ensure that the transformation zone, endocervical canal, and any associated lesion within those areas have been investigated (Figs. 12-7A and 12-7B).

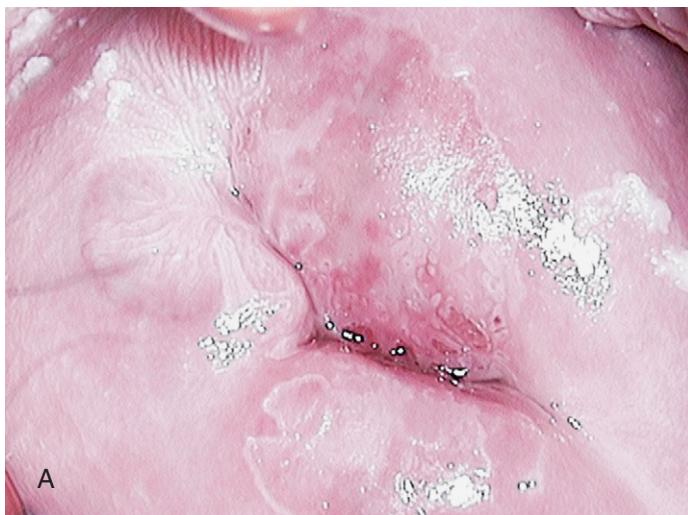

**Figure 12-4** Acetowhite cervical lesions. *A*, Transient appearance of an acetowhite lesion characteristic of a low-grade lesion on the anterior lip of the cervix at 12 o'clock. *B*, Dense acetowhite lesion with internal borders entering the os consistent with a high-grade squamous intraepithelial lesion. The squamocolumnar junction cannot be completely visualized; therefore, this is an unsatisfactory colposcopy. Biopsy of the lesion revealed a CIN II lesion.

**Conization** is an excisional technique to remove a cone-shaped or cylinder-shaped piece of cervix to obtain a specimen from the transformation zone and endocervical canal for histologic evaluation. Types include laser conization, cold-knife conization, and loop electrosurgical conization.

Other indications for conization are

- Microinvasive disease
- Positive endocervical curettage
- Discrepancy of two grades between the Pap test and biopsy (e.g., a discrepancy of two grades would be an HSIL Pap test, with no evidence of disease found on the cervical and endocervical biopsies)
- Adenocarcinoma in situ

**Figure 12-5 Acetowhite lesion with varying grades of dysplasia ranging from CIN I to CIN II.** A, An area of fine mosaic tile at 1 o'clock near opening of the os. B, Same lesion after application of Lugol's solution demonstrating the borders and extent of the lesion.

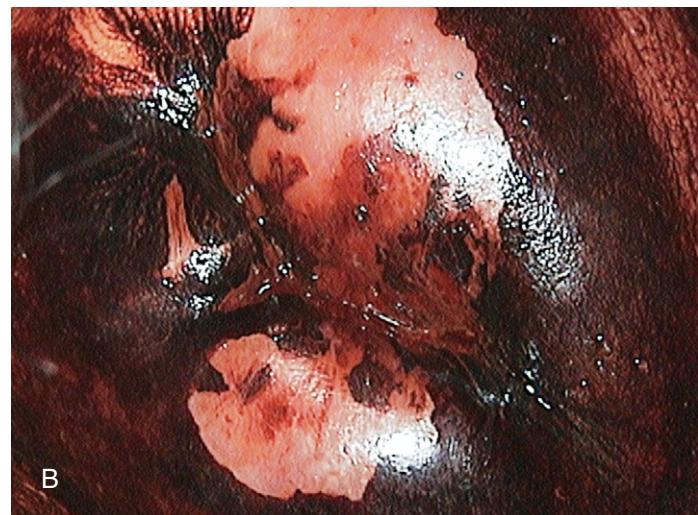

**Figure 12-6 The current, or new, squamocolumnar junction is where the squamous and columnar cells meet on the surface of the cervix at the time of colposcopy.** The entire SCJ is seen, with a small area of CIN I at 12 o'clock.

In the case of microinvasive disease or adenocarcinoma in situ, cold-knife conization is the preferred procedure to preserve tissue for optimal histologic review.

#### Colposcopy of the Normal Transformation Zone

The normal transformation zone is bordered by the original squamous epithelium and columnar epithelium. The original squamous epithelium has a smooth surface with lacy or branching vessels giving a pink color to its surface. It retains its pink color after application of acetic acid and acquires a brown color after iodine application secondary to the abundant glycogen content. The columnar epithelium is made up of a single layer of mucus-secreting tall columnar cells that line the endocervical canal and appear grapelike under colposcopic visualization. The

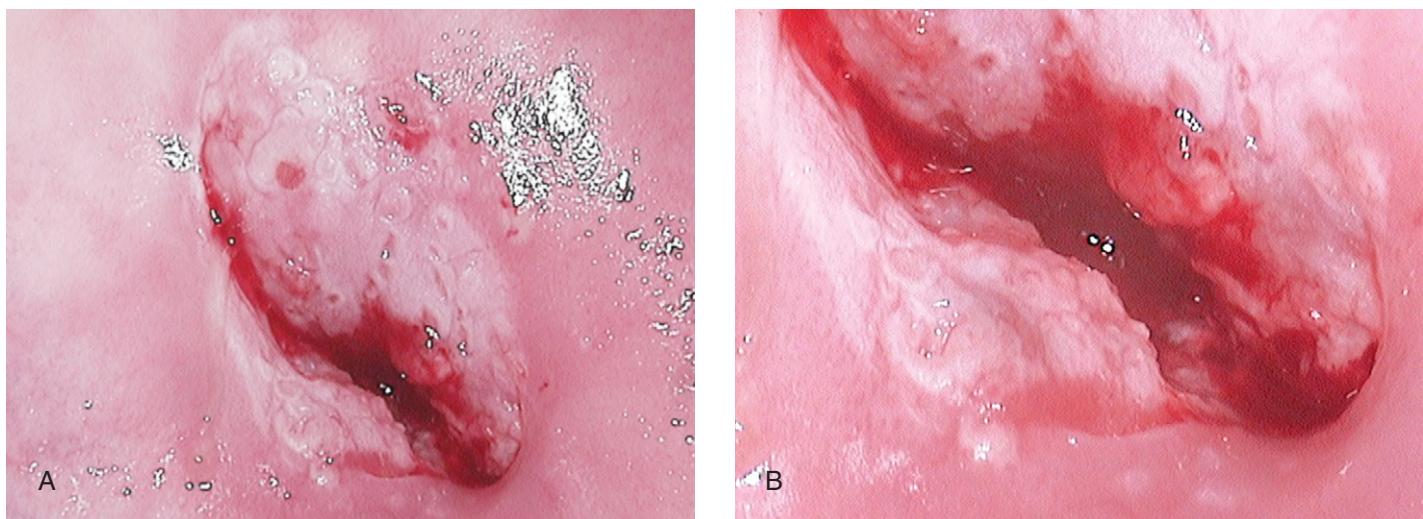

original SCJ is the border between the SCJ present at birth and the current transformation zone. The new SCJ demarcates the border between the squamous epithelium and the endocervical columnar cells at the time of colposcopy.

Within the new and original SCJ lies mature squamous metaplasia, the region on the cervix that was previously covered with columnar epithelium that has undergone metaplastic transformation secondary to hormonal influences and acidity of the vagina. It is characterized by the presence of nabothian cysts, gland openings, and branching vessels. It is similar in appearance to the original squamous epithelium and at times cannot be differentiated from it. Immature squamous metaplasia can be confused with abnormal epithelium by its reaction to acetic acid with acetowhiteness similar to CIN. Cells of immature squamous metaplasia lack glycogen and so can exhibit less staining with Lugol's solution similarly to low-grade CIN.

#### Colposcopy of the Abnormal Transformation Zone

The colposcopist uses physical characteristics of lesions revealed during colposcopy to differentiate low-grade lesions from high-grade lesions at risk for progression to malignancy. The epithelial and vascular changes present prior to or after acetic acid and Lugol's solution may be used with various colposcopic grading systems to objectively identify the grade of disease and the lesions most appropriate for biopsy. Examples of such abnormal colposcopic findings are leukoplakia, acetowhite epithelium, internal borders, punctuation, mosaic, atypical vessels, and ulceration.

*Leukoplakia* is the presence of areas of reflecting white epithelium prior to acetic acid application. The increased keratinization causing leukoplakia may be secondary to SIL, cancer, or trauma. Samples for biopsy are taken from areas of leukoplakia in addition to other abnormal lesions found during the colposcopic procedure to rule out disease. As previously mentioned, acetowhite epithelium may reveal SIL depending on its characteristics such as its color, margins, and surface contour. Another feature is the *internal border*, the presence of an internal line of demarcation separating a high-grade acetowhite lesion

**Figure 12-7 A and B, High-grade squamous intraepithelial lesion with dense acetowhite epithelium and coarse mosaic pattern extending into the canal.** Biopsy confirmed CIN III disease. The full extent of the lesion and the SCJ were not visualized; therefore, the examination is unsatisfactory.

from a low-grade lesion. In general when an internal border or margin is seen, the HSIL is centrally located closer to the SCJ. *Punctations* are vessels seen infiltrating the epithelium perpendicular to the basement membrane and when coarse in appearance are generally indicative of a high-grade lesion. If bridges are created between the vessels infiltrating the epithelium, a *mosaic* pattern is expressed with vessels running horizontal to the basement membrane. The coarse appearance of these vascular patterns and the increased intercapillary distance between the vessels further support the presence of a high-grade lesion. Finally, signs suspicious for microinvasive disease are atypical vessels and ulcerations or lakes and pools of blood. *Atypical vessels* appear as isolated, nonbranching vessels, irregular with loss of pattern. Various descriptions for atypical vessels are cork-screw and spaghetti loops. Associated with atypical vessels may be areas of spontaneous pooling of blood and ulceration. These features are highly suggestive of cancer.

## COLPOSCOPIC ASSESSMENT SYSTEMS

Several classification systems of colposcopy have been created to assist clinicians in objectively grading changes seen in the abnormal transformation zone. Two commonly used systems are the Reid colposcopic index (RCI), and the Rubin and Barbo colposcopic assessment system.<sup>3–6</sup> These colposcopic assessment systems integrate physical traits seen with the colposcope to objectively grade the level of disease.

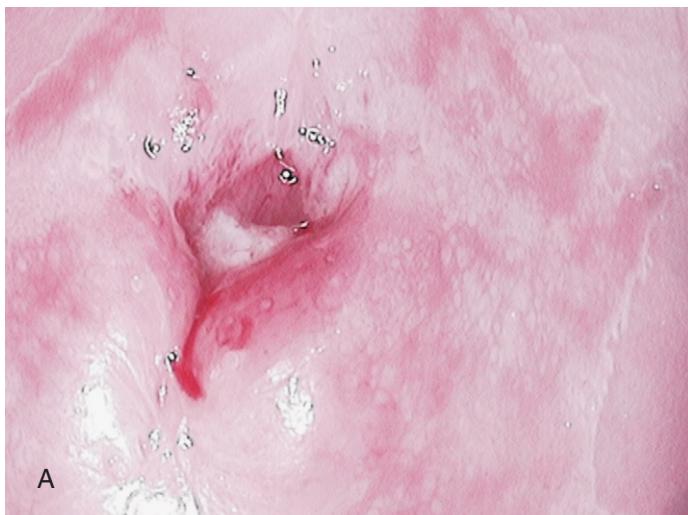

### Reid's Colposcopic Index

In RCI, a numeric value is given to a lesion based on several key features: margin, color, vascular patterns, and iodine staining (Table 12-1).<sup>7</sup> All of the colposcopic signs are determined after the application of 3% to 5% acetic acid except for the iodine staining as the last step. The numerical value places the lesion in a low-grade (CIN I) or a high-grade (CIN II/III) category.

**Table 12-1**  
**Reid's Colposcopic Index**

Colposcopic Sign	0 Points	1 Point	2 Points
Margin	Flocculated or feathered edges Indistinct margins	Smooth, straight lines Sharp peripheral margins	Rolling, peeling edges Internal border between lesions of different grade
Color	Shiny or snow white Transparent Indistinct acetowhite epithelium	Shiny, gray-white	Dull white Oyster gray
Vessels	Uniform, fine caliber Fine mosaic or punctations	Absence of blood vessels after acetic acid	Coarse punctuation and mosaicism Large intercapillary distance Dilated individual vessels
Iodine staining	Positive iodine uptake producing brown color Low grade by other criteria (<2/6)	Partial variegated iodine uptake Tortoise shell color	Mustard yellow color in uptake High grade by other criteria (>3/6)
<b>Colposcopic score</b>	0–2 = HPV or CIN I	3–4 = CIN I or CIN II	5–8 = CIN II or CIN III

CIN, cervical intraepithelial neoplasia; HPV, human papillomavirus.

**Figure 12-8 Large, high-grade dense acetowhite lesion with mosaic pattern entering the canal.** *A*, Biopsy confirmed CIN III disease. *B*, Lugol's solution applied to the cervix, with lack of staining in areas of disease.

These features are more than 90% accurate in predicting pathologic findings and assist the colposcopist in identifying and properly sampling the most severe lesion.<sup>3-8</sup>

In using Reid's colposcopic index for the case represented in Figs. 12-8A and 12-8B, the RCI score would be 2 points for margin, 1 point for color, 2 points for vessels, and 2 points for iodine staining for a total of 7 points, placing the lesion in the high-grade disease category. This patient also has an unsatisfactory or inadequate colposcopy and requires a conization.

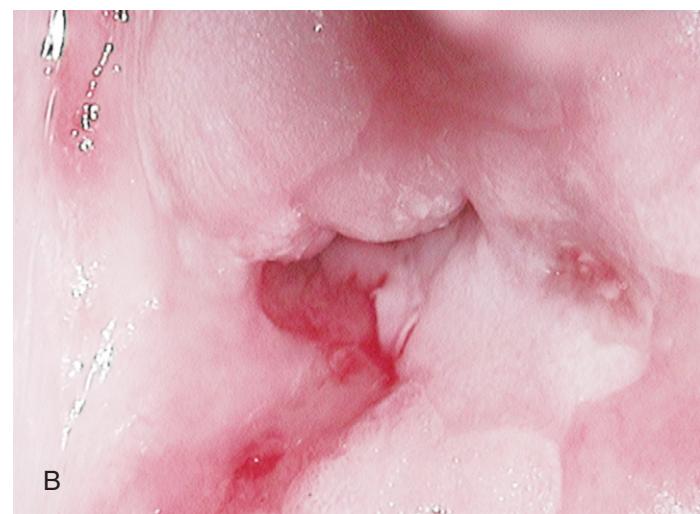

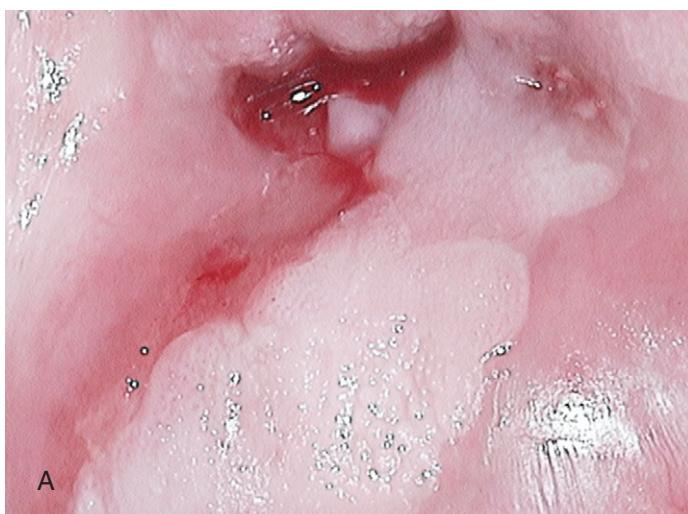

#### Rubin and Barbo System

The Rubin and Barbo assessment method uses descriptors to categorize severity of disease and focuses on presence of microinvasive disease. The key components of the Rubin and Barbo assessment include color, vessels, border, and surface pattern (Table 12-2).

Use of the Rubin and Barbo system (Figs. 12-9A and 12-9B) demonstrates a dense acetowhite lesion with rolling, peeling edges and internal borders suggestive of microinvasive disease.

#### **LOW-GRADE SQUAMOUS INTRAEPITHELIAL LESIONS**

More than 70% of LSIL lesions resolve spontaneously or remain the same without change over time. In a meta-analysis of studies examining the natural history of LSIL, 47% of lesions regress to normal within 2 years, 21% progressed to HSIL (CIN II/III), and 0.15% progressed to cancer.<sup>9</sup> Thus, most low-grade lesions remain stable or resolve, and treatment should be delayed unless progression to high-grade disease occurs. This category contains lesions with histologic features of CIN I disease or koilocytosis indicating HPV infection. The rationale for combining HPV

**Figure 12-9 Large, high-grade lesion.** *A* and *B*, Several elevated dense acetowhite areas with internal borders and peeling edges noted on entry into the os. Biopsy revealed microinvasive disease.

Table 12-2 Rubin and Barbo Colposcopic Assessment System				
Grade	Color	Vessels	Border	Surface
Normal	Pink Translucent	Fine Lacy Normal branching	Normal T-zone Geographic	Flat
Grade I HPV/mild dysplasia CIN I LSIL	White Shiny white Snow white	None Fine punctuation Fine mosaic	Diffuse Feathery Flocculated Geographic	Flat Micropapillary Macropapillary
Grade II Moderate dysplasia CIN II HSIL	White Shiny gray	None Punctuation Mosaic	Demarcated	Flat Slightly raised
Grade III Severe dysplasia CIS CIN III HSIL	Whitest Dull white Oyster white	None Coarse punctuation Coarse mosaic Dilated Intercapillary distance	Sharp Clearly Demarcated Straight Internal border	Raised
Microinvasion Frank invasion	Red Yellow Dull gray	Atypical Irregular Bizarre	Clearly Demarcated Peeling Rolling edges	

CIN, cervical intraepithelial neoplasia; CIS, carcinoma in situ; HPV, human papillomavirus; HSIL, high-grade squamous intraepithelial lesion; LSIL, low-grade squamous intraepithelial lesion.

koilocytotic changes with CIN I disease is based on the rate of progression to CIN III disease (14% for HPV koilocytotic changes and 16% for CIN I) and both demonstrate a mixture of low-risk and oncogenic HPV subtypes.<sup>10</sup> Though HPV subtypes 6 and 11 are frequently associated with low-grade disease; as many as 86.1% of women with low-grade disease have oncogenic HPV subtypes as demonstrated by the ASCUS/LSIL triage study (ALTS).<sup>11</sup> HPV 16 is the most common oncogenic subtype detected, but 18, 45, 56, 31, 33, and 35 also have been found. It is common for multiple HPV subtypes to be found in LSIL lesions (as seen in the ALTS trial) with over 58% of LSIL cases having multiple HPV subtypes. Certain factors determine whether HPV infection will translate to LSIL disease. Such factors are longevity of the HPV infection, young age, and the presence of oncogenic HPV subtypes. Typically, the presence of HPV infection, especially in young populations, is indicative of sexual activity.<sup>12</sup> The younger the onset of sexual activity in the presence of an immature transformation zone, the greater the risk of development of LSIL. The rate of squamous metaplastic maturation appears critical for LSIL development. As women approach their 30s, detection of HPV infection declines from the initial peak in late adolescence. This decrease appears to be due to a reduction in new sexual partners and to cell-mediated immune response to HPV. In summary, infection with oncogenic HPV subtypes and persistence of HPV infection for more than a year are strong risk factors for progression from LSIL to HSIL.<sup>12</sup>

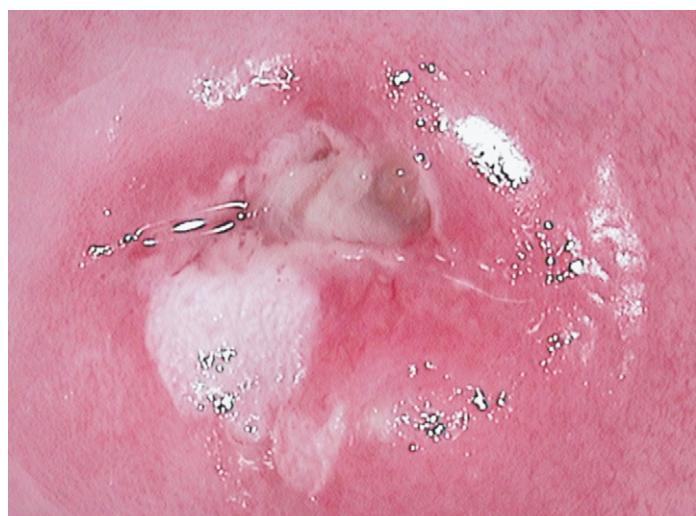

### Colposcopic Features of Low-grade Disease

Colposcopic features of low-grade disease include the following:

- Color: transient, shiny, snowy acetowhite lesion or translucent, faint acetowhite lesion

- Margin: geographic, feathery, flocculated lesion with indistinct borders
- Surface contour: flat satellite lesions or exophytic condyloma
- Vessels: no vessels seen or fine punctuations and mosaic pattern, normal intercapillary distance (50 to 250 µm)
- Iodine: partial uptake or poor uptake with pale yellow iodine staining for condylomatous lesions

An example of a low-grade lesion is shown in Figure 12-10.

**Figure 12-10** Low-grade lesions (flat condylomata) between 6 and 7 o'clock.

## HIGH-GRADE SQUAMOUS INTRAEPITHELIAL LESIONS

The main purpose for colposcopy is to identify lesions most likely to progress to cancer, in particular high-grade disease. To have the highest impact in preventing cervical cancer, clinicians should focus on screening women from age 20 to 39 years, when the rate of CIN III is highest.<sup>13</sup> The average rate of progression from LSIL to HSIL is approximately 10% to 20% following an LSIL Pap smear. Duggan et al<sup>14</sup> in a longitudinal study demonstrated that 18.6% of 342 women with a cytologic diagnosis of LSIL progressed to CIN II or III. However, in patients with high-grade disease the potential for progression if untreated is significant.<sup>15</sup> A natural history study of 894 women with CIN II over 50 to 78 months revealed regression, persistence, and progression rates of 54%, 16%, and 30%, respectively.<sup>16</sup> In a limited series of patients untreated for CIS, the reported progression rate was 12% to 70%. The diagnosis of HSIL includes CIN II, CIN III, and carcinoma in situ. The rationale for combining CIN II and CIN III is based on similarities on cellular morphology, HPV subtypes associated with invasive cancer, aneuploidy, and malignant potential. However, many authors believe that CIN II and III should not be grouped together and point out the potential for CIN III to develop de novo.<sup>15</sup> The theory that cervical dysplasia progresses stepwise from CIN I to II and finally to III has been questioned by studies demonstrating women with CIN III and no evidence of current or previous history of CIN I.<sup>17</sup> In addition, HSIL is monoclonal, similarly to invasive cancer, while 32% of LSIL is polyclonal.<sup>18</sup> However, at present there is sufficient reason to consider CIN II as having malignant potential to justify the same management guidelines as CIN III.

Risk factors for progression to high-grade disease are

- Oncogenic HPV types
- Cigarette smoking
- Multiple pregnancies
- Multiple sexual partners
- Long-term contraceptive use
- Immunosuppression

Persistent infection with oncogenic HPV subtypes, in particular HPV 16, has consistently played a role in the progression to HSIL. In patients with normal cytology who demonstrated continual positive HPV 16 infection for a duration of 2 years versus transient infection, 44% of these women developed CIN at the end of the studies, and those with persistent positivity had more severe lesions.<sup>19</sup> In a study by Moscicki et al, clearance rate for HPV over 5 years was 92%. Those whose disease persisted harbored HPV 16 subtype.<sup>12</sup> The potential to advance to high-grade disease within a 2-year period in cytologically normal women stresses the importance of persistent HPV 16 in determining risk for HSIL.<sup>19</sup>

Several studies confirm that cigarette smoking is directly related to progression to high-grade disease, and its effect is increased by time of exposure and years of smoking.<sup>20–23</sup> In addition, size and degree of dysplasia correlates with the amount of cigarette smoking by the individual. Oral contraceptive pills, cigarette smoking, and HPV 16 subtype had little or essentially no relationship to CIN I disease, in contrast to high-grade disease.

Women in an immunodeficient state, in particular HIV-infected women, are at greater risk for developing CIN than HIV-negative women. Various studies give the estimated prevalence of CIN to be 20% to 77% in HIV-positive women.<sup>24–26</sup> In a meta-analysis of examining risk of CIN in HIV-positive versus HIV-negative women, the relative risk of CIN in HIV-positive women was five times as high as in HIV-negative women.<sup>27</sup> The higher prevalence of HPV may be the role of HIV as a cofactor in the increased replication, persistence, or reactivation of acquired HPV infection.<sup>28</sup>

Additional risk factors such as low socioeconomic status and sexual behavior of the male partner need to be taken into consideration.<sup>29</sup>

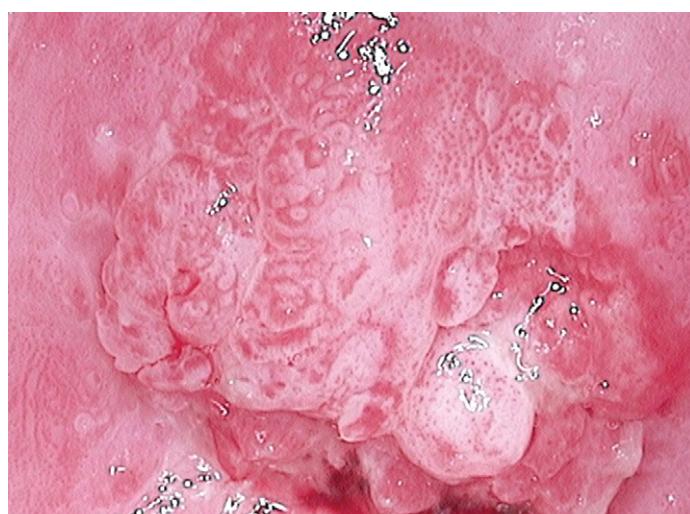

### Colposcopic Features of High-grade Disease

Interobserver and intraobserver agreement in diagnosis of high-grade disease is more accurate than in diagnosis of low-grade disease.<sup>30</sup> Most attribute this disagreement to the abnormal vascular patterns seen in high-grade lesions that assist in differentiating these lesions from low-grade lesions. Most severe lesions are found near the SCJ, and particular attention must be placed on sampling and visualizing disease entering the endocervical canal.

Typical colposcopic features of high-grade disease are the following:

- Color: persistent dull, oyster white dense acetowhite lesion
- Margin: sharp, demarcated, smooth borders, rolling and peeling edges, with or without internal border within a lower grade lesion (lesion within a lesion)
- Surface contour: raised and elevated lesion
- Vessels: coarse punctations or mosaic pattern, wide intercapillary distance between vessels, mosaic lesion with central punctuation or umbilication
- Iodine: lacks staining, mustard yellow color

Typically in colposcopy the most severe lesion is sampled to avoid patient discomfort. However, complex lesions may require more samples to assure accurate diagnosis. An example of a lesion demonstrating high-grade features is shown in Figure 12-11.

**Figure 12-11** High-grade intraepithelial lesion with a combination of coarse mosaic pattern and punctations.

## CANCER

Atypical vessels, areas of ulceration and spontaneous bleeding and dull yellow or reddish tone may indirectly suggest colposcopic evidence of stromal invasion. The borders are frequently peeling or rolled, with lakes and pools, and easily friable. If the lesion is visible, immediate biopsy is warranted. Several studies have revealed the inaccuracy of detection of occult invasive squamous cell carcinoma by colposcopy in as many as 50% of cases.<sup>31,32</sup> Other abnormal colposcopic findings seen with microinvasion are thick, elevated acetowhite epithelium, coarse mosaic pattern and punctuation, and keratosis. The deeper the invasion, the greater the frequency of atypical vessels seen in the majority of patients with 3 to 5 mm of invasion having atypical vessels detected on colposcopy.<sup>33</sup> An example of typical features of microinvasive disease is shown in Figure 12-12.

### Colposcopic Features of Cancer

Colposcopic features of cancer include the following:

- Color: red or dull gray and yellow necrotic appearance
- Margin: sharp, demarcated, with rolling and peeling edges
- Surface contour: raised, polypoid, nodular, exophytic lesion, ulcerative
- Vessels: corkscrew- and comma-shaped vessels, bizarre shapes with abrupt changes in size
- Iodine: lacks staining

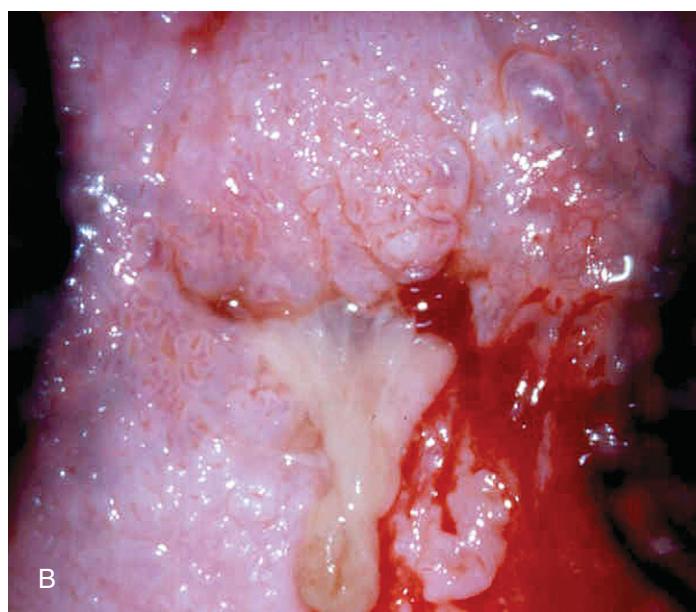

Diagnostic conization may be necessary for sufficient histologic confirmation of depth of invasion or invasive disease. Figures 12-13A and 12-13B are reflective of lesions of concern for cancer.

## COLPOSCOPY IN PREGNANCY

The goal of cervical screening during pregnancy is to identify invasive disease. Colposcopy can be challenging secondary to all the normal physiologic changes of pregnancy and requires great expertise in localizing disease. The pregnant state does not

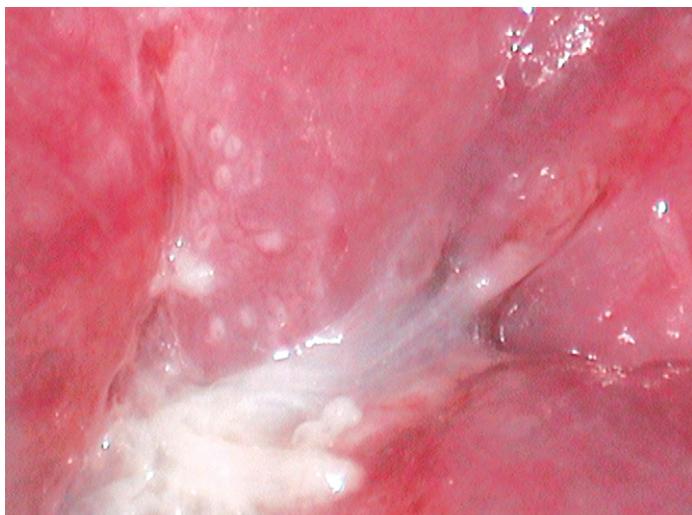

**Figure 12-12** Dense acetowhite lesion with atypical vessels suspicious for microinvasive disease.

**Figure 12-13** Colposcopic appearance of invasive cancer.

A, Endocervical mass with bizarre vessels suspicious for cancer and confirmed by biopsy. B, Large, irregular, papillary acetowhite lesion with lakes and pools and atypical vessels consistent with cancer. Biopsy revealed invasive cancer.

accelerate cervical neoplasia, and there is no difference in survival between pregnant and nonpregnant women with cervical cancer. The incidence of SIL found during pregnancy is 1% to 2% with greater than 85% of the cytologic abnormalities being LSIL and approximately 14% HSIL. Detection of histologic CIN in all pregnant patients can range between 0.19% and 0.53%.<sup>4,35</sup> Invasive cancer presents in 1/3000 pregnancies, with more than 70% presenting in stage I and IIA and a typical mean age of 32 years.<sup>36</sup> Some of the physiologic changes are softening of the cervix, increased vascularity and mucus production, hypertrophy of the fibromuscular stroma, and eversion of the endocervical canal, all due to the high estrogen state. In addition, the cellular changes such as immature metaplasia, decidualization, basal cell hyperplasia, and the Arias-Stella reaction can make

**Figure 12-14 Thick tenuous mucus in the os of a pregnant woman with squamous metaplasia at 12 o'clock.**

accurate cytologic assessment difficult. Colposcopic evaluation is limited by extensive immature squamous metaplasia, increased vascularity causing upgrading of cervical lesions, and thick endocervical mucus (Fig. 12-14). However, it allows conservative management of cytologic abnormalities of the cervix with delay of treatment until after delivery. Views differ about whether sampling is necessary during pregnancy in absence of concern for microinvasive disease.<sup>37–40</sup> Most investigators agree on performing a biopsy if there are colposcopic signs suggestive of microinvasion (atypical vessels), a gross lesion on the cervix, or a large, high-grade lesion covering most of the ectocervix (Fig. 12-15). If a biopsy is necessary, the most severe lesion should be sampled with Monsel's solution in hand to apply to the biopsy site. Though there are few risks for infection and hemorrhage from biopsy, most colposcopists wait until the second trimester

**Figure 12-15 Dense acetowhite lesion covering the entire posterior lip of the cervix in a pregnant patient.** Note the coarse mosaic and punctations on the inferior border. Biopsy confirmed microinvasive disease.

to sample the cervix.<sup>41</sup> Generally by 20 weeks' gestation the SCJ is easily seen as a result of eversion of the endocervical canal, and most colposcopies will be satisfactory.

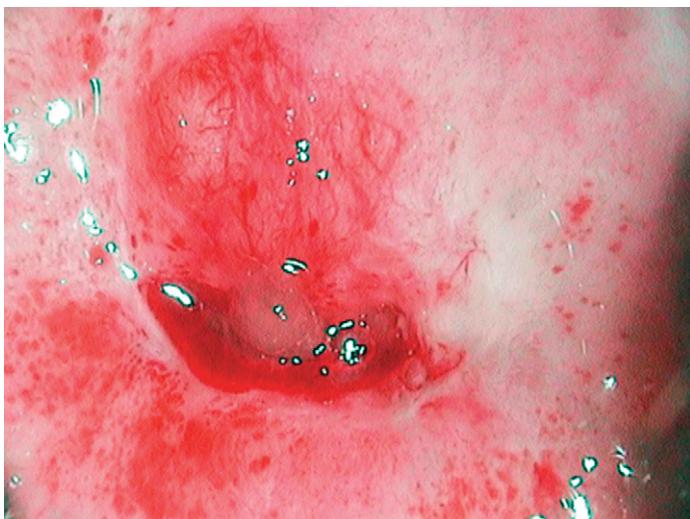

Once cytologic, colposcopic, and if needed histologic evaluation is complete and no evidence of microinvasive or invasive disease is noted, then follow-up with colposcopy or cytology every 8 weeks can be done with repeat colposcopy with sampling after delivery. Diagnostic cone biopsy is reserved for cases in which microinvasive or invasive disease is suspected from histologic evaluation of a simple biopsy or a cytologic test suspicious for cancer with inconclusive colposcopy or colposcopic-directed biopsy or adenocarcinoma in situ is found. A wedge biopsy may be performed instead of standard conization to decrease morbidity. Owing to the risk of preterm labor, premature rupture of membranes, and excessive bleeding, endocervical curettage is not recommended.<sup>37</sup> Low-grade disease may be followed with only repeat colposcopy postpartum, while high-grade disease should be followed with repeat colposcopy with or without cytology every 8 to 12 weeks.<sup>41</sup> There is a high regression rate for cervical dysplasia after delivery, with rates of 74% for CIN II and 54% for CIN III.<sup>42</sup> The regression rate of LSIL to normal can be as high as 65%. Postpartum colposcopic evaluation of cytologic abnormalities found during pregnancy should take place 8 to 12 weeks after delivery. Treatment and follow-up are determined by cytologic, colposcopic, and histologic confirmation of disease.

Nonetheless, the diagnosis of microinvasive disease may require wedge or cone biopsy to exclude invasive disease. Conization during pregnancy is associated with significant morbidity consisting of hemorrhage, preterm labor, and maternal chorioamnionitis.<sup>43</sup> Additionally in as many as 50% of cone biopsies performed during pregnancy, there may be residual CIN disease.<sup>44</sup> Therefore, clear indications are needed. Vaginal delivery in the presence of only microinvasive disease is appropriate.

Several factors direct care in the case of invasive cancer during pregnancy. Important variables are stage of disease, gestational age of the fetus, and the patient's desire to continue the pregnancy. If the cancer is detected at an early stage and beyond 20 weeks' gestation, the option of delaying treatment until there is fetal viability is reasonable.<sup>45</sup> When the cancer is further advanced or found in the first trimester of pregnancy, consideration of immediate treatment needs to be discussed with the patient. If pregnancy is continued, preferred treatment for early-stage disease is a cesarean section for delivery and radical hysterectomy with node dissection.<sup>46</sup>

## POSTMENOPAUSAL CERVIX

Postmenopausal squamous epithelium is pale because of the loss of stromal blood supply, and the cervix may appear red owing to the thin epithelium and easy visualization of the subepithelial capillaries. On application of acetic acid, a distinct area of whitening may not be apparent, since atrophy may complicate the ability to identify the most severe area (Fig. 12-16). Because it is devoid of glycogen, Lugol's solution will stain the cervix and vagina a pale yellow color. In certain cases, Lugol's solution can help identify areas most likely to be CIN versus atrophy. Another challenge in the postmenopausal patient requiring colposcopy is

**Figure 12-16 Atrophic postmenopausal cervix after application of 3% to 5% acetic acid.** Nabothian cyst at 11 o'clock with prominent vessels. No distinct lesion was identified, and only endocervical curettage (ECC) was performed. The ECC result was negative.

**Figure 12-17 Trichomonas infection with the "strawberry cervix" seen after application of acetic acid.** Colposcopy was delayed until treatment was completed.

the location of the SCJ in the endocervical canal. The external os may be stenotic and difficult to enter with an endocervical speculum. A short course of intravaginal estrogen may be necessary to soften the cervix and increase the glycogen content to allow for better visualization.

## COLPOSCOPIC CHALLENGES

Despite the various colposcopic assessment systems, particular cases provide a challenge to the colposcopist. As previously mentioned, atrophy of the epithelium can make identifying the most severe lesion difficult in the postmenopausal patient not on hormone replacement. The presence of infection may result in a higher grading than the histologic diagnosis. When active infection is suspected, colposcopy should be delayed until the infection is treated (Fig. 12-17). Differentiating between normal changes and real disease such as the acetowhite of squamous metaplasia versus the acetowhite of CIN I is a dilemma. Radiation can cause dramatic changes such as bizarre-appearing blood vessels and pale areas, making colposcopy challenging to the most experienced colposcopist. Women exposed to DES in utero have cervical structural changes and vaginal epithelial abnormalities. Vaginal changes appear to be dependent on total dose of exposure, and close colposcopic evaluation of the cervix and vagina is necessary. A potential risk from DES exposure is the development of clear cell adenocarcinoma of the vagina and cervix.<sup>47</sup> After an extensive colposcopic evaluation has been performed, the upper vagina should be palpated to ensure no evidence of cancer. Common changes are the cervical collar, hypoplastic cervix, coxcomb cervix, pseudopolyp, shortened fornix, and vaginal strictures.<sup>48</sup> These changes should be documented and suspicious areas sampled. However, aggressive treatment in the absence of cancer should be avoided, since many of these changes will disappear over time.

## MANAGEMENT AFTER COLPOSCOPY

Colposcopy allows for identification of the most severe lesion for proper sampling. In general, agreement within one grade of disease among the initial Pap test, colposcopic impression, and histologic grade is preferred. However, the colposcopic impression and histologic diagnosis are the gold standard and ultimately determine management and treatment of disease. In instances of discrepancy between the Pap test and the gold standard, a full review of the slides and possibly a repeat colposcopy are performed. Patients with CIN I or no evidence of disease by colposcopy or histology may be followed with Pap tests per the ASCCP Consensus Guidelines.<sup>49</sup> Patients with biopsy-confirmed high-grade disease (CIN II/III) may require excisional or ablative therapy depending on the severity of grade, volume of disease, extension of disease into the endocervical canal or the rest of the lower genital tract, glandular involvement, HIV status, and patient compliance and desire for fertility. Types of ablative therapy are cryosurgery, diathermy, cold (Semm) coagulation, and carbon dioxide laser. Advantages of these procedures are preservation of cervical tissue, anatomy, and function, allowing for future follow-up with cytology and colposcopy and lack of interference with fertility. The disadvantage is lack of histologic evaluation for confirmation of biopsy results. This may be an issue in the case of an inexperienced colposcopist when the most severe lesion is not sampled or disease in the endocervical canal is missed. In this circumstance, invasive and glandular abnormalities may be missed and lead to inappropriate treatment. Therefore, the following critical criteria must be adhered to ensure a good outcome:

- Visualization of the squamocolumnar junction
- Visualization of the entire lesion or lesions

- No evidence of glandular pathology
- Negative endocervical curettage
- Patient compliance

If there is any doubt, excisional treatment should be considered in the form of LEEP (loop electrosurgical excision procedure), LLETZ (large loop excision of transformation zone), or conization. LEEP utilizes a fine loop wire attached to a high-frequency electrical generator that allows precise removal of abnormal tissue from the cervix. This is a common outpatient procedure for cervical disease and has a success rate of over 95%. The procedure allows for minimal tissue to be excised and sufficient material for diagnosis. The disadvantage is the cautery effect, which can create a heat artifact causing some difficulty in evaluating the margin of the specimen.

The key issue in the management of patients with cervical disease is proper counseling about the potential for recurrence and critical need for consistent follow-up. With regular cytologic follow-up and appropriate referral for colposcopy, the risk of future invasive disease is minimal.

## KEY TERMS

**Abnormal transformation zone:** areas on the cervix or vagina that may contain columnar epithelium and squamous metaplasia and that often contain intraepithelial neoplasia with an abnormal colposcopic pattern.

**Acetic acid (3% to 5%):** a contrast solution to enhance the detection of cervical neoplasia during colposcopic examination.

**Acetowhite epithelium:** used to describe epithelium that initially looks normal but appears white after the application of acetic acid. Suggestive of intraepithelial neoplasia or human papillomavirus (HPV) infection, in which case the term subclinical papilloma infection (SPI) is used.

**AGC (atypical glandular cell of undetermined significance):** term used in the Bethesda cytologic classification to indicate abnormal glandular cells that are not sufficiently abnormal to allow a definite diagnosis of neoplasia.

**ASC-US (atypical squamous cells of undetermined significance):** term used in the Bethesda cytologic classification to indicate abnormal squamous cells that are not sufficiently abnormal to allow a definite diagnosis of neoplasia.

**Bethesda classification:** a cytologic classification developed in the United States in 1988, which defines two levels of squamous neoplasia (low-grade or high-grade squamous intraepithelial neoplasia).

**Carcinoma in situ:** a morphologic alteration of the epithelium that usually precedes, occasionally gives rise to, and is usually present in the vicinity of invasive carcinoma. The full thickness of the epithelium is replaced with neoplastic cells.

**Cervical intraepithelial neoplasia (CIN):** a premalignant change in the cervical epithelium that can progress to cervical carcinoma. The degree of change from mild to severe is described as CIN I, II, or III.

**Colposcope:** an instrument used to magnify and examine the epithelium of the transformation zone to identify abnormal areas in the lower genital tract that warrant biopsy. It is a stereoscopic binocular field microscope with a long focal length and powerful light source. Lower magnification yields

a wider view and a greater depth of field for observation. Higher magnification can reveal small features such as abnormal blood vessel patterns.

**Colposcopy:** examination of the cervix, vagina, and occasionally the vulva with the colposcope after the application of a 3% to 5% acetic acid solution; in addition, utilized to obtain directed biopsies of suspected lesions representing neoplasia.

**Cone biopsy, conization:** an excisional technique to remove a cone-shaped or cylinder-shaped piece of cervix for diagnosis or treatment of intraepithelial neoplasia.

**Cold knife cone:** Using a scalpel as the tool for conization of the cervix for diagnostic purposes.

**Cryotherapy:** freezing of the cervix to abate abnormal epithelium.

**Diagnostic excisional procedure:** obtaining a specimen from the transformation zone and endocervical canal for histologic evaluation, which includes laser conization, cold-knife conization, LEEP, and loop electrosurgical conization.

**Dysplasia:** describes varying degrees of cervical intraepithelial neoplasia. It may be mild, involving approximately one third of the epithelium (CIN I); moderate, involving approximately two thirds of the epithelium (CIN II); or severe, involving full thickness of the epithelium (CIN III).

**Endocervical curettage (ECC):** a biopsy procedure used to obtain endocervical tissue for histologic diagnosis.

**Endocervical sampling:** use of an endocervical curette or a cytobrush to obtain a specimen for histologic evaluation; or of a cytobrush for cytologic evaluation.

**Endocervical assessment:** method of evaluating the endocervical canal for the presence of neoplasia by means of colposcopy or endocervical sampling.

**Endocervical curette:** obtains a histologic sample by scraping the endocervical canal. The distal end of the basket is sharp and acts as a blade for curettage. A cytobrush may be rapidly spun in the endocervical canal to provide a specimen.

**Endocervical speculum:** may be necessary to obtain a satisfactory colposcopy that includes visualization of the entire squamocolumnar junction.

**Endometrial sampling:** endometrial biopsy, "dilation and curettage," or hysteroscopy used to obtain a specimen for histologic evaluation.

**Human papillomavirus (HPV):** a subgroup of papillomaviruses, which are small DNA tumor viruses that are classified by their DNA sequences.

**Koilocytosis:** a cellular change associated with papillomavirus infection, which includes perinuclear cavitation and nuclear atypia.

**Leukoplakia:** an area that appears white to the naked eye even before the application of 3% acetic acid.

**Loop electrosurgical excision procedure (LEEP):** a procedure that utilizes a fine loop wire attached to a high-frequency electrical generator that allows precise removal of abnormal tissue from the cervix.

**Lugol's solution:** an iodine based contrast solution that is mainly used when examining the vagina but may also be used in cervical colposcopy. It is less irritating and equally effective when diluted to half strength with water or saline.

**Monsel's solution:** the most common hemostatic agent used for lower genital tract biopsy or excision. It works best in a

toothpaste consistency. Silver nitrate sticks and gel foam also may be used.

**Mosaic pattern:** the rosette appearance of capillary vessels in an abnormal transformation zone.

**Native squamous epithelium:** the normal original squamous epithelium found in the vagina and on the portio of the cervix.

**Normal transformation zone:** area of columnar epithelium and squamous metaplasia that has a normal colposcopic pattern.

**Punctuation:** the stippled appearance of capillary vessels in an abnormal transformation zone.

**Radiation dysplasia:** abnormal cytologic smear from patients who have been treated by ionizing radiation for lower genital tract malignancies. These patients have increased risk of recurrent disease.

**Satisfactory colposcopy:** a colposcopic examination in which the entire transformation zone, including the squamocolumnar junction, is adequately visualized plus the margin of any visible lesion. If this area is not visualized, the colposcopy is termed unsatisfactory.

**Squamocolumnar junction (SJC):** the junction of the squamous epithelium and columnar (glandular) epithelium, usually located near the external cervical os.

**Squamous intraepithelial lesion (SIL):** abnormal squamous cells according to the Bethesda classification. Low-grade (LSIL) corresponds to koilocytosis and CIN I. High-grade (HSIL) corresponds to CIN II and III.

**Squamous metaplasia:** a physiologic process by which squamous tissue replaces columnar tissue.

**Subclinical papilloma infection (SPI):** coloscopically evident papillomavirus infection not clinically visible. Area looks normal to the naked eye but coloscopically appears white after acetic acid application.

## Section 2 General Gynecology

### Chapter 13

# Endometriosis

David B. Redwine, MD

#### KEY POINTS

- Endometriosis is probably the most common cause of pelvic pain seen by gynecologists.
- Delay in diagnosis is common because pelvic pain due to endometriosis is often dismissed as “normal” or misdiagnosed as something else.
- Medical therapy is directed at reduction of estrogen-dependent symptoms, some of which may not be due to endometriosis.
- Surgical therapy is directed at eradication of endometriosis and symptoms caused by it.
- Infertility associated with endometriosis improves following surgery but not medical therapy.
- The invasive nature of the disease makes excision the most effective surgical treatment.
- Successful surgical treatment involves accurate visual diagnosis.

Endometriosis is estimated to affect approximately 10% of women, making it one of the most common diseases affecting humankind. Asymptomatic disease that has not been diagnosed may increase the prevalence even higher. For example, up to 40% of parous and apparently asymptomatic women undergoing laparoscopic tubal sterilization have been found to be affected. The ubiquitous nature of endometriosis has not necessarily led to a clear understanding of the disease. Historically, controversy has accompanied all facets of the definition, origin, diagnosis, and treatment of the disease, although modern insights are finally leading to a more accurate distillation of opinion.

#### DEFINITION

Endometriosis is tissue somewhat resembling eutopic endometrium that is found outside the uterus. Although for many decades it had been believed that endometriosis was identical to endometrium, this notion is incorrect.<sup>1</sup> The most common and most specific symptom of endometriosis is pelvic pain, which can be of several types.

#### EPIDEMIOLOGY

The true epidemiology of endometriosis has been mischaracterized by early misleading observations, which have been repeated by rote for decades. These notions have been magnified by errors of visual diagnosis at surgery.

Sampson in the 1920s noticed that 56% of married women with surgically diagnosed chocolate cysts of the ovaries had conceived. Because at that time the “normal” fertility rate among married couples was thought to be 100%, the notion was advanced that endometriosis caused infertility. The inverse side of this unfounded conclusion was that pregnancy might protect against the disease. Because none of the 23 patients in this original study was menopausal or teenaged, the notion arose that endometriosis did not occur in these age groups. As a result, this one seminal paper<sup>2</sup> sowed several bad seeds: that infertility was a prime symptom, that pregnancy protected against the disease, that it did not occur in teenage women, and that menopause could cure the disease. Modern clinicians will recognize these notions existing today but may not realize that of the 23 patients with chocolate cysts described by Sampson, most of the cysts were corpora lutea, not endometriotic. Some of the most widely held notions surrounding endometriosis have therefore come from women who apparently did not even have the disease. This combination of errors guaranteed the confusion that surrounds the disease today. Indeed, in retrospect, it seems simplistic to conclude that the correct theory of origin or important modern treatment principles should arise from one of the first publications on the disease.

Early onset of menses, heavy menstrual flows, müllerian outflow tract anomalies, a positive family history, and nulliparity have been positively associated with endometriosis in past studies, whereas exercise, cigarette smoking, and pregnancy have negative associations. It is unclear whether any of these associations represents a truth or is simply a result of selection bias stemming from the particular criteria used to assemble study subjects. As one example, it is clear that most women with endometriosis do not have müllerian outflow obstruction defects, which could theoretically impede the outflow of menses and predispose to reflux menstruation, thus facilitating the establishment of disease. Alleged loose epidemiologic associations do not automatically lead to helpful insights or useful therapies.

To know the true epidemiology of endometriosis requires a more perfect knowledge of the disease. Such knowledge would include, among other things, the cardinal symptoms of the disease, the age groups affected, more accurate diagnosis in the office and at surgery, and a comprehensive understanding of how endometriosis behaves in the pelvis and how it responds to treatment. Even better epidemiologic understanding may follow more complete understanding of the molecular genetic basis of endometriosis, a subject finally attracting overdue attention.<sup>3</sup> Currently there is no noninvasive test that is 100% accurate in diagnosing all stages of endometriosis, so the true prevalence of

## General Gynecology

the disease could be known only by performing diagnostic surgery on asymptomatic women, which is not feasible from a research standpoint. Thus the fundamental misunderstandings of endometriosis have persisted for decades. Even observational papers that have sought to accurately characterize clinical aspects of the disease have turned out to be misleading.

### PATHOGENESIS

#### Classical Teaching: Sampson's Theory of Reflux Menstruation

There has been a dramatic shift in opinion of the origin of endometriosis as a consequence of modern research. Sampson's theory of reflux menstruation, once the most widely accepted theory of origin of the disease, is now in the slow process of being discarded. This theory should not be used as the basis for research or clinical treatment, because it appears to be invalid.

Supporters of this theory allege the following: During menses viable particles of normal endometrium travel in a retrograde direction against the normal peristaltic action of the fallopian tubes and are regurgitated out the tubal fimbriated ends. After these endometrial particles enter the peritoneal cavity they are attacked and destroyed by some as-yet unidentified immunologic process that has not been investigated. Women destined to develop endometriosis were felt to have a defective immune system that does not attack these particles, allowing them to continue to exist and to attach to peritoneal surfaces where they proliferate, invade, and become the disease called endometriosis. The ovaries are the most frequently involved sites of occurrence of the disease because these organs are the pelvic surfaces closest to the tubal ostia and are the first to receive the regurgitated endometrial tissue fragments. Otherwise, the distribution of pelvic disease results from a combination of several factors: the effect of gravity and the clockwise circulation of peritoneal fluid down the descending colon and sigmoid, across the pelvis from left to right, and up the ascending colon. Although billions of endometrial tissue particles or individual cells have been refluxed in probably tens or hundreds of millions of women over the years, the important initial steps of attachment, proliferation, and invasion of refluxed endometrial cells all occur sequentially in less than 24 hours. This is why it has been and will always be impossible to obtain the important photomicrographic proofs of attachment, proliferation and invasion. Such rapid attachment, proliferation, and invasion is also why studies on "invisible" microscopic endometriosis<sup>4</sup> have not found these important initiating steps.

Because reflux menstruation can't explain all sites of occurrence of disease, endometriosis may have multiple other pathogenetic origins.

#### Modern Thinking

A more modern theory of the origin of endometriosis would embrace current knowledge of the disease, including the following known proven facts, which directly oppose the precepts of the theory of reflux menstruation, as well as those of vascular or lymphatic spread:

- Endometriosis is not identical to endometrium, but differs in dozens of fundamental and profound ways.<sup>1</sup> Endo-

metriosis therefore cannot be an autotransplant as predicted by Sampson's theory, because autotransplants remain similar or identical to the eutopic tissue of origin.

- The initial attachment of refluxed endometrium to the peritoneum and secondary proliferation and invasion of these cells hasn't been demonstrated by photomicrography in biopsies taken from human females. Regardless of how short a time attachment, proliferation, and invasion may span, the billions of instances of this occurrence guarantee that such evidence should exist by now. Because such photographic proof would be simple to obtain, the lack of such photographs is the most concrete evidence against the theory of reflux menstruation.
- The most common site of involvement is the cul-de-sac, not the ovaries, as originally suggested by Sampson, but endometriosis can occur in remote locations outside the peritoneal cavity, as well as in males.
- Endometriosis seems to be positionally static, sometimes locally invasive with surrounding fibromuscular metaplasia, but there is no evidence of progressive geographic spread throughout the pelvis with advancing age, as Sampson's theory would predict. Most untreated women do not have surgically proven progression of disease. The age-related evolution in color appearance of endometriosis may spuriously give the impression of disease spread if early, subtle disease was not recognized.
- Endometriosis occurs in consistent patterns in the pelvis, intestines, and diaphragm, not in a random distribution.
- The cure rate by conservative excision is greater than 50% per surgery, not 0% as predicted by Sampson's theory. Cure is more difficult in teenagers and in women with widespread disease.
- If recurrent endometriosis is found after excision, it is virtually always superficial, with fewer areas of pelvic or intestinal involvement.
- Endometriosis is only very rarely associated with müllerian defects, which would theoretically facilitate reflux menstruation.
- Pulmonary endometriosis is extremely rare, as are coexisting cardiac atrioventricular septal defects. Hematogenous spread of endometriosis would require a high prevalence of either or both of these pathologic entities, so hematogenous spread through the uterine veins can be ruled out as a major origin of disease.
- Lymphatic endometriosis is extremely rare, effectively ruling out lymphatic spread of disease.

In the vacuum left after discarding reflux menstruation, hematogenous spread, and lymphatic spread as theories of origin of endometriosis, coelomic metaplasia of embryologically patterned mesenchyme and epithelium or embryologically patterned rests emerges as the leading candidate for the origin of endometriosis. At the moment of conception, polygenic, environmental, and chance factors combine to result in embryologically patterned tracts of tissue being laid down between 6 and 8 weeks of embryogenesis. These tracts of tissue generally follow the pathways of normal organogenesis of the female pelvic organs across the posterior coelomic cavity, but can be found elsewhere in the body, depending on defects of differentiation

and migration that may occur in the tiny volume of the embryo. Incomplete dedifferentiation of the müllerian tract in males sets the stage for later occurrence of disease in the bladder or prostate of elderly males undergoing estrogen therapy for palliation of symptoms due to metastatic prostate cancer. In females, these embryologically patterned tracts either already contain endometriosis or consist of substrate, which may undergo metaplasia into endometriosis and the associated fibromuscular metaplasia, which can be seen when the disease involves parenchymal structures such as the uterosacral ligaments, intestine, or bladder. These tracts are most commonly found within the posterior pelvic peritoneum because that is the main migratory pathway of organogenesis, but undifferentiated substrate may extend more deeply. It is possible that when ovarian production of estrogen begins at pubarche, these tracts exhibit varying degrees of biologic response, depending on the potentialities imparted during embryogenesis.

Early endometriosis in teenagers can be colorless because capillaries are not prominent. Individual glands, however, are readily visible to the trained surgeon's eye, appearing like specks of tapioca. The glandular elements of endometriosis secrete a paracrine substance that may cause an inflammatory response in surrounding tissue and destabilize adjacent capillaries, resulting in local fibrosis and occasional hemorrhage. Underlying fibromuscular metaplasia may occur either as a result of this paracrine secretion or because of hormonal stimulation of mesenchymal substrate. With the passage of time, surrounding fibrosis may give a whitish or yellowish appearance to the disease, and fibromuscular metaplasia will result in whitish nodularity. Because glands do not bleed and not all endometriotic lesions are well-vascularized, hemorrhage is not a consistent histologic or morphologic feature of endometriosis, even in the presence of advanced angiogenesis or invasive disease. Blood is not a product of the glands and stroma of endometriosis, but comes from blood vessels, so it is somewhat incorrect to say that endometriosis bleeds. In some older patients with more biologically active disease or leakage of chocolate fluid from endometrioma cysts, a dark, hemorrhagic component may seem more apparent, although a fibrotic component may still prevail. This age-related evolution in color appearance of the disease is largely due to reactive changes surrounding areas of active endometriosis. These changes, such as fibrosis, hemorrhage, and fibromuscular metaplasia, are sequelae of endometriosis. Older patients do not have more areas of pelvic involvement, and most untreated patients do not have progression of disease between surgical investigations. Most women will have developed their lifetime load of endometriosis by their early twenties, with ongoing fibromuscular metaplasia or enlargement of ovarian endometrioma cysts occurring in a minority.

This modern theory of origin predicts exactly what is seen after surgical excision. If all embryologically patterned tracts of tissue have changed into endometriosis, as has usually occurred by the mid-twenties, removal of these tracts can cure the disease. If some tracts have not undergone metaplasia, as might be the case in teenagers, these tracts might escape excision because there is no distinguishing characteristic that would allow the surgeon to identify them for removal. In such cases, a certain rate of recurrence might be expected, especially in women who had undergone excision as teenagers, although the

amount of disease at reoperation is typically less than that found at the initial surgery. After excision in some patients, müllerian-directed epithelial growth factors associated with tissue healing may allow metaplastic formation of superficial deposits of endometriosis around the margins of an excised area or, rarely, in the center of an excised area.

## SYMPTOMS

The symptoms associated with endometriosis are pain and infertility, pain being the more common and more specific symptom. Although endometriosis may be the most common cause of pelvic pain seen by gynecologists, not all pain or infertility in women with endometriosis is necessarily due to the disease. Less common causes of pelvic pain include other diseases of the uterus, tubes, or ovaries; intestinal diseases; urologic processes; muscular syndromes of the pelvis or abdominal wall; and pelvic or abdominal adhesions. Given the widespread distribution of estrogen and progesterone receptors throughout the body, some of these other nongynecologic causes of pain may also exhibit aggravation before or during menses. Accurate diagnosis of pain specifically due to endometriosis and prediction of the patient's prognosis after treatment are both made more difficult by this lack of exact correlation of symptoms with the disease. Nonetheless, women with endometriosis can exhibit consistent patterns of symptoms highly suggestive of the disease because the sites of disease can produce characteristic symptoms.

### Dysmenorrhea

*Dysmenorrhea* refers to painful menses and is often the first symptom of endometriosis. A common history in women with endometriosis is the memory of severe pain with menses from an early age, frequently from menarche or even before. The term immediately brings to mind uterine cramping as the prototypical characteristic of dysmenorrhea. However, clinicians must be cautious about blaming the uterus for all pain during menses. Pain during menses could be due either to uterine cramps or to simultaneous occurrence of menstrually timed aggravation of nonuterine pain, including endometriosis. Dysmenorrhea is therefore a common but somewhat nonspecific symptom associated with endometriosis. Both endometriosis pain and uterine pain can radiate into the sacral region, whereas uterine pain can radiate up to the umbilicus and into the upper anterior thighs.

### Nonmenstrual Pelvic Pain

Menstrual pain can worsen in severity and duration over several years and may eventually begin to occur in the luteal phase of the ovarian hormonal cycle, before menses begins. The pain may cause absence from school for up to several days each month, and sport or social activity may be curtailed due to the pain. The pain frequently is trivialized by family and friends as "just cramps" even though it is not necessarily directly associated with menses, and the patient is encouraged to "just deal with it" as part of being a woman. The patient may be seen as somewhat of a malingerer, especially if seen by a physician who finds nothing apparently wrong on abdominal examination or diagnostic imaging scan. This trivialization of the patient's pain by family, friends, and medical practitioners leads to a delay in diagnosis of 10 to 15 years in many cases.

## General Gynecology

By late teenage years, the patient may be aware of a sharp character of the pain and may use adjectives such as “stinging,” “burning,” or “knifelike” to describe the pain. When describing her pain, the patient may clench a fist as if holding an invisible knife and stab at her pelvis or make a twisting thrust of the unseen blade toward the interviewer. The pain can eventually begin around the time of ovulation, in which case it may be diagnosed as simple ovulation pain, and may increase in severity as the menstrual flow approaches. During menses, the pain can be greatly aggravated; some patients may also be able to discriminate the occurrence of uterine cramping on top of pain that began before the flow. The pain may abate after menses, although some patients may still be aware of pain at a lower level even during the “good” times of the monthly cycle.

**Dyspareunia, Dyschezia**

Endometriosis is most commonly found in the cul-de-sac, medial broad ligaments, and uterosacral ligaments (Table 13-1), where it can cause specific and consistent symptoms. These common areas of involvement are located immediately adjacent to both the end of the vagina and the rectum. Accordingly, any physical stimulation to these diseased areas can be painful. Endometriosis of the cul-de-sac and uterosacral ligaments will frequently be associated with dyspareunia and painful bowel movements during menses because these actions will mechanically impact on the disease.

Obliteration of the cul-de-sac occurs when the rectum is adherent across the posterior cervix or lower uterine segment with simultaneous adherence to the uterosacral ligaments. This signifies invasive disease of the uterosacral ligaments, cul-de-sac, and usually the anterior wall of the rectum. Sacral back pain, rectal pain, rectal pain with flatus or intercourse, rectal pain with sitting, and painful bowel movements throughout the month are

characteristic symptoms of obliteration of the cul-de-sac. Many patients describe rectal pain with vaginal intercourse. Because intestinal endometriosis rarely penetrates to the mucosa, cyclic rectal bleeding is an uncommon sign, even with significant bowel wall involvement.

**Lateral Pelvic Pain**

Endometrioma cysts of the ovaries can cause chronic ipsilateral pain and fullness due to swelling of the cyst. Intermittent sharper exacerbations of pain may occur, with leakage of cyst contents. Such leakage can cause pain that can last for several days and can initially mimic an acute abdominal emergency. Superficial endometriosis of the ovarian cortex appears to be asymptomatic. Periovarian adhesions due to endometriosis can contribute to lateral pain because an ovarian cyst of any type can increase in size and place traction on such adhesions. This pulls on the peritoneum where the adhesion inserts and can result in pain.

Pain caused by invasive disease of a uterosacral ligament can occasionally radiate into the back or upper posterior thigh. Endometriosis of the pelvic sidewalls or lateral to the sigmoid colon or cecum near either pelvic brim can also cause ipsilateral pain. Endometriosis invading from the peritoneum to involve the sciatic or obturator nerve can cause pain or motor dysfunction in the distribution of those nerves, especially during menses.

Constriction of a ureter occurring due to entrapping fibrosis extending from a large uterosacral ligament nodule can cause both ipsilateral low pelvic pain as well as ipsilateral renal or ureteral colic. Actual invasion of the ureter by endometriosis is rare. When the constriction occurs slowly over the course of several years, ureteric symptoms may be absent, even when the ipsilateral kidney is destroyed by ureteral obstruction. When an endometrioma cyst compresses a ureter or when the ureter is constricted by surrounding fibrosis or invaded by endometriosis, cyclic stricture of the ureter may occur, especially in the luteal or menstrual phase of the cycle. This can produce cyclic symptoms of ureteral obstruction such as flank pain and backache.

**Lower Back Pain**

Endometriosis of the uterosacral ligaments may radiate pain into the lower back, especially if invasive disease or obliteration of the cul-de-sac is present. Uterine pain can also radiate to this area.

**Bladder Pain, Frequency, Dysuria**

Superficial lesions of the bladder peritoneum are usually asymptomatic. Lesions invading the muscularis may cause symptoms of dysuria and urgency throughout the month, with some perimenstrual aggravation of pain. Because the bladder mucosa is rarely involved, hematuria is rare. Occasionally, frequency and urgency seem to be the result of irritation of the pelvic plexus by invasive disease of the uterosacral ligaments. Interstitial cystitis can cause bladder pain, and this can worsen during menses also, contributing some confusion to the case of a woman with bladder pain.

**Irregular Vaginal Bleeding**

Although it is said that irregular or heavy menses may occur with increased frequency among women with endometriosis, this

**Table 13-1**  
**Sites of Pelvic Involvement in 2115 Patients with Biopsy-proven Endometriosis\***

Pelvic Site	Number (Frequency) of Involvement
Cul-de-sac	1521 (71.9%)
Left broad ligament	1038 (49.1%)
Left uterosacral ligament	878 (41.5%)
Right broad ligament	871 (41.2%)
Right uterosacral ligament	795 (37.6%)
Bladder	600 (28.4%)
Left ovary	233 (11.0%)
Right ovary	209 (9.9%)
Left fallopian tube	134 (6.3%)
Right fallopian tube	90 (4.3%)
Left round ligament	49 (2.3%)
Right round ligament	27 (1.3%)

\*Treated at the Endometriosis Treatment Program at St. Charles Medical Center, Bend, OR.  
476 patients with obliteration of the cul-de-sac or Stage IV disease have been excluded because most patients do not have such disease and most clinicians will not commonly encounter such disease.

is a very nonspecific multifactorial symptom that contributes little or nothing to the diagnosis. Vaginal endometriosis occurs in the posterior fornix, and this can bleed perimenstrually or after hysterectomy. Vaginal endometriosis represents extension of invasive endometriosis of a uterosacral ligament or of a rectal nodule associated with obliteration of the cul-de-sac.

### **Partial Bowel Obstruction**

Symptoms of partial bowel obstruction during menses occur almost exclusively with nodular disease of the ileum. With progression of the nodularity and ileal distortion, partial obstructive symptoms are possible throughout the month. Symptoms of partial obstruction due to colonic endometriosis are rare due to the larger diameter of the large intestine. Complete bowel obstruction due to endometriosis almost never occurs.

### **Irritable Bowel Syndrome**

Nodular disease of the large or small bowel may be associated with alternating constipation and diarrhea, bloating, or intestinal cramping. Peritoneal endometriosis without bowel involvement can also cause irritable bowel symptoms, apparently because the bowel can be irritated by laying against these endometriotic areas or irritated by the increased volume of reactive peritoneal fluid that can be associated with endometriosis.

### **Perimenstrual Chest and Shoulder Pain**

Diaphragmatic endometriosis is rare and occurs most frequently on the right hemidiaphragm. Ipsilateral chest and shoulder pain during or just before menses is a common symptom. This pain can sometimes radiate into the neck or down the arm and can be described as resembling a muscular ache. Some patients may progress to suffer symptoms all month long, with severe menstrual aggravation of pain. Occasionally a patient may need to sleep in a sitting position to relieve the pain.

### **Abdominal Wall Pain**

Umbilical endometriosis presents as a small darkly hemorrhagic nodule located usually in the inferior midline of the umbilicus. Pain and swelling may occur during menses, occasionally associated with a slight bloody discharge from the umbilicus.

Scar endometriosis occurs most commonly after cesarean sections, but can also be found after hysterectomy. A rare and specialized form of scar endometriosis has occurred after prenatal diagnostic amniocentesis. Scar endometriosis manifests as a slowly growing lump, which may enlarge slightly and become more painful during menses.

Inguinal endometriosis arises from nodular endometriosis of the round ligament as it traverses the inguinal canal, causing a tender lump most commonly found overlying the right pubic ramus, which may be more painful and slightly larger during menses. This lesion is one of the earliest types reported, probably because it was so obvious on examination and presented an easy surgical target.

### **Nonpelvic Pain**

With increasingly deranged differentiation and migration of müllerian tract derivatives during embryogenesis, endometriosis can be found outside the abdominal cavity, with pain as a result. Endometriosis has been reported to involve the posterior thigh,

posterior knee, left neck, brain, cauda equina, thorax, and liver in females and the bladder and prostate in elderly males undergoing estrogen therapy for palliation of metastatic prostate cancer.

### **Asymptomatic Endometriosis**

Apparently asymptomatic endometriosis may be diagnosed during pelvic surgery done for other reasons, such as tubal sterilizations. After removal of such "asymptomatic" disease, some previously "asymptomatic" patients may realize for the first time in their lives that they were, in fact, symptomatic. The visual appearance of endometriosis does not guarantee whether the disease is symptomatic or not. Disease with a subtle morphology may hurt, whereas disease with a spectacular morphology may not.

### **Infertility**

Fecundity is decreased in women with endometriosis compared to age-matched women without endometriosis. Although fertility may be lower because of endometriosis, it is not eliminated. Even women with untreated severe disease may become pregnant, although success takes longer. When a patient has unsuccessfully attempted pregnancy for 2 years or more, this may indicate some other cause of infertility besides endometriosis, especially if superficial disease is present. Therefore, in women with long-standing infertility, treatment directed at endometriosis will be less successful because this group of women will be more likely to have some other cause of infertility. Important among the other causes of infertility among women with endometriosis is the age-related decline in fertility of both females and males.

Many women with infertility due to endometriosis also suffer from pain. Rarely will a patient present only with the symptom of infertility. After successful treatment of their disease, however, some of these "pain-free" infertile women will realize that they actually were having pain as well; the pain was thought to be low-level or "normal."

## **DIAGNOSIS**

Because endometriosis is the most common cause of pelvic pain in reproductive-age women, it should always lead the list of differential diagnoses. A presumptive diagnosis of endometriosis can be made in most patients on the basis of a characteristic history of pain and characteristic findings on pelvic examination. Abdominal examination is rarely helpful, although occasionally a large ovarian cyst will be palpated, or nonspecific direct tenderness in the lower quadrants will be present. Leakage of an ovarian endometrioma can be associated with symptoms of an acute abdomen initially, with clearing of the pain spontaneously over several days.

### **Pelvic Examination**

The pelvic examination is important both for the diagnosis of endometriosis as well as for prediction of the likelihood of pain relief following surgical treatment. Given the ubiquitous nature of the disease, gynecologists in training must first become expert in mastering the pelvic examination as it relates to endometriosis, then later worry about the examination as it relates to less common entities such as pelvic infection, ovarian cysts, pelvic adhesions, uterine retroversion, and uterine enlargement.

The external genital examination will rarely yield any useful information contributing to the diagnosis of endometriosis, although rare cases of endometriosis of an episiotomy scar will be manifest as a tender lump, which is occasionally discolored by underlying hemorrhage and which is more obvious with menses.

Speculum examination of the cervix may reveal hemorrhagic spots less than 3 mm in diameter located within the squamous epithelium. Occasionally there may be a droplet of blood on the epithelial surface adjacent to the spot (Fig. 13-1). This may be cervical endometriosis, although biopsy is the only way to be sure. The speculum should also be directed posteriorly to examine the posterior vaginal fornix. Often, cases of nodular endometriosis of the uterosacral ligaments or cul-de-sac that are invading the vagina are missed because the speculum is used only to examine the cervix, and the posterior blade hides the lesion. Endometriosis of the posterior fornix may have several morphologies, including subtle epithelial piling (see Fig. 13-1), small bluish cysts, and red hemorrhagic fleshy lesions.

Manual pelvic examination for endometriosis should focus on four specific areas: the uterus, the left and right uterosacral ligaments, and the cul-de-sac. Although endometriosis uncommonly involves the uterus, the uterus may still be an important cause of pain unrelated to endometriosis. During bimanual palpation of the uterus, the size, shape, position, and consistency should of course be noted. However, one of the most important things the examiner can do is to gently squeeze the uterus between the fingers of the external and internal hands to see what degree of tenderness might be present and whether this reproduces any component of the patient's pain. When the uterus is retroverted, it is almost impossible to determine if it might be a source of pain because only its posterior wall can be palpated through the cul-de-sac. Any tenderness ascribed to the uterus when uterine retroversion is present could be caused either by the uterus or by cul-de-sac endometriosis.

After examining the uterus, ovarian enlargement and tenderness should be sought. Normal ovaries are not always palpable. Enlarged ovaries are easier to detect but not always discretely because the adhesive process associated with advanced cases of endometriosis may cause the uterus and enlarged ovaries to move as one indistinct mass.

The examiner's attention should now shift to the most important part of the examination: gentle palpation of the cul-de-sac and uterosacral ligaments. These are among the areas most commonly involved by disease, and these areas can be easily reached by most physicians during examination, although the length of the examining physician's fingers becomes an important limiting factor. The external examining hand will not be helpful in detecting positive findings in these commonly involved areas because the external hand cannot press deeply enough to reach the posterior pelvis. Also, discomfort associated with attempting this deep palpatory maneuver with the external hand will mask positive findings. Therefore, the cul-de-sac and both uterosacral ligaments should be examined only with the examiner's internal fingers, without any use of the external examining hand. Each of these three areas should be gently palpated or stroked while watching the patient's face. A normal pelvic examination should not provoke pain. If the patient's face winces, or if she arches her back or pushes away from the end

**Figure 13-1 Endometriosis of the vagina occurs in the posterior fornix and represents extension of nodular disease of a uterosacral ligament or a rectal nodule.** Such disease can be easily seen if the speculum is directed toward the fornix. Some lesions are hemorrhagic. Other lesions, such as this one, may be manifest as epithelial piling without hemorrhage. Notice the superficial cervical endometriosis, which appears to be asymptomatic.

of the table, these are positive findings suggestive of endometriosis. Extremely rarely the anterior vaginal wall may have nodularity and tenderness, which is an indication of invasive disease of the trigone region of the bladder. Nodularity in any of these areas should be noted, and the patient should be asked if palpation of each particular site reproduces any symptoms. This clinical pain mapping is helpful because nodularity, tenderness on examination, and reproduction of symptoms by examination are findings predictive of a better prognosis following surgical removal of endometriosis in these areas.<sup>5</sup>

Some patients cannot describe their pain succinctly and may have equivocal or no findings on pelvic examination. These patients may have some other reason for pain besides endometriosis and the prognosis for pain relief following treatment for endometriosis is low.

### Diagnostic Tests

The morphological manifestations of endometriosis are most frequently rather two-dimensional with little invasion or three-dimensional volume. Ultrasound, magnetic resonance imaging (MRI) or computed tomography scans are therefore negative in most cases but may be helpful in obese patients, who are difficult to examine, or if a uterine component of pain is present. If a patient has uterine symptoms, an abnormal uterine scan, and has completed her child-bearing, hysterectomy may be a rational treatment option.

Because intestinal endometriosis rarely penetrates from the seromuscular layer through to the mucosa, intestinal barium studies and colonoscopy are notoriously negative in all but the most advanced cases. Advanced cases of obliteration of the cul-de-sac with involvement of the anterior rectal wall may be suggested by MRI or rectal ultrasound, but symptoms and pelvic examination will have already suggested the presence of such disease even if scans are not performed. When lesser degrees of nodularity and tenderness are found on pelvic examination, imaging scans will usually be negative.

Endometriosis of the urinary tract will not always be found on scans either. Like intestinal endometriosis, bladder disease beginning on the peritoneum rarely penetrates through to the mucosa, so cystoscopy is rarely positive. Constriction of one or both ureters may be identified by imaging tests in patients with suggestive symptoms, with silent loss of renal function identified in extreme cases.

Ovarian enlargement may be undetectable by pelvic examination in some patients, either due to obesity interfering with the accuracy of the examination or because ovarian size is still below the threshold of clinical detection by the individual examiner. Imaging scans can arrive at an accurate assessment of solid and cystic portions of the ovary, the diameter of a cyst, the thickness of the wall of the cyst, and the consistency of the fluid contents. Ovaries involved by endometrioma cysts are frequently described as “complex” on scans because they have a solid component, which can represent normal ovarian tissue, and a cystic component, which is thick walled and filled with hyper-echogenic fluid representing old thick bloody (“chocolate”) fluid. Hemorrhagic corpora lutea may have a similar imaging signature. Although peritoneal fluid volume can be increased with endometriosis, frank ascites is uncommon. Findings suggestive of ovarian malignancy include thick-walled septations of cysts, internal or external excrescences, and associated ascites.

In the uncommon instance when diagnostic imaging is positive or extremely suggestive of endometriosis, the patient’s symptoms and findings on pelvic examination are frequently flagrant, and the correct diagnosis of endometriosis will be obvious at surgery. When imaging is negative but disease exists, the findings will also be obvious to the trained surgeon’s eye. Surgical investigation is thus more accurate than any scan. Positive scans focus attention on their findings, and other areas of disease not identified by scanning can be overlooked during surgery. For example, an ovarian endometrioma cyst will be easily identified on imaging scans, and the surgeon may focus only on its removal during surgery, leaving other areas of endometriosis behind. Negative scans do not guarantee absence of pathology and should not be used to ignore a patient’s complaints. The patient’s pain is the most important factor in the decision to treat, and the pelvic examination is usually more helpful than any scan.

The CA 125 level may be elevated or normal with endometriosis. This test may also be elevated or normal with a variety of other gynecologic pathologies, including adhesions, adenomyosis, leiomyomata, ovarian cancer, or unknown causes. For these reasons, the CA 125 test lacks the sensitivity and specificity that would make it a useful test for diagnosing endometriosis.

### Surgical Diagnosis

Surgery is the most accurate measure of the sites of and extent of involvement and is most commonly done by laparoscopy. The visual appearances possible with endometriosis are protean, the spectrum ranging from the extremely subtle to the spectacular. All visual manifestations may be present in a single patient. Errors of diagnosis can be made at either end of this morphologic spectrum. Invisible microscopic endometriosis has not been proven to be a concern in diagnosis, treatment, prognosis, or recurrence.<sup>5</sup> The incidence of unanticipated endometriosis existing in apparently visually normal peritoneum is directly

**Table 13-2**  
Incidence of Unanticipated Endometriosis in Visually Normal Peritoneum, According to Distance of Observation

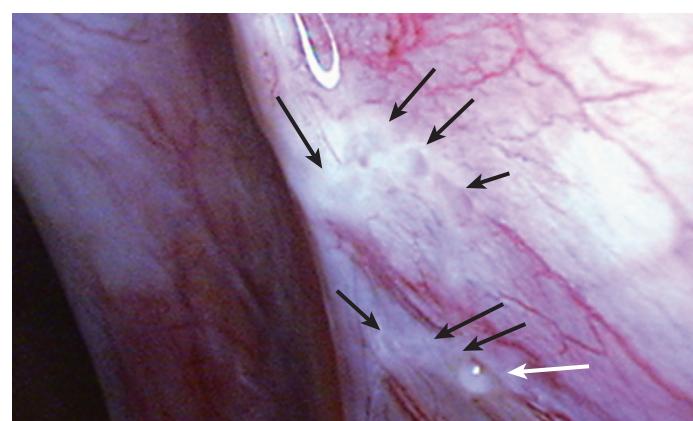

Rights were not granted to include this table in electronic media.  
Please refer to the printed publication.

From Redwine DB: Invisible microscopic endometriosis: a review. *Gynecol Obstet Invest* 2003;55:63–67.

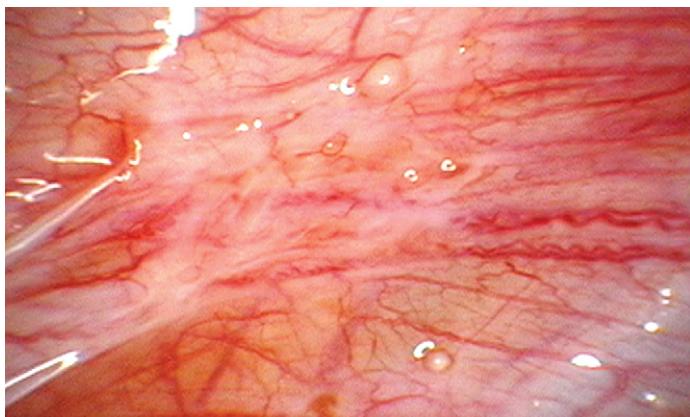

related to magnification used during surgical inspection and can be effectively reduced to almost zero with near-contact laparoscopy (Table 13-2).

There is a premium on accurate identification of early forms of the disease, because failure to identify extant disease will give the spurious impression of the development of new disease or of progressive geographic spread if previously unidentified subtle disease has become more obvious by the time surgery is done.<sup>6</sup>

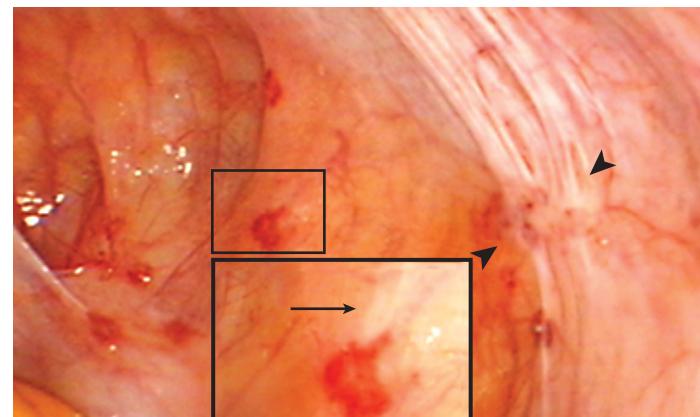

Women in the teenage years may have disease that is extremely subtle and colorless, sometimes with adjacent clear papules, which appear to be localized collections of glandular secretions either on or just beneath the peritoneal surface (Figs. 13-2 and 13-3). Close examination with the tip of the laparoscope within 1 cm of the pelvic surfaces will disclose individual gland/stroma complexes of endometriosis without surrounding hemorrhage or fibrosis. These findings may be missed if only panoramic viewing of the pelvis is performed. In some patients the disease is stable in appearance over the patient’s

**Figure 13-2 Subtle endometriosis of the right uterosacral ligament in a young woman.** Individual gland/stroma complexes of endometriosis are seen (black arrows). These colorless, clear, macular lesions secrete a paracrine substance, which may remain trapped beneath the peritoneal surface, although occasionally clear papules (white arrow) may be present, which appear to be extrusion of secretions trapped under a monolayer of peritoneum.

**Figure 13-3** With the passage of time, these subtle lesions of the left broad ligament are associated with increased clear papular change, faint whitish fibrosis, and beginning angiogenesis but no hemorrhagic change.

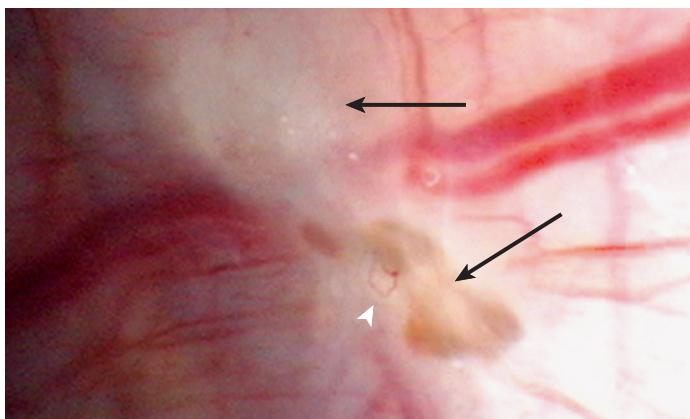

**Figure 13-5** With the passage of time, further hemorrhage and fibrosis may occur. A hemorrhagic area of the right cul-de-sac (small box) is seen on magnification to lie adjacent to a clear macule of endometriosis (large box) and may contain a gland/stroma complex of endometriosis obscured beneath the hemorrhage. The base of the right uterosacral ligament demonstrates thickening of whitish fibrosis and entrapment of old dark blood between the arrowheads.

symptomatic lifetime; in others, the predetermined biologic potential of the disease will result in reactive sequelae, which can change the morphology of the disease over time.

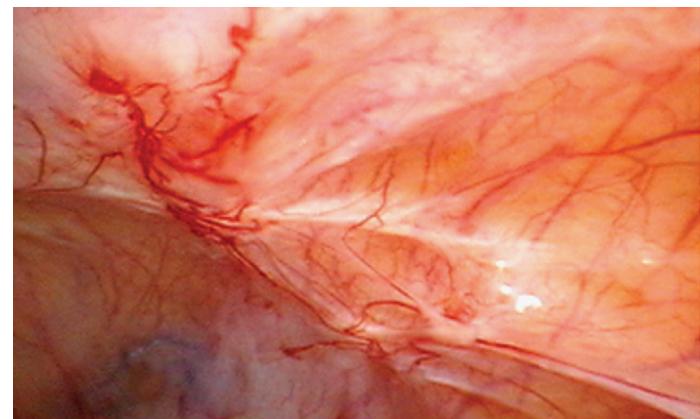

With the passage of time, the paracrine secretions of endometriosis may cause superficial peritoneal fibrosis surrounding the lesions, with a resultant whitish coloration. If the paracrine secretions destabilize adjacent capillaries, a hemorrhagic appearance may be associated with the disease, resulting in either a reddish or blackish hue adjacent to the disease (Figs. 13-4 and 13-5). Occasionally the paracrine secretions can stimulate angiogenesis, and some lesions may be associated with adjacent or overlying obvious (Fig. 13-6) or subtle (Fig. 13-7) neovascularity. Particularly active lesions will continue to incite reactive fibrosis, and the scarring over the active lesion will become thicker as well as whitish or yellowish and will obscure visualization of the gland/stroma complexes, which may formerly have been

visible. This is the well-known morphology of “burned-in” endometriosis (Fig. 13-8). This formerly was termed *burned-out* endometriosis, a term that erroneously implied to several generations of gynecologists that no active disease was present, when actually very active disease has simply been buried under thick, reactive fibrosis. Classic “black powderburn” lesions tend to be most common in women after age 30. Biopsy of such lesions may simply return old hemorrhage, because the endometriosis responsible for provoking the bleeding may be some distance away. With further passage of time, pelvic areas predestined to undergo fibromuscular metaplasia will do so, leading to an increased volume of disease.

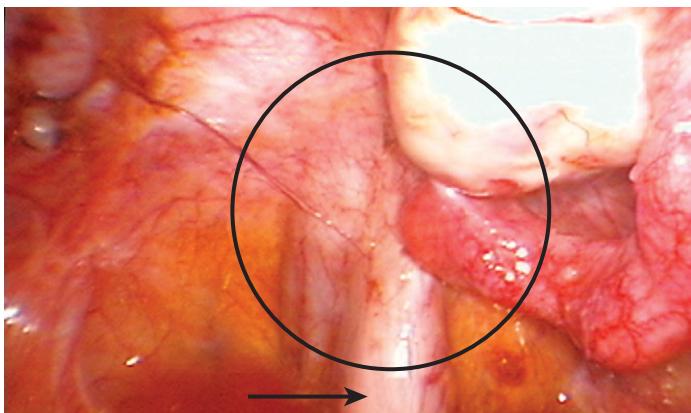

The uterus can occasionally be involved by endometriosis (Fig. 13-9), and this represents a clinical problem of diagnosis

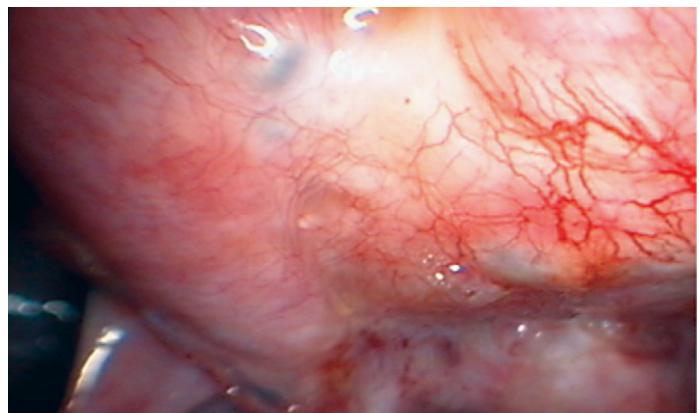

**Figure 13-4** Subtle lesions of endometriosis (black arrows) of the right bladder peritoneum with adjacent dark hemorrhage. Faint whitish fibrosis is forming within the peritoneum, slightly obscuring the retroperitoneal vascular pattern. Angiogenesis is beginning, evidenced by a tiny capillary loop (white arrowhead).

**Figure 13-6** This endometriosis of the cul-de-sac exhibits thicker fibrosis and advanced angiogenesis, which some lesions display over time. The individual gland/stroma complexes of endometriosis are now largely hidden beneath the increasing fibromuscular metaplasia.

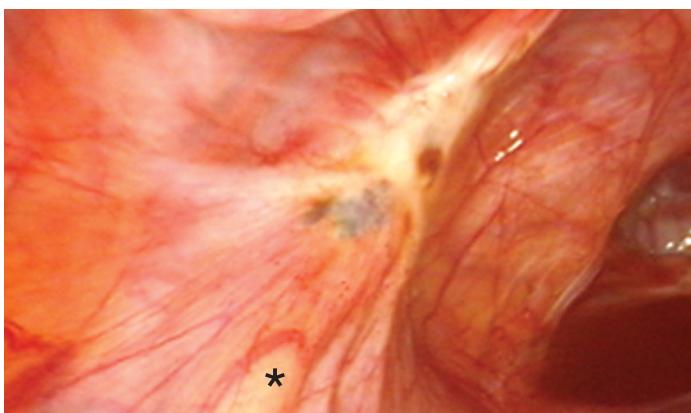

**Figure 13-7 Advanced invasive disease can exist with little or no hemorrhagic changes.** This patient has partial obliteration of the cul-de-sac, with the rectum (arrow) tented up to the right uterosacral ligament. The right ovary and fimbriated end of the tube are also adherent to and obscure this area (circle). Invasive disease of the uterosacral ligament and anterior rectal wall is present without any hemorrhagic change, although mild neovascularity overlies the entire region.

**Figure 13-9 The uterus is infrequently involved by endometriosis, most commonly on its posterior surface.** The disease can be manifest as subserosal collections of dark blood associated with unseen gland/stroma complexes, sometimes with impressive neovascular changes.

that is distinctly different from peritoneal disease. Whereas normal peritoneum is transparent and underlying disease can be separated from identifiable normal surrounding structures, the uterus is opaque. Endometriosis on the serosa may be isolated or may signify the underlying presence of invasive disease of the myometrium, which cannot be easily distinguished or separated from normal uterine tissue.

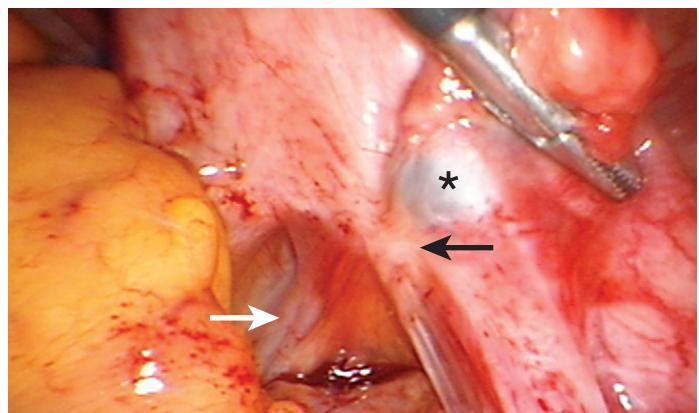

Fibromuscular metaplasia is most common in parenchymal structures, such as the uterosacral ligaments (Fig. 13-10) or the muscularis of the bladder or bowel (Figs. 13-11 and 13-12), in which case the morphology at surgery will be nodular and the histologic picture will be adenomyotic. The age-related evolution in color appearance of endometriosis can give the spurious impression that new disease is appearing.

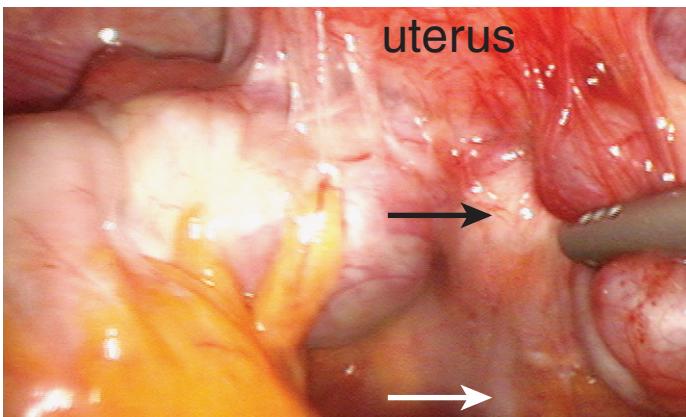

**Figure 13-8 This powderburn lesion of the left broad ligament overlies the path of the left ureter (asterisk).** Black hemorrhagic changes are present both in the center of the dense yellow-white fibrosis as well as at its edge. The most active disease is buried in the center of the yellowish fibrotic nodule. When the fibrosis eventually completely obscures the hemorrhagic component, the malapropism “burned out” disease might be applied, instead of the correct term of “burned in” disease.

Not all peritoneal epithelial changes are due to endometriosis. Laser vaporization can leave behind flecks of carbon as well as treatment granulomas, which overlie incompletely treated endometriosis (Fig. 13-13). Carbon deposits can induce a foreign body giant cell reaction, which can be a new source of pain. Carbon may mimic old hemorrhage associated with endometriosis, but its chief contribution to the diagnosis of endometriosis is the possibility that incompletely treated endometriosis lies beneath it. Laser vaporization can also cause superficial adhesions overlying incompletely treated endometriosis (Figs. 13-14 and 13-15).

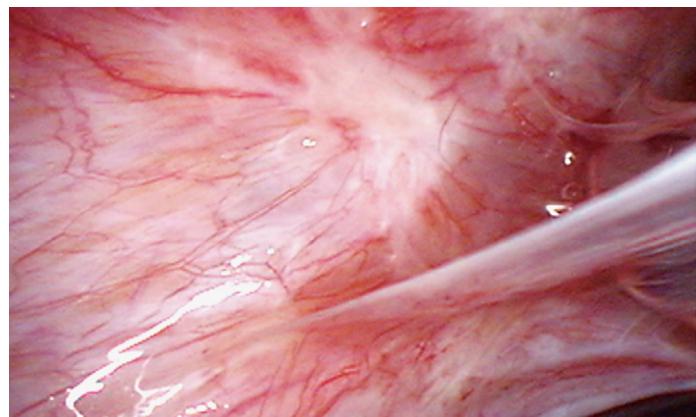

All pelvic and intestinal areas involved by endometriosis can be visualized by a laparoscope inserted through an umbilical port. Occasionallyatraumatic graspers may be helpful in

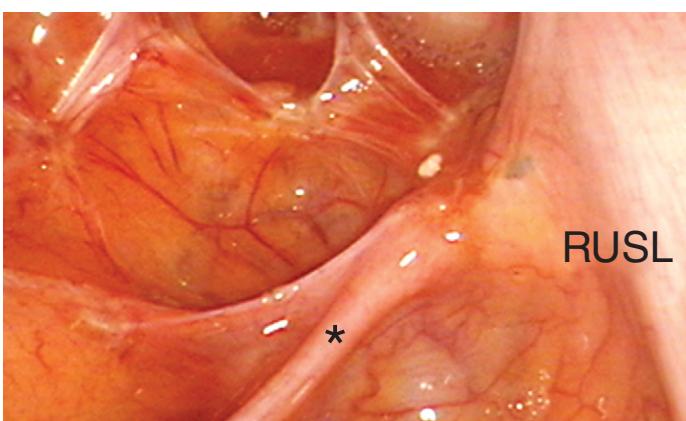

**Figure 13-10 The right uterosacral ligament (black arrow) is involved by invasive endometriosis manifest as a yellowish nodule with no associated hemorrhage.** The normal rectum (white arrow) is slightly tethered to this nodule, which will histologically show fibromuscular tissue surrounding gland/stroma complexes of endometriosis. A small right ovarian cyst (asterisk) is also adherent to this region.

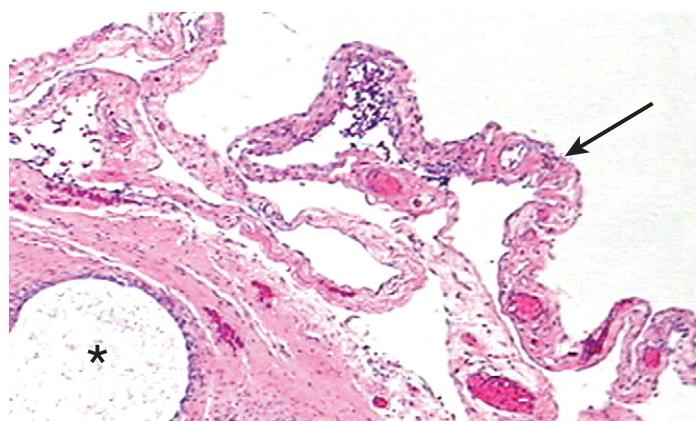

**Figure 13-11 Obliteration of the cul-de-sac.** The normal rectum (white arrow) can be seen to lead to a portion of the rectum which is rounded in appearance (black arrow) and adherent to both uterosacral ligaments. The ovaries are also adherent to their ipsilateral uterosacral ligaments. When the wall of the rectum is rounded, the muscularis is involved by significant endometriosis and some type of rectal surgery will be necessary to ensure complete removal of all invasive disease.

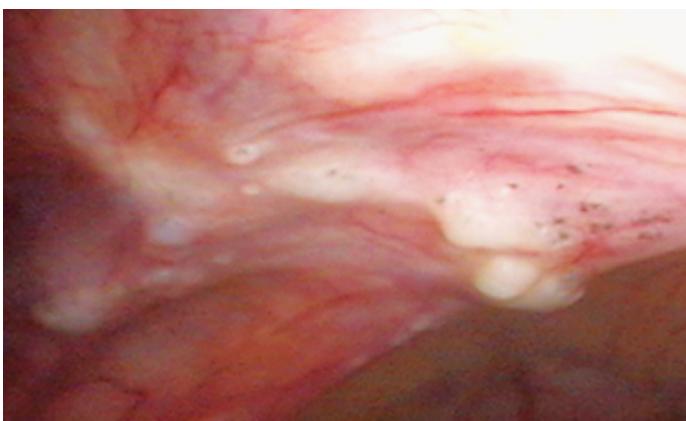

**Figure 13-14 This patient underwent laser vaporization of endometriosis performed by an experienced surgeon.** At second-look laparoscopy, persistent superficial endometriosis was present, as well as filmy adhesions induced by laser therapy.

**Figure 13-12 The normal rectum (asterisk)** leads into a small rectal nodule which is fused with a retroperitoneal nodule extending from the adjacent right uterosacral ligament (RUSL). Nearby, areas of active endometriosis in the cul-de-sac are associated with peritoneal scarring and retraction.

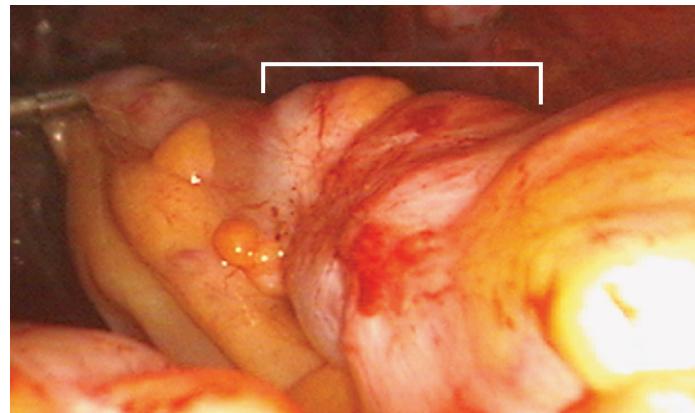

**Figure 13-15 Photomicroscopy of the lesion seen in Figure 13-14.** Superficial filmy adhesions with slight vascularity (arrow) were present over untreated superficial endometriosis (asterisk).

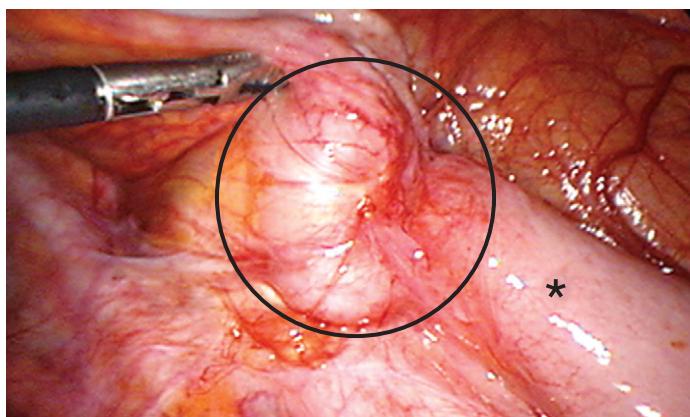

**Figure 13-13 Laser vaporization can leave behind abnormalities that can be confused with endometriosis.** Discrete flecks of carbon are usually easily distinguished from hemorrhage because of their dark black color with sharp borders. The white papular lesions are composed of a combination of incompletely treated endometriosis and foreign body giant cell reaction.

examining the ileum or redundant sigmoid colon loops, because even large nodules can be initially hidden (Fig. 13-16). Disease of the ileum can be superficial, in which case it is distributed linearly along the antimesenteric aspect of the ileal wall, or invasive and nodular (Fig. 13-17), in which case symptoms of obstruction may be present. Endometriosis of the appendix is often manifest as a white fibrotic area, which may curl the appendix upon itself so that it cannot be straightened out (Fig. 13-18). Disease of the cecum is rare and is frequently located near the base of the appendix (Fig. 13-19).

Symptomatic endometriosis of the diaphragm usually involves the posterior diaphragm and is not always visible with a laparoscope inserted through an umbilical port but is always visible through a second small-diameter laparoscope inserted beneath the right costal margin (Fig. 13-20).

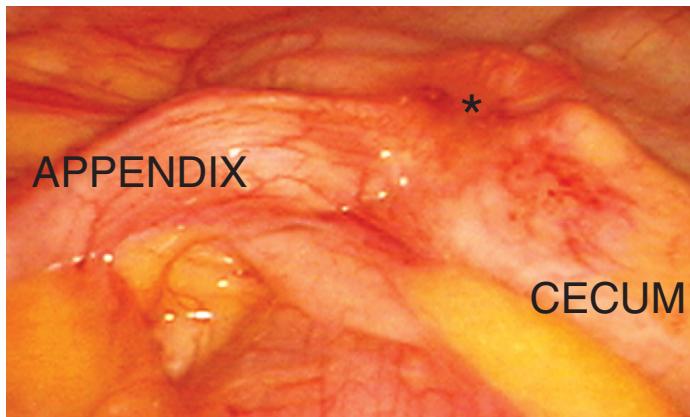

**Figure 13-16** A large nodule of endometriosis of the sigmoid colon (within the **white bracket**) is displayed by suspending the bowel with an atraumatic grasper. This lesion was not visible when the sigmoid was in its normal position and appears slightly smaller due to foreshortening caused by the position of the bowel in the frame.

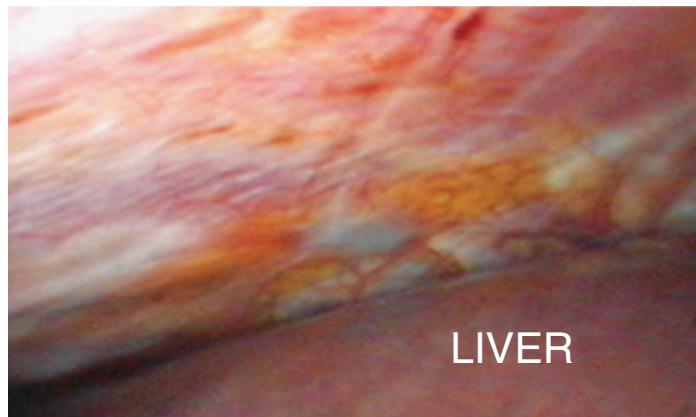

**Figure 13-17** A large obstructing nodule of ileal endometriosis is seen (within the **black circle**). The graspers at the upper left of the frame are in the vicinity of the ileocecal valve. The last portion of the normal distal ileum is marked by an asterisk. This patient lost 25 pounds in 4 months due to symptoms of intestinal obstruction and was treated by segmental resection and anastomosis.

**Figure 13-18** Endometriosis of the appendix is usually asymptomatic and frequently subtle. It is almost always manifest as whitish fibrosis (arrow), which curls the appendix toward the fibrosis. Hemorrhagic change or neovascularity is rarely present.

**Figure 13-19** The center of a cecal nodule of endometriosis is marked by the asterisk. There is slight nodularity of the bowel wall with some puckering and surrounding minimal neovascularity.

**Figure 13-20** Symptomatic endometriosis of the diaphragm is located along the posterior edge of the diaphragm and cannot always be seen with a laparoscope inserted through an umbilical port. This view was obtained through a 5-mm laparoscope inserted beneath the right costal margin and passed over the liver.

## General Gynecology

Quantifying the extent of endometriosis at surgery is problematic. The revised American Fertility Society (now called the American Society for Reproductive Medicine) classification system<sup>7</sup> of endometriosis is commonly used, but this system has limitations for measuring disease extent for the following reasons: Most of the available points score for adhesions rather than endometriosis. Of the endometriosis component of this system, most of the points are awarded the ovaries, which are not the most common site of involvement. The peritoneal surfaces of the posterior pelvis are the most common sites of involvement, but peritoneal disease is accorded only 10 points (4 points for superficial disease and 6 points for deep disease). No points are allowed for intestinal disease or disease in distant sites. Multiple manifestations of disease may produce the same point total, and there are over 100,000 possible combinations in which points can be scored.

Pelvic mapping of individual pelvic or intestinal sites of involvement is a more accurate measure of disease extent and is easier to apply than measuring the diameter of each implant and adding the results to obtain a total additive diameter of the implants.

## TREATMENT

Because fecundity is not improved by medical therapy in women with endometriosis-associated infertility and no medical therapy eradicates endometriosis, the only indication for medical treatment of endometriosis is for temporary relief of pain symptoms. Medical therapy is contraindicated in women with endometriosis-associated infertility. These patients are better served by advanced reproductive technology techniques or by surgery. Traditional medical therapies have aimed at producing states of pseudopregnancy or pseudomenopause, with resultant amenorrhea. These hormonal states induced by medical treatment were originally thought to physically eradicate endometriosis because for decades it had been erroneously thought that pregnancy and menopause physically eradicate the disease.

### Pseudopregnancy Therapy

Because some early studies identified a relatively high percentage of nulliparous women among endometriosis patients, it was concluded that pregnancy protected against the occurrence of the disease and could, in fact, cure endometriosis by a cytoidal toxic effect called *necrobiosis*. When oral contraceptive steroids were developed in the early 1960s, they were adopted as treatment for endometriosis because the estrogen/progestin mix within the birth control pills was thought to mimic the alleged beneficial effects of pregnancy. The hormone levels in early oral contraceptives (OCs) were very high compared to those of the modern era, and the dosage formulations that helped popularize OC therapy of endometriosis are no longer available. With newer, lower-dose formulations come fewer side effects, but possibly a decrease in efficacy for preventing or treating functional ovarian cysts.

Although the hormonal dosage in OCs has been reduced substantially over the years, symptom reduction during treatment is still observed in some women. There are many combinations of estrogens and progestins in OCs, and new OCs are brought to

market as others are dropped. It is impossible to mention a dose formulation that will be effective in reducing symptoms for all women for all time, but general guidelines can be followed. A monophasic low-dose (<50 µg of estrogen) pill with a non-varying hormone level may be preferable because endometriosis or troublesome breakthrough bleeding might be stimulated by changing hormone levels. A pill with less than 20 µg of estrogen may be associated with a higher incidence of breakthrough bleeding. Continuous therapy for 3 to 6 months without a withdrawal bleed may be preferable to cyclic therapy resulting in a menstrual flow every 28 days. Although presence of a menstrual flow probably has nothing to do with initiation of endometriosis, dysmenorrhea, whatever its cause, may be lessened during this induced amenorrhea. Newer contraceptive skin patches are available that contain similar hormones delivered by some OCs, but these have not been studied specifically for treatment of endometriosis symptoms. However, one would expect efficacy similar to OCs.

Medroxyprogesterone acetate (MPA) 30 mg orally for 90 days to mimic the high progesterone state existing in pregnancy resulted in decreased pain and a decrease in nodularity and tenderness on examination in many patients during therapy. Norethynodrel, a progestin, given orally at dosages of 30 mg daily for 6 months was reported to relieve pain in most patients during therapy and to be associated with a culdoscopically confirmed cure rate of almost 80%. The long-term outcome after cessation of therapy is unknown.

### Pseudomenopausal Treatment

Symptomatic postmenopausal endometriosis occurs less commonly than premenopausal symptomatic disease. The historical notions that either natural or surgical menopause physically eradicates endometriosis are clearly incorrect, although endometriosis certainly may be less symptomatic during estrogen deficiency of any origin. Accordingly, medications that decrease or suspend the production of estrogen by the ovaries have been developed.

Danazol was the first medicine approved in America for treatment of endometriosis. Although it is an androgen with masculinizing side effects, it was originally thought to produce primarily a pseudomenopausal state. It was later found to produce a chronic anovulatory state, similar to OCs, by reducing the midcycle luteinizing hormone (LH) surge. The recommended dose of 600 to 800 mg orally daily for 6 months is associated with a high prevalence of androgenic side effects, some irreversible, including acne, hirsutism, clitoral hypertrophy, temporal hair loss, or deepening of the voice and is equivalent to MPA given in a dose of 100 mg orally daily for 6 months.<sup>8</sup>

Gonadotropin-releasing hormone (GnRH) agonists are currently the most widely prescribed medicines for treating the symptoms of endometriosis. GnRH is secreted in a pulsatile fashion by the hypothalamus and binds to cells in the anterior pituitary gland to stimulate production of the pituitary gonadotropins LH and follicle-stimulating hormone (FSH), both responsible for normal ovarian function. The half-life of endogenous GnRH is 3.5 minutes. If the normal hypothalamic pulsatile release of GnRH is replaced by a release that is too high or too low, the pituitary gland will eventually stop producing LH and FSH in normal quantities. To capitalize on this biologic effect,

GnRH agonists bind to receptor sites on cells in the pituitary gland and, because of their long half-life of 3 to 8 hours, mimic a pulsatile GnRH signal which is too rapid and sustained, resulting in an initial increase and then a cessation of pituitary gonadotropin output. Ovarian function correspondingly increases temporarily, then subsides to menopausal status during treatment if suppression has occurred. The resultant clinical effect may be one of initial worsening of estrogen-dependent symptoms (because ovarian production of estrogen increases), followed by amenorrhea associated with improvement or absence of estrogen-dependent symptoms. Estrogen-dependent pain caused by adenomyosis, uterine fibroids, primary dysmenorrhea, ovulation pain, endometriosis, or unknown factors may all be relieved by such ovarian suppression. It is generally agreed that ovarian suppression of estrogen production by GnRH agonists is more profound than occurs with OC or danazol therapy. GnRH agonists can be given by nasal spray, injection, or pellet insertion.

Temporary improvement of symptoms on GnRH agonist therapy can be associated with an overall worsening of disease extent, as shown by reoperation 12 months after cessation of treatment<sup>9</sup> as well as a return of pain to baseline levels 9 months after cessation of therapy.<sup>10</sup> The efficacy of GnRH agonists is similar to danazol, whether the agonist is given by the intranasal<sup>11</sup> or the subcutaneous<sup>12</sup> route.

With nasal spray therapy, absorption across the nasal mucosa can be erratic, and the twice-daily dosing increases the likelihood of patient noncompliance. For these reasons, and because subcutaneous administration of some forms of GnRH agonists was found to be more efficacious than nasal administration,<sup>13</sup> intranasal therapy has largely been replaced by systemic therapy, either by injection of depot forms of GnRH agonists or by insertion of pellets of goserelin.

Gonadotropin-releasing hormone agonist therapy is associated with a significant rate of estrogen-deficiency side effects, including vasomotor symptoms, atrophic vaginitis, arthralgias, decreased libido, and weight gain. Loss of bone mineral density (BMD) appears during the first 3 months of treatment<sup>14</sup>; it remains controversial whether this is associated with irreversible loss of bone mineral content.<sup>15</sup>

Because cessation of GnRH agonist therapy is followed quickly by return of symptoms, longer durations of treatment with GnRH agonists (for 6 to 24 months) have been studied. "Add-back" estrogen therapy can be given to ameliorate hypoestrogenic side effects, including loss of BMD, with the target window of serum estradiol being between 30 and 50 pg/mL. Above this window, endometriosis may be stimulated to remain symptomatic. Below this window, bone loss may be substantial. Estrogen-only add-back therapy can increase pain due to endometriosis, so other add-back schemes have been studied.

Add-back therapy with norethindrone 5 mg daily without oral conjugated equine estrogens, 0.625 mg daily, preserved BMD without provoking symptoms.<sup>16</sup> MPA<sup>17</sup> and levonorgestrel have also been used effectively as add-back therapies. Add-back therapies have challenged the historical concept of "pseudo-menopausal" therapy of endometriosis by GnRH agonists because such treatments have created a hybrid class of therapy.

Gonadotropin-releasing hormone agonist therapy is expensive, does not eradicate endometriosis, and long-term treatment

is associated with symptoms in many women despite add-back therapy. These concerns may limit the use of such treatment in some patients.

Gestrinone (ethynodiol diacetate) is an antiprogestin that causes a decrease in serum estradiol as well as in the concentrations of estrogen and progesterone receptors on cell surfaces. Approved for use in Europe, it has androgenic side effects, including clitoromegaly, deepening of the voice, and hirsutism, all of which may be irreversible. It is taken orally one to three times per week to deliver a total weekly dose of 2.5 to 10 mg.

### Efficacy of Medical Therapy

#### *Infertility*

Medical therapy directed against treatment of endometriosis alone does not improve fertility in women with endometriosis-associated infertility<sup>18</sup> and has actually been associated with a reduction of fertility in these women. This may be due either to some direct negative effect of the medications or to the fact that the natural age-related decline in fertility is manifest following 6 months or more of treatment and eventual resumption of ovarian function. Medical therapy is therefore contraindicated for the symptom of infertility associated with endometriosis. However, medical therapy as an adjunct to assisted reproductive techniques appears to be helpful. In women with infertility associated with advanced stages of endometriosis, an extended course of a GnRH agonist given before ovulation induction and intrauterine insemination was found to improve fecundity over a shorter course of GnRH agonist.<sup>19</sup>

#### *Pain*

Both high-dose (50 mg/day) oral MPA and placebo given for 3 months were associated with improvement of symptoms and surgical findings at reoperation.<sup>20</sup>

Oral contraceptives given for 12 months appear equivalent for treating pain to GnRH agonists given for 4 months followed by OCs for another 8 months.<sup>21</sup> Low-dose OCs (0.02 mg of ethinodiol plus 0.15 mg desogestrel) given for 6 months have an equivalent effect to the GnRH agonist goserelin given for 6 months, with the return of pain in most patients by 6 months after discontinuation of medication.<sup>22</sup>

Oral danazol and injections of the GnRH agonists leuprolide depot<sup>23</sup> or triptorelin depot<sup>24</sup> had equivalent effects on laparoscopic assessment of extent of endometriosis, pain, and tenderness, although reduction of the serum estradiol level was more pronounced with the GnRH agonist and the free androgen index and liver enzymes were elevated by danazol treatment.

In women with rectovaginal disease, a levonorgestrel-releasing intrauterine system used for 12 months was associated with reduction of both symptoms and size of lesions.<sup>25</sup>

#### *Future Medical Treatments*

With the advance of research, new therapies are being developed that depart radically from the traditional historical categories of pseudopregnancy or pseudomenopausal therapy. These new therapies may allow more effective symptom control. These include aromatase inhibitors and medications to block angiogenesis. Also being studied are GnRH antagonists, which have similar actions as GnRH agonists, although without the

initial stimulation of ovarian estrogen production. Selective progesterone modulators, RU486, and tumor necrosis factor- $\alpha$  inhibitors are also being studied. It will be important to judge whether these medications are advanced on the basis of the response of symptoms rather than eradication of endometriosis.

### Ablative Surgical Treatment

Some surgical treatments do not require extensive tissue dissection and can be applied quickly, potentially by any surgeon. These include thermal ablation performed by laser vaporization, monopolar or bipolar electrocoagulation, argon beam coagulation, endocoagulation, and harmonic scalpel coagulation. The many variables affecting each of these treatments reduce their efficacy, one of the most important being the depth of destruction possible with each energy system. Although depth of tissue destruction may depend in part on the technique used by a particular surgeon, it is generally agreed that all thermal ablation techniques have the potential of incomplete treatment because of inadequate depth of tissue destruction. For example, the carbon dioxide ( $\text{CO}_2$ ) laser may vaporize only 100 microns in one short burst, whereas endometriosis may invade several centimeters beneath the visible surface. Deeper tissue destruction is possible with the laser in continuous mode. In some cases, the laser beam may be passed across the tissue too swiftly to allow any chance of eradication of even superficial disease. With monopolar electrocoagulation, the maximal depth of destruction may be only 1 or 2 mm, and the zone of desiccated tissue that builds up around the active electrode serves as an insulator that retards further flow of electrons, thus effectively limiting severely the depth of destruction by electrocoagulation. Bipolar electrocoagulation can be associated with a higher sustained temperature than monopolar coagulation because the close approximation of the bipolar paddles can allow continued electron flow and heat generation even when the tissue between the paddles is desiccated. Also, when the tissue between the paddles is desiccated, electrons will begin to pass through tissue alongside the paddles. This gives a much larger and possibly more dangerous electrosurgical “footprint” than monopolar coagulation. The details of electrocoagulation, such as the type of electrosurgical generator, power settings, type of active electrode, manner of use, and visual endpoint of adequate destruction, have not been adequately described in the literature. This lack of detailed instructional information makes its clinical use inconsistent.

With any thermal ablation technique, all important endpoints depend on the opinion of the surgeon. What is being destroyed, the depth of invasion of the pathology, and how completely it has been destroyed are all controlled only by the surgeon's opinion. The visual endpoint of adequate thermal destruction is ill-defined, other than for laser vaporization of superficial endometriosis, in which case normal yellow retroperitoneal fat is exposed. With all thermal ablation techniques, disease that may be deeply invasive will be treated identically to superficial disease, because the surgeon remains unaware of the difference. Thus, thermal ablation techniques effectively transform all endometriosis into superficial disease in the surgeon's eye. Unintentional damage to underlying structures is another danger of thermal ablation techniques, and the surgeon's understandable hesitancy to burn an underlying vital structure is yet

another contributing factor resulting in treatment that is too superficial and possibly incomplete.

### Surgical Excision

Many experts in endometriosis treat the disease by surgical excision, which may allow complete removal of superficial or invasive disease. Excision is the only form of treatment with cure of disease documented among reoperated patients. Conservative excision can usually be performed entirely laparoscopically, although laparotomy may be necessary for extreme cases with profound pelvic distortion, diaphragmatic involvement, or multiple areas of intestinal involvement. Excision may be performed with scissors, electrosurgery,  $\text{CO}_2$  or fiber lasers, or harmonic scalpel. Small-diameter (3 mm) monopolar scissors are a versatile tool, allowing multiple operations with one instrument, thus decreasing instrument changes (Table 13-3).

In addition to appropriate instrumentation, the surgeon must have a strategy that will allow the case to progress. Fortunately, endometriosis exhibits recurring patterns of pelvic involvement, which can be treated virtually the same way every time. Thus, a surgeon will need to learn only five or six separate techniques to manage most of the cases that will be seen.

In severe cases, the ovaries may be involved by endometriosis, with bilateral endometrioma cysts, which often are adherent to the uterosacral ligaments and/or pelvic sidewalls (see Fig. 13-10 and 13-11) and may obscure the posterior pelvis completely (Fig. 13-21). The size of these cysts may impede all other endometriosis surgery, so it is most advantageous to begin by puncturing and draining such cysts for decompression.

Endometrioma cysts of an ovary are best treated by cystectomy, because only drainage and burning the cyst wall is associated with a high rate of persistence. The ovary involved by an endometrioma cyst is frequently adherent either to the pelvic sidewall peritoneum, the ipsilateral uterosacral ligament, or both. The cyst wall is typically thick and fibrous, which helps the cystectomy process. After cortical incision to expose the cyst wall (Fig. 13-22), ovarian cystectomy is most typically performed using twoatraumatic graspers, one to pull on the cyst wall, the other to provide countertraction on the normal ovarian cortex. Cystectomy will proceed fairly smoothly in most cases

**Figure 13-21** Enlarged, adherent ovaries may call attention only to themselves but can hide impressive pathology. Complete obliteration of the cul-de-sac was hidden beneath these ovaries.

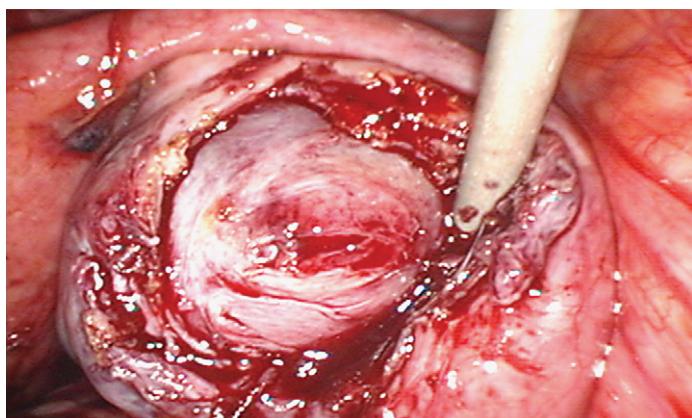

Table 13-3 Range of Functions Possible with Different Surgical Techniques for Endometriosis in Typical Use

†Suture can be cut with the CO<sub>2</sub> laser, but this is not recommended unless a backstop for the laser beam is used.

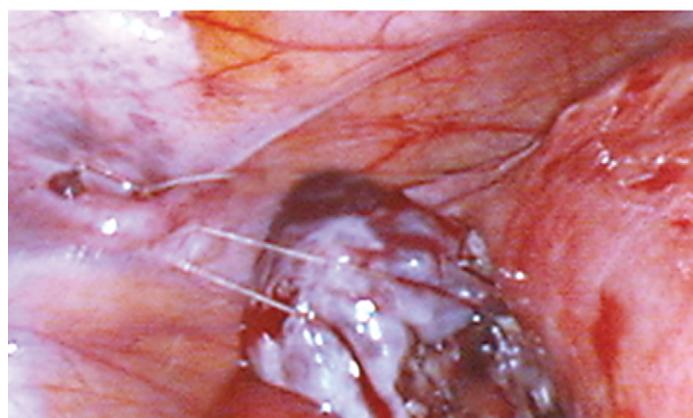

until the process encounters the area where the ovary is adherent to the uterosacral ligament. At this point, the cyst wall, ovarian cortex, and uterosacral ligament are all fused tightly together. It is helpful to approach this problem from the exterior of the ovary by simply amputating the small fused area from the rest of the ovary. The cystectomy process can be completed more easily, and the area of ovary that is still fused to the uterosacral ligament can be removed separately with disease of the ligament. When the ovary is adherent to the peritoneum of

the ovarian fossa, this peritoneum is commonly involved by endometriosis, frequently with impressive retroperitoneal fibrosis. This peritoneum can also be removed.

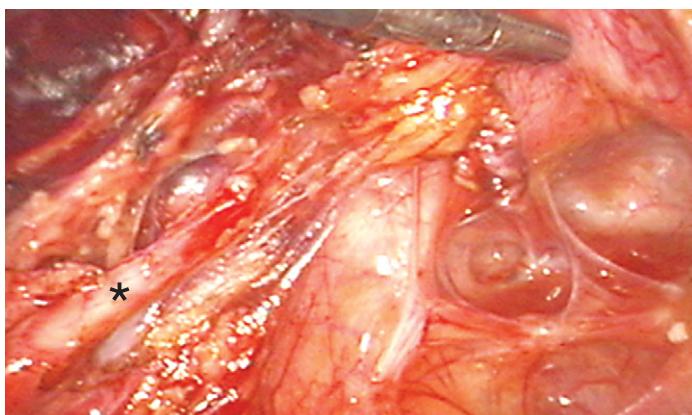

When surgery is performed on or around the ovaries, postoperative adhesions may form, especially if adhesions were already present. To reduce the chance of dense periovarian adhesions from forming, temporary ovarian suspension may be helpful.<sup>26</sup> The ovary can be suspended (Fig. 13-23) from the ipsilateral round ligament with 3-0 or 4-0 absorbable sutures

**Figure 13-22** Enlarged ovary incised to expose the underlying ovarian cyst.

**Figure 13-23** The left ovary has undergone ovariolysis and cystectomy. It has been suspended from the left round ligament with 3-0 Vicryl suture to avoid re-adherence to the raw surgical site on the left pelvic sidewall.

**Figure 13-24** The left ureter (asterisk) has been freed from retroperitoneal fibrosis related to endometriosis. The diseased peritoneum has been dissected bluntly and with electrosurgery from the ureter and is being held by the graspers.

or with nylon sutures that pass through the abdominal wall and can be removed 1 week postoperatively. An additional advantage of ovarian suspension is that it keeps the ovaries out of the surgical field during the rest of the case.

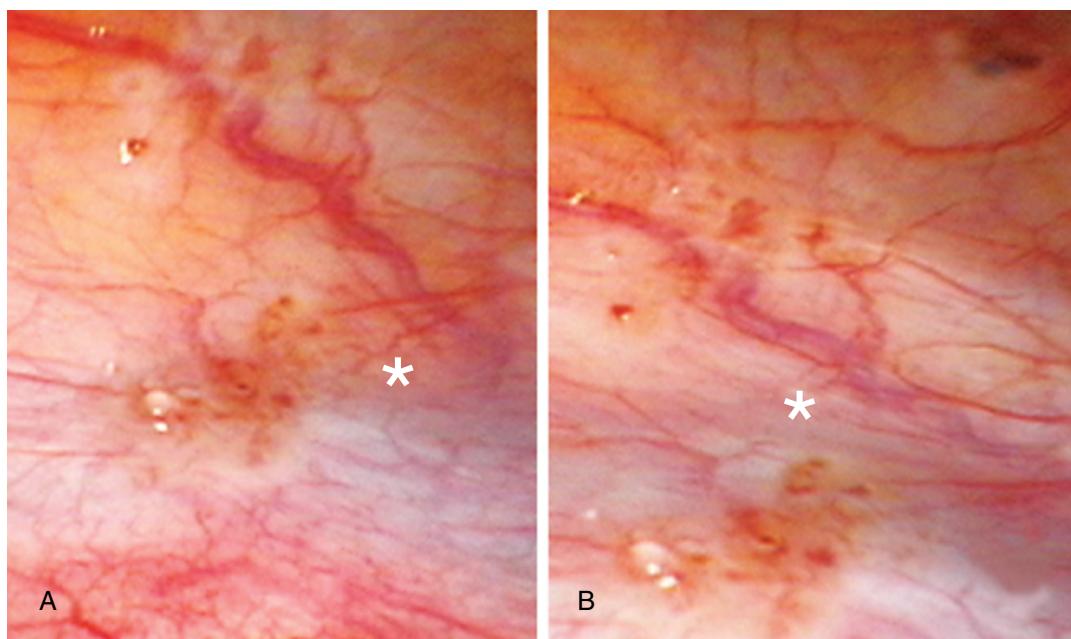

Invasive endometriosis of a uterosacral ligament can be excised by first creating a releasing incision in relatively normal peritoneum lateral and parallel to the ligament. The ligament can be bluntly undermined laterally and then separated from the posterior cervix by transection above the invasive disease. The ligament can then be isolated medially by a peritoneal incision

alongside it. The cut edge of the ligament adjacent to the cervix can then be grasped and the ligament shaved off the pelvic floor, with the line of excision occurring in soft, normal tissue.

When endometriosis is more biologically active, the peritoneum may be thickened and yellow, thus obscuring the active disease. Furthermore, retroperitoneal scarring associated with invasive disease may involve retroperitoneal structures, including the ureter and pelvic vessels. Dissection once again begins through normal peritoneum, but quickly involves ureterolysis (Fig. 13-24) or angiolytic, because all retroperitoneal fibrosis must be removed for complete excision of the disease.

Superficial peritoneal involvement can be identified by easy movement of the peritoneum containing the lesions over an underlying positionally static structure (Fig. 13-25). This is treated by grasping the abnormal peritoneum and tenting it up and away from underlying vital structures. An incision is created in normal peritoneum adjacent to the abnormality, and the abnormal peritoneum can be dissected away from the underlying normal tissue with blunt dissection or shaving with laser or electrosurgery.

Invasive disease of the bladder may require partial-thickness or full-thickness cystectomy. When the ureter is stenotic due to restrictive fibrosis or invasion by endometriosis, the origin of the ureteral pathology is always the ipsilateral uterosacral ligament. Treatment may require difficult ureterolysis followed by segmental ureteral resection and anastomosis. Simply relieving the obstruction by segmental resection/anastomosis and leaving the offending uterosacral ligament disease behind will guarantee continuation of symptoms and invite re-occlusion of the bypassing ureter.

**Figure 13-25** Superficial disease of the bladder. *A*, An asterisk marks the edge of a rather large retroperitoneal venous structure, which will remain unchanged in position by peritoneal traction. Areas of endometriosis are located in the center and top of the frame. *B*, When the peritoneum is pulled downward with a grasper, the areas of endometriosis and small peritoneal vessels are seen to move freely over the large retroperitoneal vein, as noted by the relative change of position with respect to the asterisk.

The rectosigmoid colon is the intestinal site most commonly involved by endometriosis (Table 13-4). As the number of intestinal sites of involvement increases, the likelihood of a full-thickness or segmental bowel resection increases. In its most severe form intestinal involvement presents as obliteration of the cul-de-sac. Obliteration of the cul-de-sac represents invasive disease of the uterosacral ligaments, cul-de-sac, posterior cervix, and usually the anterior rectal wall as well. When the wall of the rectum is rounded at its adherence to the posterior cervix, the muscularis is involved by significant endometriosis. Obliteration of the cul-de-sac is most efficiently treated by en bloc resection, which does not always require a segmental bowel resection to be done. The ileum, appendix, and cecum are less commonly involved by endometriosis. Intestinal disease can be treated by partial thickness, full-thickness, or segmental bowel resection as required. This can be done laparoscopically or by laparotomy. Disease of the appendix is treated by appendectomy.

Symptomatic diaphragmatic endometriosis penetrates the full thickness of this rather thin muscle and is usually concentrated along the posterior diaphragm near the posterior chest wall. The best treatment results are obtained by laparotomy with full-thickness resection of the affected areas of the diaphragm followed by repair with permanent suture.

Umbilical endometriosis is treated by local excision. Endometriosis of a surgical scar occurs most commonly following cesarean section. Scar endometriosis of a low transverse incision is commonly located near the end of the incision, more frequently on the right side. The endometriosis always involves the fascia and rarely communicates with the uterus or peritoneal cavity. The subcutaneous fat is sometimes minimally involved. Excision of fibrosis at all levels is curative in most cases. It is necessary in all cases to remove the portion of fascia involved by fibrosis because not all lesions will appear to be hemorrhagic. It is usually possible to close the fascia primarily without creating fascial relaxing incisions. Closure can be facilitated by flexing the operating table to reduce stretching of the abdominal wall.

Uterine cramps, either during menses or away from menses, may not be due to endometriosis. Uterine cramping is a uterine symptom that may not respond to endometriosis surgery alone. In women with uterine cramping that severely affects their lifestyle, a presacral neurectomy (Fig. 13-26) will enhance the

pain relief beyond excision of endometriosis only.<sup>27</sup> Transection or resection of normal uterosacral ligaments does not add to the pain relief of excision of endometriosis only.<sup>28</sup>

Surgery for endometriosis does not treat symptoms not due to endometriosis. Although persistent or recurrent pain following thermal ablation is frequently due to incompletely treated disease, pain following excision is usually due to something other than endometriosis because most patients will have been cured of their disease. A second excisional surgery will be less successful at pain relief than the first excisional surgery.

#### **Efficacy of Surgical Treatment**

The efficacy of a surgical technique is most accurately assessed by comparing disease extent before surgical treatment and at later reoperation. There has been no systematic, biopsy-controlled study in reoperated patients to assess the efficacy of any of the thermal ablation techniques. Aggressive excision at laparotomy<sup>29</sup> or laparoscopy,<sup>30,31</sup> however, is associated with a cure rate of more than 50%, even in patients with disease resistant to other forms of therapy. Excision of endometriosis is associated with impressive and long-lasting symptom reduction and quality of life improvement. Excision has been shown by a randomized, controlled trial to be more effective than placebo surgery in relieving pain due to endometriosis.<sup>31</sup>

Thermal ablation techniques have looked toward symptom reduction, rather than disease reduction, as a measure of efficacy. In a randomized, controlled trial, laser vaporization of peritoneal endometriosis was found to reduce pain compared to placebo surgery by 6 months after treatment.<sup>32</sup> Electrocoagulation or resection has been found to improve fecundity in endometriosis-associated infertility in early-stage disease in a randomized, controlled trial,<sup>33</sup> although an Italian study did not confirm this.<sup>34</sup> After surgical treatment of endometriosis, ovulation augmentation with clomiphene citrate combined with intrauterine insemination has been shown to improve fertility.<sup>35</sup>

Ovarian cystectomy is superior to cyst puncture, drainage and coagulation of endometriotic cysts for both pain relief and pregnancy rates.<sup>36</sup>

#### **Efficacy of Combined Medical/Surgical Treatment**

Intrauterine devices containing progestins may reduce dysmenorrhea after conservative surgical treatment of endometriosis.<sup>25,37</sup> A 3-month course of nasal GnRH agonist has not been found to contribute to pain relief after excision of endometriosis in patients with Stage III or IV disease.<sup>38</sup>

In women who have undergone excision of ovarian endometrioma cysts, postoperative use of OCs is associated with a slightly higher rate of new cyst formation compared to untreated patients.<sup>39</sup>

### **CLINICAL COURSE AND PROGRESSION**

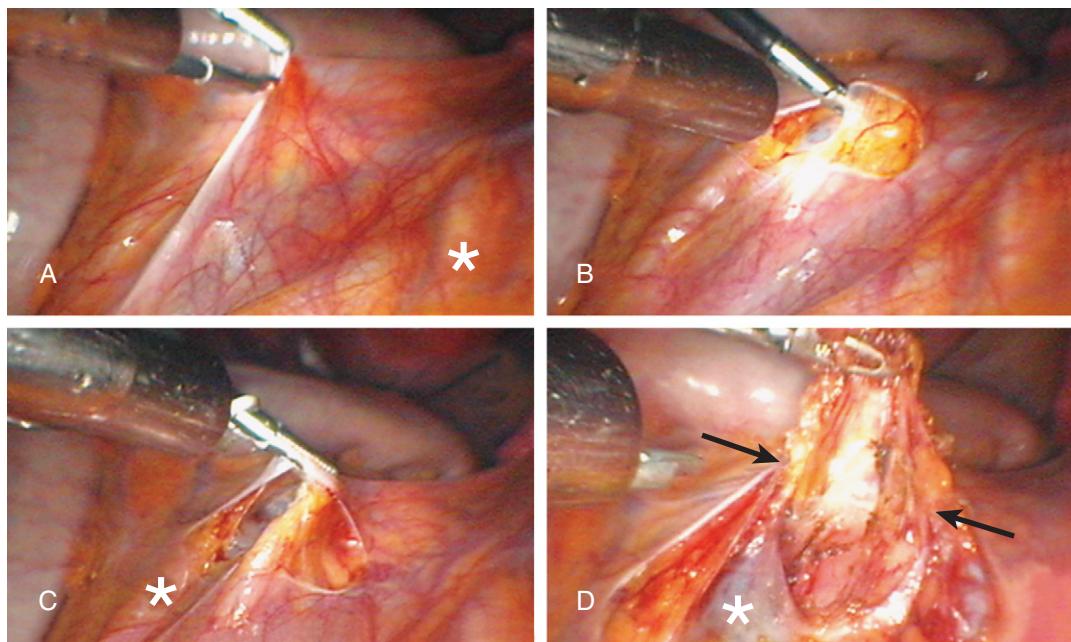

The clinical course of endometriosis is highly variable. Some women seem destined to have only scattered superficial disease, whereas others are destined to have widespread invasive disease. Many will have both superficial and invasive disease in different pelvic areas. Disease at either end of the clinical spectrum may or may not cause symptoms, and symptoms can worsen even if the disease does not. The age-related evolution in color

**Table 13-4**  
**Frequency of Involvement of Intestinal Sites among 2589 Patients with Biopsy-proven Endometriosis\***

Site	Number of Patients
Rectal nodule	342
Sigmoid	445
Ileum	116

<sup>†</sup>Total of sites of involvement exceeds number of patients with intestinal involvement because 213 patients had more than one site of intestinal involvement.

**Figure 13-26 Surgical steps in laparoscopic presacral neurectomy.** A, The peritoneum overlying the sacral promontory is elevated and the pleat of tissue created is being cut with electrosurgery. The right ureter is marked by an asterisk. B, A transverse peritoneal incision is created between the edge of the sigmoid mesentery on the left and the right common iliac vessels on the right. Blunt dissection at the left angle of this incision allows the periosteum to be exposed and the presacral plexus to be isolated. C, The edge of the sigmoid mesentery is marked by the asterisk. The left common iliac vein is seen as a bluish structure beneath the mesenteric vessels at the left margin of the peritoneal incision. The presacral plexus is being elevated by graspers and will be transected adjacent to the superior cut peritoneal edge. D, After proximal transection of the presacral plexus, it is dissected bluntly off of the underlying periosteum and from small presacral vessels. The left common iliac vein (asterisk) is seen. The presacral plexus will then be transected distally along a line between the two arrowheads.

appearance of endometriosis will cause the spurious impression of appearance of new disease if early, subtle forms of the disease were not correctly diagnosed at initial surgery. Actually, endometriosis appears to usually be geographically static and non-spreading by any type of measurement of pelvic involvement. Local fibromuscular hyperplasia of involved parenchymal structures associated with invasive disease or enlargement of endometriotic cysts represent the chief modes of “progression” of endometriosis, although such local proliferation does not indicate more widespread geographic involvement of more pelvic areas. This positionally static nature of endometriosis is what leads to its potential curability by excisional surgery. At the same time, the positionally static nature of the disease can contribute to a picture of success following any therapy because if it is assumed that endometriosis is progressively spreading, then lack of spread during or after treatment can be attributed to the “success” of treatment rather than simply a consequence of the natural history of the disease.

### PITFALLS AND CONTROVERSIES

Historic pitfalls surrounding endometriosis persist almost unchanged today compared to previous eras. “New” discoveries about the disease have frequently already been discovered, only to be forgotten by succeeding generations of clinicians. There

are many important examples of this phenomenon. Retroperitoneal “adenomyotic” disease was one of the first manifestations described in the literature almost a century ago, only to be rediscovered in Europe at the millennium’s end. By 1940 it was apparent that peritoneal endometriosis was more common and more clinically important than ovarian disease, but it is still thought by some that the ovaries are the most commonly involved pelvic site. Subtle endometriosis and even colorless lesions were known by the mid-20th century. In the same era, clinicians were amazed by the apparent increase in prevalence of endometriosis, attributing it to better diagnosis of subtle lesions and looking for it in age groups where it was unexpected, such as teenagers. By the 1950s, it appeared that endometriosis could be cured by conservative excisional surgery, which has once again been proven to be true.

A randomized, controlled trial is considered the “gold standard” of evidence of therapeutic efficacy. Randomized, controlled trials on endometriosis therapy have frequently been conducted with inherent fundamental errors, such as inadequate identification of disease at initial surgery or reoperation, assessing the response of symptoms rather than the response of the disease, or basing some portion of the study in part on the assumed correctness of the theory of reflux menstruation. The result of this is that errors of understanding and clinical management have become even more firmly entrenched.

# Chapter 14

## Uterine Leiomyomas

Rahi Victory, MD, Walter Romano, MD, John Bennett, MD,  
and Michael P. Diamond, MD

### KEY POINTS

- Fibroids occur commonly in reproductive-age women and can cause significant morbidity.
- Risk factors include primarily age and African American race, but incidence may also be affected by menstrual history, endogenous and exogenous hormone exposure, infertility history, and cigarette smoking.
- Symptoms differ widely but may include menorrhagia, pelvic pain and pressure, infertility, and pregnancy-related complications.
- Diagnosis can be made by radiographs, transabdominal and transvaginal ultrasound, magnetic resonance imaging, and hysteroscopy.
- Treatment includes both medical therapy, primarily in the form of gonadotropin-releasing hormone agonists, and surgical therapy using either endoscopic or open laparotomy approaches for myomectomy or hysterectomy.
- Significant controversy exists regarding many aspects of the impact, diagnosis, and management of uterine leiomyomas.

Uterine leiomyomas (leiomyomata or fibroids) are benign smooth muscle tumors of the human uterus that represent one of the most common gynecologic problems in women of reproductive age. While most leiomyomas are asymptomatic, they can result in debilitating symptoms having a significant impact on quality of life. They are the primary indication for the nearly 600,000 hysterectomies performed each year in the United States, and for 37,000 myomectomies performed annually.<sup>1</sup>

Risk factors for the development of myomas, complications and symptoms related to fibroids, and reproductive outcomes related to these benign tumors are areas of controversy. Patients are frequently confused or unaware of the range of options available for treatment of myomas. This chapter reviews the epidemiology, symptomatology, diagnosis, medical therapy, and surgical treatment of fibroids. Controversies still existing in the literature are also reviewed as are suggested future directions for research and current principles for counseling patients with fibroids.

### EPIDEMIOLOGY

The exact incidence of leiomyomas in reproductive age women is difficult to ascertain for several reasons. Primarily, the majority

of fibroids are asymptomatic, resulting in low clinical detection rates.<sup>2,3</sup> Cadaveric studies are also hampered by the fact that many fibroids regress in size with age. Furthermore, different diagnostic methodologies have highly variable sensitivities for the detection of uterine leiomyomas. In a comprehensive review of patients in the United States conducted by Schwartz, incidence rates varied from 2.0 to 12.8 per 1000 women per year.<sup>1</sup>

Age plays a significant role in the detection of fibroids, with increasing incidence rates as women approach the perimenopause, followed by fibroid regression in the postmenopausal years.<sup>4</sup> Marshall et al demonstrated that in 95,061 patients followed in the Nurses Health Study, the baseline incidence was 4.3 per 1000 women-years in women between 25 and 29 years of age, 9.0 between 30 and 34 years of age, 14.7 between 35 and 39, and 22.5 between 40 and 44, demonstrating a linear increase in incidence with increasing age.<sup>5</sup> Thus, in the group aged 40 to 44 years, there was a 5.2 fold increase in fibroid incidence compared with women aged 25 to 29 years. With declining hormonal stimulation in the postmenopausal years, incidence rates decline.<sup>2,6</sup>

Racial disparities also play a significant role in the epidemiology of leiomyomas. Multiple studies have demonstrated significant differences between patients of African American descent and white patients. Shwartz demonstrated that when adjusting for age, standardized rates of incidence were 2 to 3 times higher in black vs. white patients.<sup>1</sup> Faerstein et al demonstrated that even when controlling for age at menarche, oral contraceptive use, body size, smoking, hypertension, diabetes, and history of pelvic inflammatory disease, black patients had an adjusted odds ratio of 9.4 compared with white control cases.<sup>7</sup> More recently, Baird et al examined a random selection of patients without any specific gynecologic complaints from an urban, prepaid health plan.<sup>8</sup> This study demonstrated that both premenopausal and postmenopausal black patients had a higher rate of diagnosis of fibroids prior to the study (45% vs. 21% and 74% vs. 42%, respectively). In women with no previous history of fibroids, 59% of black women were newly diagnosed by ultrasound to have fibroids versus 43% of white women. When controlling for body mass index (BMI) and parity, black women had an odds ratio of 2.7 for the presence of leiomyoma (95% CI, 2.3 to 3.2;  $P < 0.001$ ). Black women were also found to have a higher incidence of multiple fibroid tumors (74% vs. 31%). Although there were no racial differences in fibroid size in women with a previous history of fibroids, black women with newly diagnosed fibroids were more likely to have larger leiomyomas than white women. These differences also manifest in different

## General Gynecology

management strategies, with black women being more likely to undergo hysterectomy for fibroids and at a younger age than white patients. Marshall et al demonstrated that age standardized rates (per 1000 woman-years) for fibroid incidence were lowest for Asian women, followed by white women, then Hispanic women, and substantially increased for black women (10.4, 12.5, 14.5, 37.9 per 1000 woman-years, respectively).<sup>5</sup>

### RISK FACTORS

While age and race are, epidemiologically, the most significant risk factors for the development of uterine fibroids, many other factors have been analyzed for their potential contribution to the development of these tumors. Although the impact and prevalence of these risk factors vary among specific populations, their pathophysiologic associations may be categorized according to hormonal and nonhormonal mechanisms.

#### Menstrual Factors

Multiple studies have demonstrated increased fibroid growth in response to estrogenic stimuli, with a correspondingly significant reduction in growth when gonadotropin-releasing hormone (GnRH) analogs are used to induce a hypoestrogenic state.<sup>9</sup> Thus, prolonged estrogen exposure should increase the incidence of leiomyomas. This theory is supported by data that indicate an increased risk of fibroid incidence in patients with early menarche.<sup>10-13</sup> Although these studies are not consistent with regard to populations examined, both Marshall and Faerstein demonstrated significant increases in fibroid incidence in women with menarche occurring below 11 years of age.<sup>7,10</sup> However, while both studies demonstrated increased risks, Faerstein demonstrated nearly twice the risk found in Marshall's study with an adjusted odds ratio of 2.4 (95% CI 1.1, 5.6) versus Marshall's adjusted odds ratio of 1.35 (95% CI 1.19, 1.53). In contrast, most studies demonstrate either significant decreases or trends toward decreased fibroid incidence in women in whom menarche occurred after 13 years of age.<sup>1</sup> Against referent menarchal ages of 12 or 13, patients with menarche occurring after age 13 had reductions in fibroid incidence ranging from 17% to 60%. These reductions were greatest in women who experienced menarche at age 16 or greater.<sup>9,13</sup> More recently, Wise et al examined a cohort of 22,895 African American women. For women with menarche after the age of 12 to 13, the risk progressively decreased with increasing menarchal age, resulting in a 30% reduction among women with menarche after age 15.<sup>14</sup>

Menstrual patterns also may have an effect on the risk of fibroids. Chen et al assessed risk factors for fibroids in women undergoing tubal sterilization, in a population of reproductive age women (Table 14-1).<sup>15</sup> White women with heavy menstrual flow and cycle duration longer than 6 days had significantly increased risk of uterine leiomyoma, with odds ratios of 1.4 and 1.5, respectively. However, there were no significant menstrual-related associations for African American women. Cycle regularity, dysmenorrhea, prolonged cycle length, and intermenstrual bleeding had no significant association with leiomyoma. While Faerstein found no significant association between fibroids and cycle interval, cycle duration, or menstrual irregularity, patients with menstrual flow longer than 6 days demonstrated a trend

toward increased fibroid incidence, with an odds ratio of 1.4 (95% CI 0.9, 2.1) when controlled for confounding variables.<sup>7</sup>

#### Gravidity and Parity

Women with a history of pregnancy and childbearing appear to have a reduced risk of fibroids. The risk with at least one live-born child is reduced by 20% to 50%.<sup>1</sup> The majority of studies have demonstrated that increasing parity corresponds with lower fibroid incidence, with reductions of up to 70% to 80% for women with greater than four deliveries.<sup>6,10,13,16</sup> In contrast, Faerstein found no difference in risk of fibroids when controlling for parity in a multivariate model that accounted for all relevant confounding variables.<sup>7</sup> Interestingly, Chen et al found a substantial risk reduction of up to 70% in white women with two or more live children; however, in women of African American descent, there was no relationship between parity and fibroid incidence.<sup>15</sup> Wise also demonstrated no significant impact of parity on fibroid incidence in African American women.<sup>14</sup> Thus, while it would appear that the risk of fibroids decreases with increasing parity, there is some suggestion that other factors, such as race, likely account for a greater degree of the variance in fibroid incidence. Moreover, it is possible that women with fibroids have a greater incidence of infertility (see later discussion) and thus fewer pregnancies.<sup>9</sup>

Until recently, there was no evidence that age at first delivery has a significant impact on the incidence of fibroids. In the cohort study by Wise, multivariate analyses demonstrated that African American women with progressively greater age at first delivery had significantly lower risks of uterine leiomyomas compared with women whose first delivery occurred before 20 years of age.<sup>14</sup> No such relationship has been demonstrated among white women. In contrast, there is some controversy about the significance of age at last delivery and its impact on fibroid risk. Women who deliver prior to the age of 35 are at significantly increased risk of developing or having fibroids compared with women who were older than age 35 at their last delivery.<sup>6,13</sup> In contrast, Faerstein demonstrated no significant increase in risk of fibroids in women greater than 35 years of age compared with women less than 25 years of age when controlled for covariates.<sup>7</sup> Similarly, Chen et al demonstrated no increase in risk of fibroids based on age at last delivery compared with a reference group of women less than 24 years of age whether they were white or African American.<sup>15</sup>

#### Infertility

Discussions of the impact of a diagnosis of infertility on the risk of fibroids are marred by heterogeneity in definitions of infertility, prior infertility investigations, and prior exposure to infertility-related treatments, as well as difficulty in ascertaining whether the fibroids caused the infertility or whether the infertility caused the fibroids. However, most studies suggest an association between infertility and the risk of developing fibroids. Biologically, the substantial proportion of oligomenorrheic women who constitute most infertile populations would be at risk of unopposed estrogen states with consequent impact on leiomyoma growth and development. However, to date no epidemiologic studies have specifically examined this relationship. Marshall et al demonstrated a 35% increase in fibroid risk in nulliparous patients with a prior history of infertility compared

with nulliparous patients with no history of infertility, while Faerstein found no increased risk in general, but a nearly 2.5-fold increase in risk in patients diagnosed with infertility prior to age 25.<sup>7,10</sup>

### Hormone Exposure

Animal studies have demonstrated hormonal responsiveness of leiomyomas to estrogens and progestins. Based on these studies, it is plausible that exogenous estrogen and progestin exposure would influence the risk of uterine leiomyoma. Studies examining the relationship between combined oral contraceptives (OCs) and fibroids have yielded conflicting results, with some showing increased risks and others showing no risk or risk reductions of up to 31% in women using oral contraceptives for more than 10 years. In African Americans, the evidence appears to suggest that OC users are at increased risk of fibroid growth, especially when OCs are initiated during adolescence.<sup>14</sup>

Although one study demonstrated a strong correlation between depot medroxyprogesterone acetate injectable contraception and decreased fibroid incidence, the majority of clinical studies demonstrate a significant role of progestins in stimulation of fibroid growth. At least three randomized, controlled trials of GnRH analog suppression plus progestin add-back therapy demonstrated that progestin add-back nullified the

suppressive effects of GnRH therapy, with at least one study showing an increase in fibroid growth in the progestin add-back group.<sup>17</sup>

It is well established that fibroids regress in the postmenopause period. Thus, persistent hormonal stimulation may negate the natural tendency of leiomyomas to decrease in volume and incidence following menopause. Studies of postmenopausal hormone replacement therapy suggest either no growth or a minimal increase in fibroid growth and symptomatology.<sup>18–21</sup> The studies examining this relationship have been conducted in small population samples with limited statistical power. Reed et al studied the effect of HRT use on having a first diagnosis of fibroids.<sup>22</sup> HRT use for more than 5 years resulted in a 4-fold increase in incidence of first diagnosis of uterine leiomyomas in peri- and postmenopausal women with a BMI less than 24 kg/m<sup>2</sup>.

BMI itself has been investigated as an independent risk factor for fibroid growth. Increasing BMI appears to substantially increase risk of fibroid development and growth.<sup>6,7,13,23</sup> Increasing BMI appears to lead to increased risks. Faerstein demonstrated a 2.3-fold increase in risk only for women with BMI greater than 25.4 kg/m<sup>2</sup>.<sup>7</sup> However, others have not shown a significant increase in risk related to BMI.<sup>11,12,15,24</sup> Wise demonstrated that BMI had an impact on the relationship of parity to fibroid risk.<sup>14</sup> Parous

## General Gynecology

women with a BMI less than 27 kg/m<sup>2</sup> had a 40% reduction in risk compared with nulliparous women, whereas this risk reduction was reduced to only 20% in parous women with a BMI greater than 27 kg/m<sup>2</sup>.

Cigarette smoking has consistently been shown to reduce the risk of fibroids. Most studies demonstrate a 20% to 50% reduction in fibroid risk when controlled for confounders, including BMI.<sup>6,12,13,25</sup> In contrast, Chen et al demonstrated that increased risk was present only in white smokers with a daily habit of more than 1 pack per day use.<sup>15</sup> Ex-smokers had no increased risk. Wise et al similarly demonstrated no significant change in risk among African American women based on smoking status.<sup>14</sup> Although, theoretically, smoking contributes to lower estrogen levels with consequent decreases in fibroid growth, this relationship has not been proved.<sup>26</sup> Derangements in estrogen metabolism, however, may contribute to the risk reductions observed. Furthermore, the association between decreased fibroid incidence and smoking may in part be due to the strong correlation between smoking and decreased BMI.

### Summary

In summary, many factors have a potential contribution to fibroid risk. The preponderance of risk is likely associated with age and race. Increasing age contributes to increasing fibroid incidence until the menopause at which time significant fibroid regression occurs almost universally. Menarchal age also appears to significantly affect fibroid risk. African American women are at significantly increased risk of leiomyomas. The significance of the contributions of age and race may outweigh the effect of other variables and explain the frequent discrepancy in findings between the various epidemiologic studies cited. Hormone-related risk factors appear to increase risk, but there is significant controversy among studies about the degree and nature of these risks. Furthermore, prospective large-scale studies are necessary to determine the actual contribution and significance of risk factors for leiomyomas.

### PATHOGENESIS

A variety of mechanisms have been proposed for the initiation of tumorigenesis necessary for fibroid formation. Hypotheses include genetic predisposition, menstrual cycle-related mitotic dysregulation, myometrial cell phenotype transformation in response to ischemia, and an inherent myometrial predisposition to fibroid formation. Despite the abundance of theories and evidentiary support, a specific common cause has yet to be identified in fibroid formation.

### Genetic Etiology

Fibroid tumors appear to develop from a single progenitor cell, causing them to be monoclonal. Initially, this evidence was derived from analyzing the two different alleles of the X-linked glucose-6-phosphate dehydrogenase (G6PD) enzyme in fibroid tumors.<sup>27</sup> Townsend demonstrated that each tumor had only one of the two alleles, with either only type A or type B G6PD isoenzymes present in any given tumor. Moreover, within the same uterus, different fibroids could have different alleles, establishing the individual origin of each tumor. More recently, these data have been supported by studies using methylation

sensitive restriction endonuclease enzymes that have demonstrated monoclonal origins based on analysis of the androgen receptor allele and the phosphoglycerokinase gene.<sup>28,29</sup>

### Specific Gene Defects

Further evidence for a genetic basis for leiomyomas derives from the presence of common genetic abnormalities. While the majority of fibroids are chromosomally normal, approximately 40% have chromosomal abnormalities.<sup>30</sup> Gross et al classified these abnormalities into six cytogenetic subgroups: t(12;14) chromosomal translocation, trisomy 12, rearrangements of the short arm of chromosome 6, rearrangements of the long arm of chromosome 10, and chromosome 3 and 7 deletions.<sup>30</sup>

To date, the chromosomal anomaly most commonly identified is the t(12;14)(q14-q15;q23-q24) translocation, which is evident in approximately 20% of all leiomyomas.<sup>30</sup> The q14-q15 region on chromosome 12 is significant because of its anomalous presence in other mesenchymal tumors. Rearrangements of the 12q14-q15 region have been found in gynecologic related neoplasms, including endometrial polyps and breast fibroadenomas, as well as in salivary gland adenomas, angiomyomas, hemangiopericytomas, pulmonary chondroid hamartomas, and salivary gland adenomas. This region is of particular interest because it codes for a high mobility group protein (HMGIC) that binds to DNA, inducing transcription-related conformational changes.<sup>31</sup> The HMGIC (and HMGIY; see later discussion) proteins are both expressed highly in tumor cells and during embryogenesis.<sup>31</sup> Although their precise role is not understood, it is believed that both function as proliferation factors in tissues of mesenchymal origin. Molecular analyses revealed that normal endometrium had no expression of the HMGIC protein, while chromosomally aberrant leiomyomas had high levels of HMGIC protein expression.<sup>31</sup> The 14q23-24 region is also of interest because of its specificity for uterine leiomyomas and its proximity to the estrogen receptor beta gene (ER $\beta$ ). Interaction between these two loci may factor in the development of uterine fibroids. However, to date there is no evidence to indicate up-regulation of ER $\beta$  transcription in uterine leiomyomas.<sup>32</sup> Recently the RAD51L1 gene has been implicated in 14q23-24 rearrangements, with a purported function in cell cycle regulation. However, its specific role in leiomyoma genesis has yet to be determined.<sup>26</sup>

Rearrangements of the short arm of chromosome 6 (6p21) have been found in less than 5% of leiomyomas.<sup>26</sup> This region is of interest because it codes for HMGIY, a protein with similar properties to the HMGIC gene. This protein has been demonstrated in other common neoplasias including lipomas, hamartomas, and endometrial polyps.<sup>33-37</sup> Expression is increased in fibroids with 6p21 abnormalities compared with normal endometrium, but unlike HMGIC, HMGIY expression is also present in normal endometrium and chromosomally normal leiomyomas.<sup>38</sup> Thus, its exact function in the genesis of leiomyomas is not known.

Deletional abnormalities of chromosome 7, del(7)(q22q32) for example, have been found in 17% of chromosomally abnormal fibroids.<sup>39</sup> These aberrations are often present in mosaic cell lines in fibroids. Their presence has been noted in other neoplasms such as lipomas and endometrial polyps although they are most commonly found in leiomyomas. The

specific region of 7q22 has been implicated as the region affected by deletions; however, this region codes for a variety of genes with cell growth and development functions. No specific deletion of any of these genes has elucidated the pathogenesis of fibroids.

Trisomy 12 cell lines are thought to play a role by increasing HMGIC expression.<sup>40</sup> Aberrations in chromosomes 10 and 3 also have been noted in leiomyomas, but putative genes and their role in fibroid pathogenesis remain to be identified.<sup>41</sup>

### **Heritability**

As discussed earlier, ethnicity plays a significant role in the predilection for developing uterine leiomyomas. Women of African American descent have a 2- to 10-fold increase in the incidence of uterine fibroids compared with white women, supporting a genetic predisposition to fibroids based on differing racial DNA profiles. These data may be used to help isolate specific genes responsible for these differences. However, to date, there has been no identification of a racially specific gene or alteration of gene expression leading to increased fibroid formation.

Two studies of fibroid incidence in twins validate a heritable genetic hypothesis for fibroids. The Australian twin registry demonstrated a greater than 2-fold twin-pair correlation for hysterectomy in monozygotic versus dizygotic twins.<sup>42</sup> Fibroids represent the most common indication for hysterectomy; thus supporting a genetic link for fibroids. However, this study did not specifically assess the number of uterine leiomyomas, leaving other genetic variables as potential contributors to the increased hysterectomy incidence among monozygotic twins. More recently, a Finnish twin cohort study analyzed hospitalization for fibroids and determined that there was a higher incidence of hospitalization among monozygotic compared with dizygotic twins.<sup>43</sup> However, ultrasonographic assessment demonstrated no significant increase in risk based on zygosity. The authors concluded that other risk factors may contribute as much to the incidence of fibroids as genetic predisposition.

Family history of fibroids has been reported, first by Winkler and Hoffman in 1938, who demonstrated a 4.2-fold increase in fibroids among first-degree relatives.<sup>44</sup> Two further studies demonstrated similar findings in first-degree relatives and sisters of affected individuals in a Russian population, with one study demonstrating an increase from a baseline of 2.45% to 26.1% in sisters of affected patients and to 19.7% in daughters of affected patients.<sup>45,46</sup> Schwartz et al examined familial aggregation patterns in a study of 638 women.<sup>47</sup> All patients were between the ages of 18 and 59 years and had either operative or ultrasonographic evidence of leiomyomas. These patients were matched to 617 controls. The odds ratio for leiomyomas was 2.5 in patients with a positive family history, increasing to 5.7 in patients with a family history of fibroids and a positive diagnosis prior to 45 years of age.

Further evidence of genetic associations can be derived from analysis of heritable conditions that predispose to fibroid development. For example, Reed syndrome is an inherited autosomal dominant trait that causes a significant increase in both uterine and cutaneous leiomyomas. The gene responsible codes for a tumor suppressor gene, and mutations in the gene decrease tumor suppressor function.<sup>26</sup>

### **Summary**

In summary, molecular, genomic, and epidemiologic evidence all support a genetic hypothesis in the genesis of some uterine leiomyomas. Although no specific genetic defects have been clearly linked to the initiating mechanism in fibroid development, further studies are warranted to determine whether specific genetic derangements contribute to the formation of fibroids. Since the majority of fibroids remain chromosomally normal, other factors also must play a crucial role in the pathogenesis of leiomyomas.

### **Hormonal Etiology**

It has long been believed that uterine leiomyomas are estrogen-dependent tumors. More recent evidence suggests a plausible causative role for progesterone as well.<sup>48</sup> Despite a substantial number of studies evaluating the role of sex hormones in fibroid etiology, growth, and development, controversy exists and many questions remain.

### **Estrogen**

Extensive effort has been devoted to the study of estrogen receptors and uterine leiomyomas. Although some controversy exists over the presence of increased estrogen receptors in leiomyomas, most studies indicate that fibroids have a higher concentration of estrogen receptors than does normal myometrium.<sup>26</sup> While myometrial estrogen receptor concentrations vary during the normal menstrual cycle, Sadan et al demonstrated that fibroid estrogen receptor concentrations remain elevated throughout the menstrual cycle, regardless of fibroid volume.<sup>49</sup> Others have demonstrated that estrogen receptor alpha and beta both are present in leiomyomas and that both may be up-regulated when compared with normal myometrium.<sup>32,50</sup> The finding of ER $\beta$  up-regulation in myomas is significant because of the proximity of the gene locus to the region of chromosome 14 involved in the t(12;14) chromosomal translocation commonly found in uterine leiomyomas.

Several authors have demonstrated increased concentrations of estrogen within leiomyomas.<sup>51,52</sup> Yamamoto et al showed that there was a decreased conversion of estradiol to its bioactively weaker metabolite of estrone in leiomyomas as compared with normal endometrium.<sup>53</sup> Potential causes may be related to reduced activity of 17 $\beta$ -hydroxysteroid dehydrogenase, or to increased levels of aromatase enzyme.<sup>52</sup> Via either pathway, precursors would be converted to increased levels of estrogenic compounds, with potential stimulatory effects on myometrial and hence leiomyomatous cells. These effects are thought to occur in an autocrine or intracrine manner, suggesting a local effect. This theory is supported by multiple studies that fail to demonstrate any substantial difference in serum levels of estradiol in patients with leiomyomas as compared with normal controls.<sup>54-56</sup> Estrogenic activity may also be increased by modification of the estradiol molecule. Leibr et al demonstrated higher concentrations of C<sub>4</sub> hydroxylated estradiol metabolites in myomas, the likely result of increased estradiol 4-hydroxylase activity.<sup>57</sup> The 4-hydroxylated estradiol molecule has a greater affinity for the estradiol receptor than estradiol does, thus presenting another source of locally produced growth stimulants.

To date, no evidence proves a direct role of estrogen in fibroid pathogenesis. However, estrogen has been shown to up-regulate

## General Gynecology

numerous other factors with potential effects on fibroid growth including epidermal growth factor, insulin-like growth factor, gap junction proteins, and the progesterone receptor.<sup>48</sup> By exerting an influence on the concentration of these factors it is likely that estrogen plays a significant role in the genesis of leiomyomas.

### **Progesterone**

Progesterone receptors are also found in increased concentration in leiomyomas.<sup>58</sup> Although it is controversial, it appears that fibroid progesterone receptors have also been found in increased concentrations throughout the menstrual cycle.<sup>49</sup> These findings are particularly noteworthy because during the normal menstrual cycle estrogen (normally) would stimulate an increase of progesterone receptors, yet in fibroids, this regulatory system is abolished and receptor concentration is maintained at an elevated level. Both progesterone receptor A and progesterone receptor B are expressed in fibroids with progesterone receptor A levels higher than those of the type B receptor in both leiomyomatous and normal myometrial tissues.<sup>59</sup>

In contrast to estrogen, progesterone levels do not appear to be elevated within myomas as compared with surrounding normal endometrium.<sup>60</sup> However, increased progesterone levels have been shown to increase mitotic indices in fibroids, potentiating growth both during cyclic hormonal changes in the menstrual cycle and when administered exogenously.<sup>61,62</sup> Kawaguchi et al examined menstrual cycle-dependent mitotic rates in uterine leiomyomas in 181 women.<sup>62</sup> They found that the mitotic count was highest, at 12.7 per high-powered field, in the progesterone-dominant secretory phase, achieving a middle value of 8.3 per high-powered field during menses and down to a low of 3.8 per high-powered field during the estrogen-dominant proliferative phase. Kawaguchi subsequently analyzed the effect of progesterone and estrogen on fibroid myocytes in culture.<sup>63</sup> Cells cultured in progesterone and estrogen-enriched media had more active growth and development than those cultured in an estrogen-only medium. Serum progesterone levels also are not increased in women with leiomyomas. Unless exogenously administered, the impact of progesterone appears limited to autocrine and intracrine mechanisms, where, at a molecular level, it appears to exert a significant influence on the growth and development of fibroids.

### **Growth Factors**

Both estrogen and progesterone appear to interact through a variety of growth factors in leiomyomas to induce and stimulate growth. Epidermal growth factor (EGF) and its receptor (EGF-R) can be found in both normal myometrium and leiomyoma cells. Maruo et al demonstrated that estrogen increases the local production of EGF in leiomyoma cell cultures, while progesterone synergistically increases EGF-R levels.<sup>64</sup> Several authors have demonstrated the importance of this growth factor in regulation of fibroid growth.<sup>65–68</sup> Transforming growth factor  $\beta$ 3 (TGF $\beta$ 3) mRNA levels are up to 5-fold higher in myomas compared with normal myometrium.<sup>69</sup> This factor likely contributes to increasing mitogenic potential of leiomyoma cells while also increasing extracellular matrix deposition. TGF $\beta$ 3 is of significant importance, not only because of the functional potential of the product, but also because of its proximity to the

t(12;14) breakpoint on chromosome 14, downstream of the ER $\beta$  gene. Other factors with potential contributions not yet clearly elucidated include platelet-derived growth factor, vascular endothelial growth factor, insulin-like growth factor I, basic fibroblast growth factor, and prolactin.<sup>26</sup>

Recent studies have also focused on the potential influence of alterations of the growth cycle in fibroids.<sup>62,70–72</sup> During normal menses, myocytes undergo growth arrest and potentially undergo apoptosis. However, leiomyomatous cells have increased rates of cellular proliferation with a decreased apoptotic rate compared with normal endometrium. This combination could easily explain the growth of leiomyomas as cells replicate more rapidly without dying as frequently.

Thus, within the peptide and hormone milieu of the endometrium and myometrium, significant interaction appears to occur—between genetic elements, sex steroids, and growth factors—to initiate and then stimulate the growth and development of fibroids. With further research, specific pathways demonstrating the interaction of these factors and potential initiating events or catalysts may be identified. Identification of these pathways is essential to management of both symptoms and manifestations of uterine leiomyomas.

## **CLINICAL MANIFESTATIONS**

The high prevalence of fibroids has led most authorities to attribute multiple clinical manifestations to the presence of these tumors. Despite the high prevalence of these tumors and the frequency with which they necessitate medical or surgical intervention, the majority of women remain asymptomatic. Most studies of fibroid symptomatology rely on paired comparisons before and after intervention strategies.<sup>73</sup> These studies do not accurately reflect the incidence of clinical presentations of fibroids, since the patients are selected because of one or more complications related to their leiomyomas. Moreover, because both medical and surgical strategies have significant physical and psychological impact, combined with the inevitable placebo effect, these studies cannot be relied upon to explain the true clinical nature of uterine leiomyomas.

While controversy exists about the exact role of fibroids in the generation of specific symptomatology, it is important for the practicing gynecologist to be familiar with the classic manifestations of these tumors, as they may play a role in a variety of symptoms as diverse as pelvic pain and constipation. To classify the wide range of presentations potentially attributable to fibroids, we recommend a modification of Stewart's classification system,<sup>74</sup> dividing presentations into one of four subgroups: abnormal uterine bleeding, pelvic pain or pressure including affected organ system dysfunction, reproductive dysfunction such as infertility and miscarriage, and pregnancy-related complications.

### **Abnormal Uterine Bleeding**

Abnormal uterine bleeding (AUB) is the most frequently cited symptom in women with fibroids.<sup>75</sup> While menorrhagia is the most common type of abnormal bleeding experienced, patients may have metrorrhagia or menometrorrhagia. Buttram and Reiter reviewed nine studies citing an incidence of menorrhagia between 17% and 62%.<sup>2</sup> Bettocchi et al examined women with

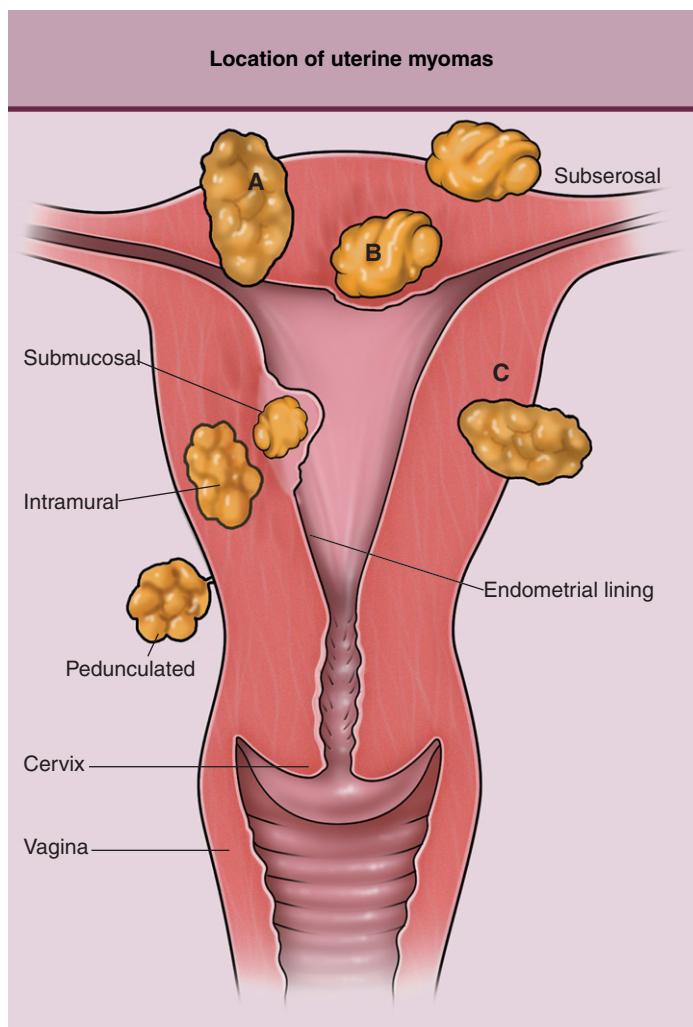

AUB who underwent hysterectomy within 2 months of having a diagnostic dilation and curettage procedure.<sup>76</sup> Hysterectomy confirmed that in 40% of these women myomas were the source of their AUB. In the Ontario Uterine Fibroid Embolization Trial (OUFET), 74% of 538 women undergoing bilateral uterine artery embolization (UAE) had four or fewer myomas.<sup>77</sup> Overall, 17% of women with myomas came in with menorrhagia and 63% with a combination of menorrhagia and pain. Chen et al reported that white women with menorrhagia had a 40% increased incidence of leiomyomas, whereas African American women had no increase in risk.<sup>15</sup>

Thirty percent of women in the OUFET trial reported having menses that lasted more than 7 days. The median pad count was 9 per day. Rybo et al demonstrated that fibroids were four times more common in women with excessive menstrual loss of greater than 200 mL.<sup>78</sup> Chen reported that in white women with fibroids, nearly 40% had a duration of menses equal to or greater than 6 days, while only 13% of African American women experienced prolonged menses.<sup>15</sup> Both African American and white women experienced an approximately 10% incidence of intermenstrual bleeding.

The mechanism of menorrhagia in women with fibroids has not been clearly delineated. Myoma location may be important in determining the severity of bleeding associated with fibroids (Fig. 14-1). Submucosal myomas may increase the likelihood of menorrhagia either by local effects on endometrium adjacent to the fibroid or by alteration of endometrium directly over the fibroid surface. However, no hysteroscopic or microscopic evidence supports this hypothesis.<sup>73</sup> Vascular changes have been suggested as a potential mechanism of fibroid-induced menorrhagia.<sup>79</sup> Myometrium adjacent to myomas undergoes venous compression leading to formation of venous lakes in the myometrium that may influence bleeding patterns. Numerous growth factors as well as local hormone and prostaglandin influences may play roles in the development of menorrhagia. These may include elevated levels of 6-keto prostaglandin F<sub>1α</sub> (PGF<sub>1α</sub>) and prostacyclin.<sup>80</sup> Others have suggested impaired endometrial hemostasis as a mechanism for altered bleeding in patients with fibroids.<sup>81</sup>

It is unclear how often leiomyomas can cause menstrual loss significant enough to cause anemia. In a small study of 61 women with AUB and moderate-to-severe anemia, 38% of patients had a submucosal myoma.<sup>82</sup> Little evidence directly correlates the presence of myomas and the incidence of iron deficiency anemia, even though they are often cited as a common cause of iron deficiency anemia in reproductive-age women.

Fibroids are also commonly associated with dysmenorrhea. In the OUFET trial, 60% of patients had dysmenorrhea.<sup>77</sup> In contrast, Lippman et al demonstrated no increased risk of dysmenorrhea in fibroid affected women compared with patients without fibroids.<sup>83</sup> However, when evaluating pain symptoms by fibroid location, these authors demonstrated a nearly 3-fold increase (29% vs. 11%) in moderate-to-severe dysmenorrhea in women with submucosal fibroids versus women without myomas. The elevated levels of prostaglandins PGF<sub>1α</sub> and PGF<sub>2α</sub> demonstrated in leiomyomatous uteri have also been associated with dysmenorrhea. Thus, it is biologically plausible that fibroids contribute to the development of dysmenorrhea.

**Figure 14-1 Locations of uterine myomas.** Submucosal fibroids intrude into or are contained in the uterine cavity; intramural fibroids are contained within the wall of the uterus, and subserosal ones create the characteristic irregular feel of the myomatous uterus. Most myomas are of mixed type, however, as illustrated by A, B, and C. (From Stewart EA: Uterine fibroids. Lancet 2001;357:293–298. Reprinted with permission from Elsevier.)

### Pelvic Pain and Pressure

Pelvic pain and pressure are the second most frequently reported symptoms. The presence of pain may be related to compression of organs or nerves, to ureteric compression from large, broad ligament or cervical fibroids, or to compression from torsion of pedunculated fibroids. Pain may also be related to prolapsed leiomyomas that undergo ischemic or necrotic changes.<sup>3</sup> Kjerulff et al recorded 41% of white and 59% of African American patients complaining of severe pelvic pain.<sup>84</sup> Chen et al found an approximately 35% incidence of severe pain in both races.<sup>15</sup> The study by Lippman et al, which evaluated 635 women who had a pelvic ultrasound and were subsequently followed for reproductive outcome, demonstrated a trend toward increased risks of dyspareunia and noncyclic pelvic pain in women found to have fibroids.<sup>83</sup> These authors also found an increased risk of dyspareunia and noncyclic pelvic pain when myomas were located in the fundal portion of the uterus. Other authors have

## General Gynecology

also found that fibroid location influences the severity and location of pain.<sup>75</sup>

Pelvic pressure symptoms can occur in women with a myomatous uterus. Few data exist on the relative contribution of fibroids to the development of these symptoms in unselected populations. The OUFET trial reported an 8% incidence of only bulk or pressure-related symptoms prior to study enrollment.<sup>77</sup> However, nearly 86% of patients complained of bulk and pressure symptoms and 57% complained of urinary urgency/frequency symptoms as components of their clinical presentation. Anterior fibroids can cause bladder dysfunction, whereas posterior fibroids may affect bowel function. Such symptoms are dependent on the volume of the leiomyomas. Bladder dynamics can be significantly altered by changes in bladder capacity, urethrovesical angle changes, and incomplete bladder emptying. Although rare, complete ureteric obstruction has been reported.<sup>85</sup> Symptoms related to urinary changes must be investigated for alternative explanations prior to surgical management of leiomyomas.<sup>2,3,86</sup> Although rare, bowel complications can be significant. In one report, a patient experienced a large bowel obstruction secondary to compressive effects of a uterine leiomyoma.<sup>87</sup>

### **Infertility**

In clinical practice, leiomyomas are frequently used to explain otherwise unexplained infertility. Indeed, between 27% and 40% of women with myomas experience infertility.<sup>2</sup> However, some authors suggest that myomas are rarely the sole cause of infertility, accounting for a true fibroid related incidence of only 1% to 2%.<sup>2</sup> Other authors rarely suggest that more than 10% of infertility cases are attributable to the presence of leiomyomas.<sup>88</sup> Pritts conducted a meta-analysis (Table 14-2) to answer three questions: (1) Is there a higher incidence of infertility in patients with fibroids? (2) Does fibroid location affect the incidence of infertility? (3) Does myomectomy enhance fertility?<sup>89</sup> Women

with subserosal and intramural fibroids did not have a higher risk of infertility, although a subanalysis of almost 4000 patients showed a strong trend toward a significant reduction in implantation rates. Women with submucosal fibroids had significantly reduced fertility. The presence of submucosal fibroids resulted in a 68% reduction in implantation and a 73% reduction in clinical pregnancy. It is important to note that this meta-analysis demonstrated no significant increase in infertility when all women with fibroids were pooled, regardless of leiomyoma location. Most authors support the concept that fibroids affect fertility with decreasing significance from submucosal to intramural to subserosal anatomic locations.<sup>90</sup> In contrast, in a study by Bulletti et al, 11% of patients with myomas and infertility went on to conceive, while 27% of patients with infertility without myomas achieved conception, a highly significant difference between groups ( $P < 0.001$ ).<sup>91</sup>

The potential for myomas to affect fertility also appears clear from studies examining the positive benefits of myomectomy on fertility rates. Bulletti's study demonstrated that women with myomectomy had an even higher pregnancy rate of 42% than the 11% rate found in untreated controls.<sup>91</sup> Interestingly, the pregnancy rate in the myomectomized group was nearly twice that of the no-myoma infertility group!

In keeping with the findings from the previously mentioned studies, patients who experience infertility and subsequently undergo in vitro fertilization (IVF) therapy also appear to have adverse effects if fibroids are present. In an analysis of seven separate studies of the effects of myomas on in vitro fertilization therapy, Donnez and Jadoul found that patients with uterine cavity-distorting myomas had a 9% pregnancy rate compared with 29.1% for patients with myomas without cavity distortion, and 25.1% for patients without myomas.<sup>92</sup> When conducting a meta-analysis of the results of these studies, these authors demonstrated a 9% pregnancy rate for women with endometrial

cavity-distorting myomas, 33.5% pregnancy rate for women with myomas not distorting the endometrial cavity, and 40% pregnancy rate for women without myomas. However, as with many meta-analyses, not all the studies independently demonstrated a significant effect of myomas on infertility therapy. Additional, recent studies appear to support a detrimental role of myomas on fertility therapy and assisted reproductive technologies. Hart et al conducted a prospective study of the effects of intramural myomas smaller than 5 cm on patients undergoing IVF therapy.<sup>93</sup> They found that, when controlled for age and number of embryos transferred, women with intramural fibroids had a 54% reduction in ongoing pregnancy rates, although biochemical pregnancy and implantation rates were not significantly different between groups in their models. It is becoming progressively more apparent that fibroids causing endometrial distortion or having extension into the endometrial cavity likely have a negative impact on the success of infertility therapy. The results appear to substantiate severe reductions in IVF success and mandate careful investigation and consideration of surgical intervention prior to assisted reproductive technology therapies.

To date two studies have examined the relationship between IVF and myomas that do not distort the endometrial cavity. Oliveira et al examined 245 women undergoing IVF and intracytoplasmic sperm injection (ICSI) with subserosal or intramural myomas determined by transvaginal ultrasound and compared these patients against 245 matched controls with no evidence of myomas.<sup>94</sup> In women with myomas less than 4 cm, there was no difference in outcome with regard to pregnancy, implantation, and abortion rates. However, women with myomas greater than 4 cm had a 30% pregnancy rate compared with a 52% pregnancy rate in women with myomas smaller than 4 cm. The number and location of the myomas had no impact on results. Check et al examined 61 women with exclusively intramural myomas, finding no difference in IVF outcomes, including positive  $\beta$ -human chorionic gonadotropin ( $\beta$ -hCG) levels, chemical pregnancies, clinical pregnancies, ectopic pregnancies, abortions, or live births.<sup>95</sup> Ng and Ho also confirmed these findings, demonstrating no difference in implantation rates (13.8% vs. 14.4%) or ongoing pregnancy rates (19.5% vs. 21.5%).<sup>96</sup> Thus, it would appear that the presence of intramural leiomyomas that have no impact on endometrial cavity architecture does not lead to any significant decrease in assisted reproductive technology success. These data are consistent with the proposed mechanisms for leiomyoma interference with implantation (Table 14-3).<sup>97</sup> Most of these hypotheses require fibroid proximity to the endometrium for a deleterious effect. The lack of such proximity and consequent endometrial distortion may significantly decrease the impact of these tumors on infertility therapy.

### Pregnancy and Pregnancy Outcomes

Between 1% and 4% of pregnancies are affected by the presence of fibroids.<sup>88</sup> The majority of these do not significantly change during pregnancy and frequently remain asymptomatic.<sup>98</sup> Some leiomyomas may shrink during pregnancy. Leiomyomas that increase in volume during pregnancy rarely grow by more than 25%.<sup>99</sup> Up to 10% of women with myomas experience some type of antepartum, intrapartum, or postpartum complication. Complications attributed to leiomyomas include recurrent

**Table 14-3**  
**Pathophysiologic Mechanisms of Fibroid-related Infertility**

- Potential effects on implantation and sperm transport as well as uterine contractility and perfusion
- Changes in the myometrial microvasculature consisting of abnormalities within tight junctions between endothelial cells
- Aberrant local expression of growth factors involved with angiogenesis

miscarriage, antepartum and postpartum hemorrhage, placental disturbances including placental insufficiency and placental abruption, increased risk of preterm labor and delivery, increased cesarean section rate, and acute ischemic changes and fibroid degeneration secondary to decreased perfusion or torsion.

Fibroids appear to increase the risk of spontaneous first-trimester miscarriage. Benson et al assessed leiomyoma presence in the first trimester by transvaginal ultrasonography usually prior to 7 weeks of gestational age.<sup>100</sup> They compared 143 patients with leiomyomas with 715 control patients without myomas. The results of this study are presented in Table 14-4. Overall, patients with myomas had a 14% spontaneous loss rate versus 7.4% for patients without myomas. Patients with a single myoma had a small but significantly higher spontaneous loss rate, with only a 0.4% increase compared with patients without myomas. However, patients with multiple myomas had a 3-fold increase in spontaneous miscarriage rates and a 16% decrease in live-birth rates. There was no correlation between fibroid size or location and loss rates. Interestingly, only one patient had a submucosal fibroid and therefore the authors could not determine the impact of these specifically located myomas on miscarriage rate. Others, however, have reported high loss figures if implantation occurs over a submucosal fibroid. Li et al observed a 17% incidence of second-trimester miscarriage in affected patients with intramural and subserosal fibroids.<sup>101</sup> The pathophysiologic mechanisms may involve abnormal calcium

metabolism and consequent irregularities in myometrial contractions.<sup>88</sup>

In one of the largest studies of fibroid-related pregnancy complications, Coronado et al examined 2065 women from Washington State with hospital discharge records indicating the presence of leiomyomas.<sup>102</sup> These authors were able to assess a wide range of pregnancy complications while controlling for confounding variables including maternal age, race, ethnicity, marital status, residence, smoking status, parity, prior cesarean delivery, maternal weight gain, hypertension, and diabetes (Table 14-5). They reported significantly increased antepartum risks, with an odds ratio of 1.87 (CI 1.59, 2.20) for risk of

any complication. Specifically, first-trimester bleeding, placental abruption, polyhydramnios, and premature rupture of the membranes were all significantly increased, with odds ratios ranging from 1.79 for premature rupture of the membranes to an astounding 3.87 for placental abruption.

Labor- and delivery-related complications were also significantly increased in these patients (Table 14-6). Patients with leiomyomas had increased labor dysfunction, an increased incidence of breech presentation, and a greater than 6-fold increase in risk of cesarean section. Adverse birth outcomes were also increased, with leiomyomas being associated with higher risks of Apgar scores below 7 at 5 minutes, malformations, birth

weight less than 2500 g, and delivery prior to 38 weeks of gestational age.

Interestingly, a recent study found no increase in risk of miscarriage in women with myomas undergoing genetic amniocentesis compared with women with myomas who did not undergo the diagnostic procedure.<sup>103</sup> The exact mechanism of action for causation of these various pregnancy-related complications is not well understood. Leiomyoma location, abnormal uterine distensibility, abnormal uterine contractility, and abnormal maternal-fetal vascularization may all play a part.

Perhaps the most common complication of myomas in pregnancy is hemorrhagic infarction, frequently termed “red degeneration.”<sup>104</sup> This syndrome occurs more frequently in enlarged myomas with volumes greater than 200 mL, usually during the second trimester. The syndrome is thought to occur as a result of vascular insufficiency, ischemia, and edema. Typically, affected patients have pain but also may have fever, contractions, nausea, vomiting, and mild leukocytosis. Diagnostic ultrasound can demonstrate changes of cystic spaces or a coarse heterogeneous pattern in up to 70% of patients. Treatment is optimally managed by anti-inflammatory agents, which have been shown to reduce duration of hospital stay and readmission.<sup>105</sup>

## DIAGNOSIS

Diagnosis of uterine leiomyomas begins with careful history-taking and physical examination. A bulky, large, irregular, or firm uterus is suggestive of the presence of leiomyomas. A careful clinical examination to determine uterine size in the presence of myomas is highly correlated with ultrasonographic findings of uterine length and subsequent pathologic specimens.<sup>106</sup> However, clinical examination has a limited capacity to differentiate submucosal, intramural, and subserosal myomas. Anatomic location often dictates management, and therefore in clinical practice diagnostic radiology frequently is employed to determine the precise location of uterine leiomyomas. Many different imaging modalities are available, including hysterosalpingography, sonography, sonohysterography, CT scan, magnetic resonance imaging, and hysteroscopy. The practical benefits and disadvantages of each are reviewed briefly.

### Hysterosalpingography

Hysterosalpingography (HSG) is a common method of assessing tubal patency. It frequently is used in the evaluation of infertile patients who are at increased risk for the presence of myomas. Myomas can be detected by hysterosalpingography if they are present within the uterine cavity or significantly distort the uterine cavity. There is an associated false-positive rate. For example, a submucosal myoma may be identified when myomas are actually intramural with extension into the endometrium, since the radiograph can distinguish only endometrial cavity distortion rather than precise fibroid location. In one study, almost 25% of hysterosalpingogram reports were incorrect when followed-up with sonohysterograms.<sup>107</sup> There was high false-positive detection of polyps and myomas by HSG that were not found on subsequent investigation with hysteroscopy. While technically simple, the procedure is invasive and frequently causes discomfort. Patients with a previous history of pelvic

inflammatory disease are at risk of recurrence following HSG.<sup>108</sup> Pretest β-hCG levels to rule out pregnancy and premedication with analgesics, nonsteroidal anti-inflammatory drugs, and antibiotics where indicated may reduce some of the associated complications. Although a viable option for diagnosis of tubal occlusion secondary to uterine myomas, HSG is not optimal in the evaluation of uteri affected by leiomyomas because of its inefficacy in providing information on myomas that do not involve the uterine cavity.

### Ultrasonography

The most common imaging modality used in the detection and diagnosis of leiomyomas is the two-dimensional ultrasound. Both transabdominal and transvaginal approaches are frequently used. Transabdominal images provide a wider field of view and are obviously less invasive; however, they cannot detect myomas smaller than 1 cm. Transvaginal approaches allow for detailed high-resolution images, giving precise location information and detection for even 4- to 5-mm myomas. However, this modality may have decreased sensitivity in detecting pedunculated, subserosal myomas or those high in the abdominal cavity, since they may remain outside the field of view.<sup>109</sup> Ultrasonographic appearances of fibroids can vary widely depending on location, size, ratio of fibrous to smooth muscle tissue, and degree of calcification.<sup>110</sup> Fibroids that have undergone degenerative changes may also demonstrate cystic, hypoechoic, or fluid-filled areas consistent with regions of necrosis. Typically myomas present as large, well-defined, echogenic, rounded lesions in the uterus.

Transabdominal ultrasound is less accurate in the identification of myomas that extend into the broad ligament.<sup>111</sup> Furthermore, because of the significant variation in ultrasonographic appearance, it has poor sensitivity in the differentiation of sarcomatous myomas from benign leiomyomas. While transvaginal ultrasonography (TVUS) improves on the detection of myomas over transabdominal scanning, it is still limited in discerning pedunculated from sessile myomas and detecting the degree to which myomas extend into the endometrial cavity. Fedele et al reported 100% sensitivity in detection of submucosal myomas with transvaginal sonography when compared with hysterectomy specimens.<sup>112</sup> One study demonstrated that TVUS was as sensitive in detecting the presence of myomas as magnetic resonance imaging (MRI), but that MRI detected twice as many myomas as TVUS.<sup>113</sup> However, detection of intracavitary abnormalities is significantly reduced in comparison with hysteroscopic diagnoses, with 63% sensitivity.<sup>114</sup>

Three-dimensional ultrasonography has recently been incorporated into gynecologic practice. This modality provides more detailed information on the uterine cavity and uterine anatomy and may reduce the required skill necessary for accurate determination of fibroid location.<sup>109,115</sup> To date there is little data on its efficacy in improving on traditional, two-dimensional ultrasound; however, it may improve volumetric assessment.<sup>116</sup> Newer studies have examined the use of three-dimensional ultrasound in conjunction with saline infusion hysteroscopy. While some authors have demonstrated improvements in the detection of intracavitary abnormalities using this technique, considerable controversy exists.<sup>117</sup> Pretorius et al suggest that it may assist in reducing hysteroscopy for potentially inoperable myomas.<sup>118</sup>

**Figure 14-2** Sonohysterogram demonstrating a large, submucosal fibroid growing cephalad into the endometrial canal. The myoma interferes with the majority of the endometrial canal. (Courtesy of W. Romano, St. Joseph's Health Care Center, London, Ontario, Canada.)

**Figure 14-4** Sonohysterogram demonstrating two anterior, submucosal fibroids and one small endometrial polyp. (Courtesy of W. Romano, St. Joseph's Health Care Center, London, Ontario, Canada.)

Hysterosonography is taking on a more significant role in the diagnosis of myomas. This technique allows clearer visualization of endometrial cavity contours. Polyps, as well as pedunculated and sessile fibroids, can all be more clearly delineated. Furthermore, this allows for specific determination of the extent of myoma presence within the uterine cavity when they are located submucosally or in the intramural regions (Figs. 14-2 to 14-5). With the use of sonographic contrast media, tubal patency also can be determined. Complications such as infection are extremely rare although precautions are recommended in patients with a prior history of pelvic inflammatory disease. The sensitivity for the detection of intrauterine abnormalities using hysterosonography compared with hysteroscopy is 88% with a

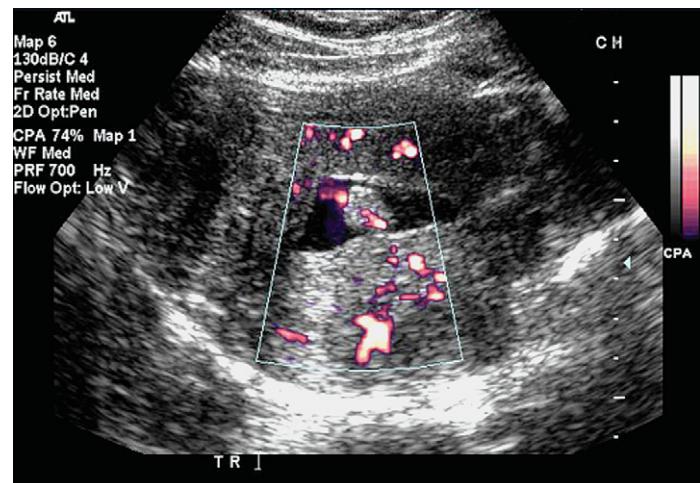

specificity of 95%.<sup>114</sup> The majority of studies examining the utility of hysterosonography in pre- and postmenopausal patients have revealed sensitivities of 88% to 100% and specificities of 76% to 96%. It has been suggested that up to 72% of hysteroscopic procedures could be avoided by use of sonohysterography and only 4% of intracavitary lesions would be missed.<sup>119</sup>

#### Magnetic Resonance Imaging

MRI is possibly the most useful technique for the diagnosis of uterine fibroids because of its accuracy in the detection and localization of uterine fibroids.<sup>120</sup> It also may provide advantages to patients undergoing fertility preserving therapy, such as myomectomy or uterine artery embolization, or when endovaginal

**Figure 14-3** Sonohysterogram demonstrating two endometrial polyps/fibroids. The first polyp is fundal, and the second arises from a point near the internal cervical os and grows cephalad. Doppler flow (not shown) demonstrated significant vascularization of the neoplasms. (Courtesy of W. Romano, St. Joseph's Health Care Center, London, Ontario, Canada.)

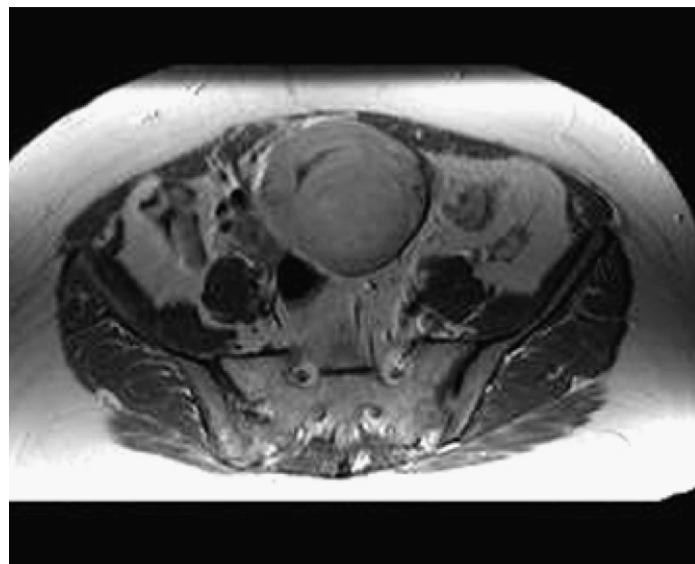

**Figure 14-5** Sonohysterogram demonstrating a large submucosal uterine leiomyoma and a concurrent endometrial polyp. Doppler flow demonstrates significant arterial vascularization and blood flow to both neoplasms. (Courtesy of W. Romano, St. Joseph's Health Care Center, London, Ontario, Canada.)

ultrasound has been equivocal or nondiagnostic.<sup>121</sup> Fibroids generally appear as homogenous, dark (i.e., low intensity), well-circumscribed masses (Figs. 14-6 and 14-7). Endometrial polyps often can be distinguished from myomas on the basis of the myometrial origin of myomas visible on MR scans. Fibroids as small as 0.5 cm can be detected using this imaging modality. When myomas grow beyond 3 cm they often have inhomogeneous architecture because of various degrees of degenerative, hemorrhagic, and necrotic changes within the tumor.<sup>120</sup> Specialized coils have been developed specifically for pelvic MR images that increase signal intensity. Several adjunctive techniques may also be useful in enhancing images, including the use of glucagon for restriction of bowel activity, rectal air insufflation, and oral contrast media.<sup>111</sup> In addition to localization of myomas, MR angiograms can help in detection of collateral ovarian blood supply to uterine myomas. This is particularly useful information for patients considering undergoing uterine artery embolization (UAE), since fibroids with ovarian blood supply may not respond adequately to UAE procedures.

Despite the high resolution of MRI for uterine fibroids, its utility is limited in determining pathologic differences in degenerating fibroids or in distinguishing benign leiomyomas from their malignant counterparts, leiomyosarcomas. Additionally, despite its proven efficacy, the substantial costs associated with MRI have generally limited its use in routine evaluation of uterine leiomyomas.<sup>109</sup>

### Hysteroscopy

Hysteroscopic evaluation of myomas is the gold standard for evaluation of intrauterine extension of fibroids. This technique is particularly useful in women with submucosal fibroids and polyps amenable to surgical intervention at the time of hysteroscopic evaluation. Hysteroscopic evaluation allows for accurate

**Figure 14-6 T1-weighted MR image in axial view after gadolinium injection.** The MRI depicts a large uterine leiomyoma, with compression of the posterior myometrium and distortion of the endometrial canal. (Courtesy of W. Romano, St. Joseph's Health Care Center, London, Ontario, Canada.)

localization of submucosal fibroids and for clear delineation of pedunculated and sessile myomas and polyps. This technique also provides visualization of the extent of endometrial distortion caused by intramural myomas and the extent to which tubal ostia may be occluded by adjacent myomas. The advantages of this technique include direct visualization, potentially simultaneous therapeutic intervention, out-patient or office setting use, and minimal complications. The disadvantages include inability to detect intramyometrial extension, need for significant analgesia/sedation or anesthetic, and potential for rare but significant complications associated with operative hysteroscopy (see Chapters 38 and 39).

de Vries et al reviewed the evidence comparing saline infusion sonography (SIS) with hysteroscopy for the evaluation of endometrial abnormalities.<sup>119</sup> Although SIS had between 88% and 100% sensitivity, these values were still lower, in general, than the reference category of hysteroscopy.

### MANAGEMENT

Because the vast majority of uterine myomas are asymptomatic, in most cases no therapeutic intervention is necessary. Patients experiencing complications related to the presence of leiomyomas generally have several options for management: medical therapy, embolotherapy, and surgical therapy. The choice depends on many factors including severity of symptomatology, desire for future fertility, comorbid conditions, and access to physicians with appropriate surgical knowledge, skill, and equipment.

## General Gynecology

Implicit in consideration of management options is ruling out the potential for malignancy within a myomatous mass. The incidence of uterine leiomyosarcomas is 1.7 per 100,000 women, with an incidental finding of leiomyosarcoma in asymptomatic uterine fibroids of 1 in 2000.<sup>86,122</sup> Schwartz et al analyzed six studies evaluating typical clinical presentations of patients with leiomyosarcoma. The majority of patients were near 45 to 50 years of age and had an enlarged uterus (>6 week size).<sup>123</sup> The authors found that 95% of leiomyosarcomas present as the largest or only uterine mass. The importance of correctly diagnosing uterine myomas is highlighted by reports of inadvertent treatment of leiomyosarcomas with GnRH agonist therapy.<sup>124</sup>

### Medical Management

Medical management of leiomyomas is a rapidly expanding field aimed at reducing the symptoms associated with fibroids without the risks and complications of surgical intervention. Medical therapy involves manipulation of factors that contribute to fibroid growth by either reducing the concentration of growth factors, using competitive antagonists against hormones, interfering with growth factor receptor function, altering uterine blood flow, or altering endometrial properties. To date, many different agents have been used but generally may be categorized into six primary modalities: endometrial suppression drugs, GnRH agonist therapy, antisteroid therapy, androgen therapy, leiomyoma receptor growth factor antagonists, and most recently uterine blood flow-altering drugs.

### Oral and Injectable Contraceptives

Oral contraceptives have long been used in the control of abnormal uterine bleeding by reducing endometrial growth. They are frequently used in clinical practice to control fibroid-related menorrhagia despite the lack of evidence supporting their efficacy. In theory, reducing endometrial growth should reduce bleeding; however, there is no practical or theoretical evidence to support a decrease in bulk- or pain-related symptoms. Although no direct evidence links fibroid growth and progestins, medroxyprogesterone acetate may actually stimulate growth of uterine leiomyomas.<sup>125</sup> In fact, the data regarding OCs suggest an increase in the incidence of leiomyomas if initiated prior to the age of 16 years.<sup>10</sup> Because of the relative safety of OCs and the contraceptive benefits, their use may provide a reasonable first-line approach to the control of fibroid-related menorrhagia in patients over age 16. However, in patients with bulk-related symptoms, no evidence supports the use of oral contraceptives and other agents with proven efficacy in reducing leiomyoma volume should be considered.

### Levonorgestrel Intrauterine Systems

In contrast to OC use, fibroid-related menorrhagia and fibroid volume may be reduced in patients using levonorgestrel intrauterine contraceptive systems (LN-IUS). The endometrial suppressive effects of this device are well documented, but its efficacy in the treatment of myomas is only recently being evaluated. Traditionally, intrauterine devices have been contraindicated in patients with fibroids because of the frequency of endometrial cavity distortion leading to decreased contraceptive efficacy. However, one study demonstrated a decreased inci-

dence of leiomyoma development in patients using the LN-IUS for more than 5 years, with decreased uterine surgery and hysterectomy rates as well.<sup>126</sup> A study conducted in a small population of women demonstrated decreased myoma volume within 6 to 18 months of LN-IUS use. Although the LN-IUS controls fibroid-related menorrhagia by progestin-induced endometrial suppression, it is believed to exert its effect on fibroid volume by increasing the concentration of insulin-like growth factor-binding protein-1, thereby reducing a potential leiomyoma-related growth factor.<sup>127</sup>

### Nonsteroidal Anti-Inflammatory Drugs

Nonsteroidal anti-inflammatory drugs (NSAIDs) that can significantly reduce abnormal uterine bleeding do not appear to reduce fibroid-induced menorrhagia. In two studies, no benefit was shown in patients undergoing therapy with either naproxen or ibuprofen if myomas were present.<sup>128,129</sup> Moreover, there is likely no alteration in fibroid volume and growth, resulting in no significant benefit in the use of these agents in fibroid-affected patients.

### Gonadotropin-releasing Hormone Agonists

GnRH agonists are the most common form of medical therapy employed in the treatment of leiomyoma-related symptomatology. These agents are thought to exert their influence by inducing a hypoestrogenic state unfavorable to fibroid and endometrial growth. Thus, use of these agents can potentially reduce both bleeding- and bulk-related symptoms. While there are many different agents, most studies have examined the use of leuprolide acetate. The route of administration can significantly influence the efficacy of these agents. Friedman et al demonstrated that intranasal administration of leuprolide acetate resulted in no reduction in uterine volume compared with a 53% reduction when it was administered subcutaneously, with a concurrently higher level of mean serum estradiol concentrations in patients undergoing intranasal administration.<sup>130</sup>

The majority of studies indicate that fibroid and uterine volume can effectively be reduced on average by 50% with the use of these agents.<sup>131</sup> However, individual leiomyomas have a high degree of heterogeneity in their response to GnRH agonists, with response rates varying from 0% to 100% after 3 to 6 months of continuous therapy.<sup>132</sup> Response is usually seen within 1 to 2 months of therapy and maximal response after 12 weeks. The greatest proportion of shrinkage occurs after the first month and subsequently progressively declines.<sup>133</sup> Reductions of up to 38% have been demonstrated in the surface area of submucosal myomas at 8 weeks of therapy.<sup>134</sup> Uterine volume can similarly be decreased on average by 25% to 80% with maximal reductions achieved after 12 weeks of therapy.<sup>135</sup> The reduction in uterine volume extends to reductions in the intrauterine cavity. Two studies used hysteroscopy to demonstrate reductions in the volume of the endometrial cavity. The first study demonstrated a reduction of 35% at 8 weeks,<sup>136</sup> while the second demonstrated that prolonged use resulted in a 40% decrease at 24 weeks.<sup>137</sup> The efficacy of GnRH agonists appears to be dependent on circulating levels of estrogen. Thus, women with obesity or without a significant suppressive response to GnRH agonist administration have reductions in amenorrhea and volume decrease.<sup>138</sup> Up to 10% of myomas will have no response to therapy (Table 14-7).

**Table 14-7****Factors Contributing to Failure of GnRH Agonist Therapy for Treatment of Leiomyomas**

- Leiomyoma histopathologic subtype
- Extracellular matrix composition
- Steroid and growth factor receptor content
- Intracrine production of steroid hormones and growth factors
- Paracrine-mediated growth stimulation
- Fibroid location and number

Gutmann et al demonstrated a 5-fold increased degree of hyalinization in myomas that were unresponsive to leuprolide acetate in a small study of 12 patients with surgical histopathologic evaluation following short-term administration of depot leuproreotide.<sup>139</sup> Pedunculated fibroids may have an attenuated response as compared with myomas contained within the uterus.

Lemay et al reviewed data on symptom improvement following GnRH agonist use<sup>134</sup> (Table 14-8). Even patients without significant myoma shrinkage experience up to 92% improvement in symptoms following GnRH agonist therapy. Additionally, there can be improvements in hematocrit, hemoglobin, and iron indices. These improvements provide not only symptomatic benefit, but can make potential surgery safer by reducing the impact of blood loss and the need for transfusion and allowing for preoperative autologous blood donation.

**Preoperative**

The use of GnRH agonists preoperatively for uterine leiomyomas may be one of the most effective strategies for improving outcomes. There are preoperative, intraoperative, and postoperative benefits. Preoperative GnRH agonist use is the subject of a meta-analysis of 21 randomized controlled trials.<sup>140</sup> Preoperative hemoglobin was significantly increased by 1.3 g/dL and hematocrit by 3.1%, uterine size decreased by 159 mL and 2.2 gestational weeks, and fibroid volume decreased by 12 mL.

**Intraoperative**

Intraoperative benefits included a 58 mL reduction in blood loss at hysterectomy and a 68 mL reduction in blood loss at myomectomy. Although these values are statistically significant, their clinical relevance is questionable. Despite the reduction in blood loss, the rate of blood transfusion did not significantly differ between groups. The odds ratio for vaginal hysterectomy was substantially increased in patients undergoing GnRH agonist treatment, with a nearly 5-fold increase in vaginal hysterectomy rate in treatment patients, although the largest trial with a placebo-controlled group demonstrated no difference in surgical approach. These differences may be attributable to other patient factors including previous pelvic surgery, history consistent with adhesions, and physician skill and preference. However, physicians found an 8% reduction in risk of difficult surgery in pretreated patients. For patients undergoing abdominal hysterectomy, the choice of Pfannenstiel incision was more common, with an OR of 0.36 for vertical incisions, a significant clinical value in light of the increase in wound complications associated with vertical incisions. Patients also benefited from a decreased duration of operating time and a 1.1 day reduction in hospital stay. However, in a study of 426 patients undergoing laparoscopic myomectomy, patients who had received GnRH therapy prior to surgery had a higher risk of conversion to open laparotomy.<sup>141</sup>

**Postoperative**

Overall, postoperative complications did not differ in groups undergoing myomectomy, but there was a 38% reduction in risk of postoperative complications with hysterectomy including blood loss and pyrexia. Compared with no treatment, postoperative hemoglobin and hematocrit values appear to be elevated, but these results were not evident in placebo-controlled trials. Of interest is the finding of a 4-fold increase in risk of myoma recurrence 6 months postoperatively in patients who had received treatment. It has been hypothesized that this is due to shrinkage of small myomas that subsequently become undetectable at surgery but then undergo regrowth postoperatively.

**Complications**

Several complications are associated with the administration of GnRH agonists for uterine myomas. The most important is the rapid regeneration of myomas and regrowth of the uterus within 6 months of cessation of treatment.<sup>132</sup> Often these increases occur within weeks of treatment cessation. Friedman et al demonstrated that within 3 months of cessation fibroids exhibited regrowth to 88% of their original size.<sup>142</sup> This may be due, in part, to a rapid return of ovarian steroidogenesis following treatment cessation, or it may involve the return of uterine blood flow to pretreatment levels. Matta et al demonstrated that pretreatment uterine artery resistive indices were 0.52, peaked at 0.92 at 4 months of treatment, and were 0.59 at 6 weeks posttreatment.<sup>143</sup> Shaw found that blood flow was strongly correlated with uterine and fibroid volume, with increasing resistive indices seen with decreased fibroid and uterine volumes.<sup>144</sup> Others have found that the relationship of uterine blood flow to fibroid growth may even be predictive of GnRH agonist treatment success.<sup>133</sup>

Although two thirds of women are amenorrheic during GnRH agonist therapy, menses often return within 4 to 10 weeks after

**Table 14-8****Beneficial Effects of GnRH Agonist Treatment on Clinical Symptoms of Myomas**

Symptom	Improvement (%)
Dysmenorrhea	95–100
Abnormal bleeding	93–100
Pelvic pain	85–95
Pelvic pressure	75–93
Urinary frequency	50–94
Dyspareunia	69–80
Constipation	66–78
Abdominal bloating	69–75

## General Gynecology

cessation of treatment. Patients with a history of menorrhagia are at risk for recurrence. Symptoms may reappear following myoma regrowth, but some studies support a prolonged benefit after cessation of therapy. Up to 65% of patients remain symptom free after therapy, and two thirds of patients may continue to avoid operative intervention 8 to 12 months after the completion of therapy.<sup>145</sup> Some patients derive enough resolution of their symptoms to avoid subsequent hysterectomy.<sup>146</sup>

**Hypoestrogenic Side Effects**

In general, administration of GnRH agonists results in profound pituitary suppression of gonadotropin release and a consequent state of hypoestrogenemia. Hypoestrogenemia results in menopausal-like symptoms. Several studies have examined the side effects of GnRH agonist treatment and described their incidence compared with patients receiving placebo and a Cochrane review also evaluated odds ratios for four adverse outcomes (Table 14-9).<sup>131,132,140,147,148</sup> These side effects may in general be classified as physiologic changes, physical changes, and nonphysiologic effects. Hot flashes (hot flushes) occur with the highest frequency and are the most debilitating, often resulting in intolerance and treatment discontinuation. Combined with the accompanying diaphoretic episodes, these symptoms limit the utility of these drugs in the long-term treatment of fibroids.

While physiologic changes are particularly distressing to the patient, physicians frequently focus on the bone loss that occurs with prolonged GnRH agonist therapy. Because of the hypoestrogenic state, bone remodeling is altered and new bone formation decreased. Initially, concerns were derived from studies of young women undergoing long-term GnRH agonist treatment for the suppression of pelvic endometriosis. In these women, after 6 months of therapy, 5% to 6% of the trabecular

bone in the lumbar spine was lost. Although most patients regained the lost bone following treatment cessation, the age-dependent decrease in new bone deposition resulted in concern about prolonged GnRH use. More recent studies in patients with fibroids have demonstrated smaller decreases, with a maximal bone loss of 3%.<sup>134</sup> It is postulated that the diminished loss results from treatment of perimenopausal women with increased body mass index as compared with patients undergoing therapy for endometriosis. However, treatment for longer than 6 months often is discouraged owing to concern about potential bone loss.

Other rare but significant complications include fibroid degeneration, which results in episodes of pain, fever, and bleeding. Frequently these patients come to the emergency room for acute pelvic pain management. Some patients also undergo degenerative vascular changes resulting in massive hemorrhage necessitating emergent management.

Thus, while GnRH agonist treatment affords considerable efficacy in reduction of both fibroid volume and related symptomatology, the effect is limited to continuation of drug administration. Absence of suppression results in myoma regrowth and a return of symptoms in a substantial proportion of treated patients. Short-term treatment carries a significant degree of morbidity, and long-term therapy is contraindicated because of concerns regarding bone loss. Although some patients continue to benefit following cessation of GnRH administration, the adverse effects and cost of this drug reduce its efficacy as a long-term treatment strategy.

**Add-back Therapy**

Concerns regarding side effects and decreased efficacy of GnRH agonist therapy led several investigators to consider hormonal add-back regimens to ameliorate the side effects induced by short- and long-term GnRH agonist use. Following an initial 3-month treatment period, patients are started on regimens including progestin only or estrogen and progestin. Theoretically, this would allow for long-term suppressive therapy while minimizing potential side effects, risks, and complications and would be particularly beneficial in temporizing symptomatic perimenopausal patients.

**Progestin Only.** Studies of progesterone add-back have been disappointing. If initiated simultaneously with the GnRH agonist, hot flashes are reduced, but fibroids do not shrink significantly compared with pretreatment levels. In a randomized controlled trial, when norethindrone was initiated after 3 months of GnRH agonist therapy, bone mineral density decreased by 3% but then stabilized over the ensuing year of therapy.<sup>149</sup> However, fibroids regained 92% of their original volume with progesterone add-back therapy. Other authors have demonstrated a maximum of 20% reduction in fibroid volume with progesterone add-back therapy. Thus, while these regimens improve the side effect profile of GnRH agonists, they significantly impede the therapeutic efficacy, limiting their usefulness.

**Estrogen and Progestin.** Friedman initially tested a combined regimen in a small population of five patients with fibroids treated with leuprolide for 3 months, followed by initiation of a cyclic regimen of 0.625 mg of conjugated equine estrogen and 5 mg of medroxyprogesterone acetate daily for 24 months.<sup>150</sup> The initial leuprolide-only phase resulted in a 50% volume

**Table 14-9**  
**Adverse Effects of GnRH Agonist Therapy for Treatment of Fibroids**

Adverse Effect	Incidence (%)	OR	95% CI
Physiologic changes			
Hot flashes	80-100	6.5	4.6, 9.2
Diaphoresis	45-63	8.3	4.5, 15.3
Physical changes			
Breast changes	11-47	7.7	2.4, 24.9
Vaginitis/vaginal dryness	5-29	4.0	2.1, 7.6
Bone loss	3-6		
Other changes			
Depression	11-23		
Decreased libido	3-34		
Emotional lability	8-32		
Sleep disturbance	10-45		
Nausea	10-19		
Arthralgia	8-14		
Headache	20-26		
Fibroid changes			
Hyaline degeneration	1-2		
Submucosal vascular disruption	<1

Data from references 131, 132, 140, 147, and 148.

reduction in fibroids that was maintained during the course of add-back therapy, with no detrimental effects on bone mineral density.

Subsequently, Friedman evaluated a combined regimen in a randomized controlled trial of 51 premenopausal women.<sup>149</sup> Patients had a 25% reduction in uterine volume with add-back therapy at 1 year, although there was a significant decrease in bone mineral density that remained at study completion.

On the basis of results of add-back therapy trials, it is evident that patients amenable to GnRH agonist treatment would benefit from some estrogen-progesterone combined therapy in either continuous or cyclic regimens. These patients may experience some diminution of symptoms but are at risk for decreased efficacy and potential bone loss. Alternative therapies for the prevention of bone loss, including bisphosphonates, may reduce the complication of bone loss and in combination with add-back therapy provide a rational option for symptomatic women nearing menopause, unwilling or unable to undergo surgery, or wishing to preserve fertility.

#### **Alternative Forms of Medical Therapy**

The complications and side effects of GnRH agonists have led to the development of several alternatives in the medical management of uterine myomas.

#### **Antiprogestin**

Antiprogestin such as RU 486 have been used in the treatment of leiomyomas. Two studies have demonstrated that even at low doses there is a reduction in fibroid volume of 25% to 50% at 12 weeks.<sup>151</sup> This effect may be mediated through alteration of uterine blood flow, to an even greater degree than that seen with GnRH agonists. Although these studies were promising, numbers were small and firm conclusions cannot be drawn about the safety and efficacy of long-term use without further analysis.

Selective progesterone receptor modulators (SPRMs) represent a relatively new class of drugs with both agonist and antagonist activities at progesterone, glucocorticoid, and androgen receptors.<sup>152</sup> Although their use in the treatment of uterine myomas is currently investigational only, initial results appear to show promise in both control of symptoms and reduction in myoma volume.<sup>153</sup>

#### **Androgens**

Androgens used in the treatment of uterine fibroids include danazol and gestrinone. Danazol provides reversible pituitary suppression by binding to multiple steroid receptors and indirectly suppressing LH and FSH production. Danazol has been compared with the GnRH agonist buserelin in a prospective trial of 164 women.<sup>154</sup> Patients receiving danazol had a 57% reduction in fibroid volume at 6 months, compared with 76% in patients receiving buserelin. De Leo examined the effects of danazol following GnRH agonist discontinuation and found that fibroid volume had a 30% lower rebound compared with volume in control patients.<sup>155</sup> Others have found that minimal dosages of danazol may alleviate symptoms despite a lack of efficacy in reducing fibroid volume.<sup>156</sup> Currently, danazol is not indicated for long-term use and must be considered in light of its potential androgenic side effects and the rare consequence of virilization.

Gestrinone, a synthetic derivative of nortestosterone, was used in a prospective trial for the treatment of fibroids in 100 patients.<sup>157</sup> While 73% of patients had a significant reduction in fibroid volume similar to that observed with GnRH agonist therapy, 20% to 100% of patients suffered androgenic side effects, including acne, hirsutism, and weight gain. These changes reversed with treatment cessation, and only 4% of patients discontinued therapy because of side effects. This may be a viable option in patients who wish to minimize fibroid regrowth and are willing to accept the potential hyperandrogenic consequences of therapy.

#### **Aromatase Inhibitors**

The incorporation of aromatase inhibitors into ovulation induction, pioneered by Mitwally et al, has stimulated renewed interest in the use of these agents in the treatment of uterine myomas.<sup>158</sup> At present there are only case reports of the use of the newer orally administered aromatase inhibitors for the treatment of uterine leiomyomas<sup>159</sup>; however, concerns have been raised regarding the significance of potential long-term estrogen suppression resulting from chronic administration.<sup>160</sup>

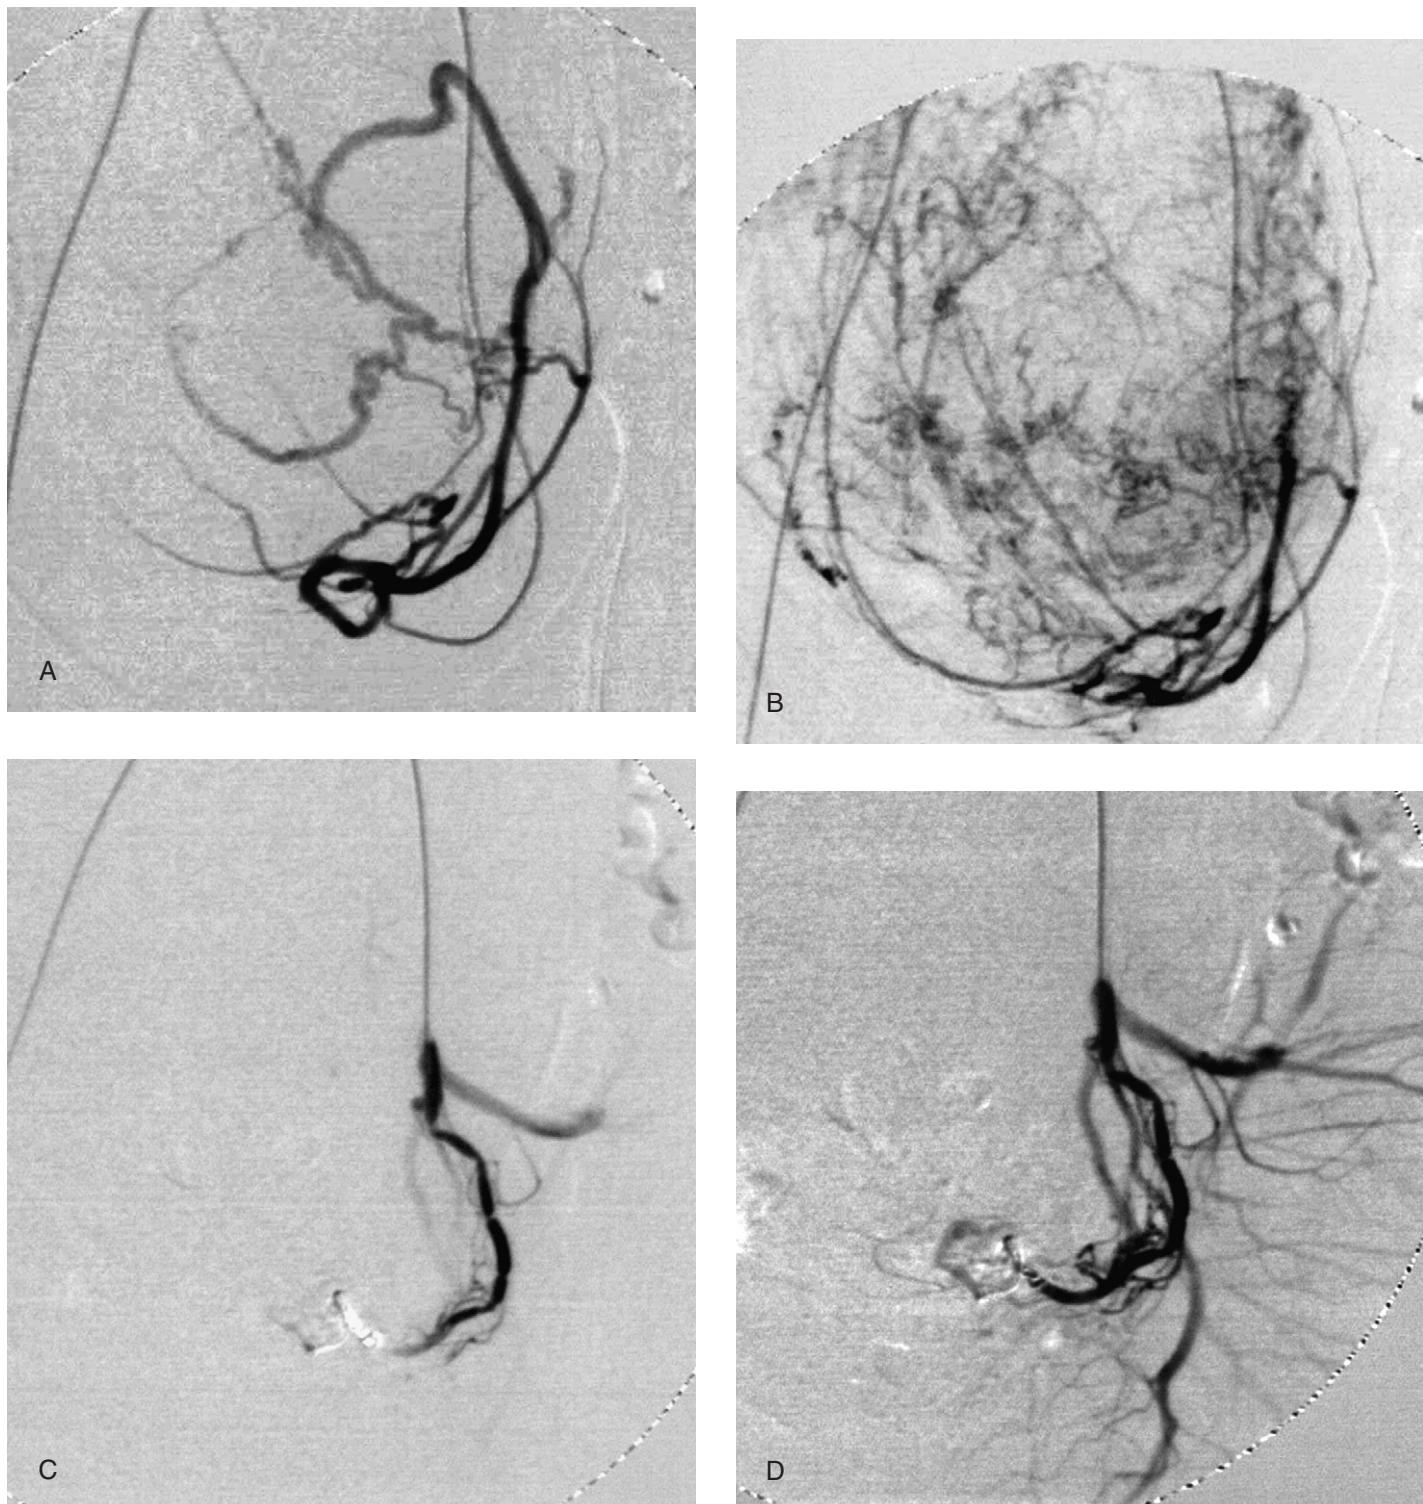

#### **Other Antiestrogens**

Many compounds with antiestrogenic activity have been used to reduce fibroid volume, including clomiphene citrate, tamoxifen, and raloxifene. The side effects, potential risks, and lack of large prospective studies currently limit the use of the majority of these drugs. Selective estrogen receptor modulators have had some limited success.<sup>161</sup> Further studies may reveal new antiestrogens with growth-inhibiting efficacy for leiomyomas, but at present no data supports the use of these agents in clinical practice.

#### **Embolotherapy**

The fact that reduced uterine blood flow corresponds with significant decreases in fibroid and uterine volume contributed to the development of uterine artery embolization. This technique was first described in 16 patients in Paris.<sup>162</sup> Using coils, microspheres, and most recently a transvaginal clamp, the uterine arteries or those feeding the myoma are selectively occluded. Patients are treated using conscious sedation and are monitored either overnight or as outpatients.

Fibroids are particularly well-suited to this treatment because of the hypervascular peripheral supply and the hypovascular central core. This pattern allows for central infarction and necrosis of the myoma when the external blood supply is compromised. Uterine artery embolization (UAE) techniques take advantage of this pathophysiologic finding to induce irreversible necrosis and consequent fibroid volume reduction. Patients should be preoperatively evaluated by a gynecologist, and diagnostic testing for the number, size, and location of fibroids is indicated. Using either a unilateral or a bilateral femoral approach, the vascular bed supplying individual fibroids or the uterine arteries is embolized (Fig. 14-8). Selective embolization of fibroid vascular beds may result in decreased complications and decreased postoperative pain. Radiographic exposure is significant but not excessive. In one study, patients received an average of 44 angiographic exposures, with a mean ovarian exposure of 22 cGy and a mean fluoroscopy time of 22 minutes.<sup>163</sup>

**Figure 14-8** A, Digital subtraction angiogram of the left uterine artery and peripheral supply to a uterine myoma. The image depicts early dye infusion prior to uterine artery embolization. B, Digital subtraction angiogram taken prior to uterine artery embolization. The image depicts continued spread of dye, highlighting the typical observed pattern of hypervascularity in uterine leiomyomas. C, Digital subtraction angiogram taken immediately after uterine artery embolization. Note the massive reduction in peripheral and central blood supply to the myoma. D, Digital subtraction angiogram taken after uterine artery embolization. This image demonstrates the complete and persistent occlusion of arterial flow to the myoma, with consequent redistribution of blood flow to peripheral blood vessels. (Courtesy of J. Bennett, St. Joseph's Health Care Center, London, Ontario, Canada.)

Results indicate that fibroid volume reduction, symptomatic improvement, and patient satisfaction all are high. Up to 85% of patients report significant reductions in menorrhagia and bulk-related symptoms following embolization procedures.<sup>164</sup> On average, up to 50% of fibroid volume can be reduced within 6 months of therapy. Similarly to GnRH agonist therapy, the majority of shrinkage occurs over the first few months of therapy, although some further volume reductions can be seen between 6 and 12 months after the procedure.

The OUFET trial recently reported on findings in a large population of women undergoing uterine artery embolization.<sup>77</sup> Five hundred thirty-eight patients underwent bilateral uterine artery embolization with polyvinyl alcohol particles. The study was composed of 65% white women, with a mean age of 43 years, 50% of whom were nulliparous, and 30% of whom were desirous of retaining their fertility potential. The majority of patients had 2 to 4 fibroids (44%), and 60% of all fibroids were intramural. At 3 months postembolization, the mean reduction in fibroid volume was 23% for fibroids less than 200 cm<sup>3</sup> pretreatment, 38% for fibroids 201 to 400 cm<sup>3</sup>, and 49% for fibroids greater than 401 cm<sup>3</sup>, with reductions in uterine volume of 11% to 44% depending on pretreatment uterine volume.

Effects on symptoms were dramatic, with 83% of women reporting improvement in menorrhagia, mean reductions of over 2 days in menstrual duration, and a 50% reduction in pad count on the heaviest day of menstrual flow. Interestingly, 7% of patients reported worsening of menorrhagia following the procedure. Dysmenorrhea was reduced in 77%, bulk in 84%, and urinary urgency in 86% of patients.

The effect of UAE on future pregnancy is not well understood. Theoretically, the consequent restriction of uterine blood flow through the uterine arteries could result in utero-placental insufficiency. Goldberg et al reported that, based on the first 50 reported cases of pregnancy following embolization, patients were at increased risk for malpresentation (17%), fetus small for gestational age (7%), premature delivery (28%), cesarean delivery (58%), and postpartum hemorrhage (13%).<sup>165</sup> Although these figures are increased compared with unaffected patients, no data indicate that risks following embolization are significantly greater than those experienced by other patients with similarly sized fibroids. However, Chen et al reported a greater than 40% risk of miscarriage following UAE and suggested that the procedure be limited to patients who do not desire fertility.<sup>166</sup> Patients must be counseled that data regarding safety in pregnancy is lacking and there are both theoretical concerns and some early evidence that patients are at risk of increased complications. Early consultation with an obstetrician and close follow-up should be considered mandatory.

Although this procedure appears safe and efficacious, several complications exist. Overall, complications occur in less than 0.5% of patients. The most important concern following embolization is potential infection, with these patients at risk for hysterectomy. However, there is no consensus on the use of antibiotic prophylaxis for this procedure. Infection-related death has been reported following embolization, so careful consideration of the risks and benefits of antibiotic use should be made for each patient.<sup>167</sup> Fibroids with intracavitary exposure may be at increased risk of infective complications.<sup>168</sup> Because of the inflammation and necrosis that occurs in the process of

fibroid ischemia, leukocytosis and febrile morbidity are common. Thus, markers of infection are frequently present even under sterile conditions. Sudden increases in temperature greater than 38.5°C associated with increasing pain, foul discharge, or hypotension are of particular concern and mandate formal evaluation for possible infection. MRI may be helpful in delineating infection.

Other authors have raised concerns regarding diminished ovarian reserve observed in patients following uterine artery embolization. Smaller occlusive particles may embolize into the ovarian blood supply and cause occlusion or restriction of blood flow, resulting in decreased ovarian function. Patients over age 45 years may be at increased risk of premature ovarian failure following embolization. In one study, 43% of women over age 45 subsequently had ovarian failure.<sup>169</sup> While selective arterial embolization and larger particle sizes should resolve some of these concerns, women over age 45 should be warned of the potential complication of diminished ovarian function and the attendant menopausal symptoms.

Additional complications may include pain, which commonly is severe over the initial 24 hours following embolization and may last up to 2 weeks. Pain can be well controlled with patient-controlled narcotic analgesic pumps and liberal use of anti-inflammatory agents. Prolonged pain in conjunction with fever should raise concerns about a possible septic uterus. Rare complications, including transcervical passage of necrotic submucosal fibroids, bowel necrosis, uterine infarction, and infection of other pelvic organs including the appendix, have been reported. Although these complications are rare, they can result in significant morbidity and mortality if diagnosis and acute intervention are delayed.

Up to 16.5% of procedures will fail owing to early treatment-related factors such as inability to catheterize, arterial dissection, incorrect diagnosis, and excessive myoma size.<sup>170</sup> Patients with submucosal or extremely large myomas may be at increased risk of treatment failure. Approximately 10% of patients with embolization had regrowth or recurrence of myomas at 2 years of follow-up.<sup>170</sup> Thus, while this therapy provides highly efficacious short-term results, long-term safety and efficacy have not been fully evaluated. Patients must be informed of the potential risks of both early and delayed procedure failure prior to embolization.

Surgical intervention following embolization occurs in 4% to 5% of patients.<sup>171</sup> The majority of these patients subsequently undergo hysterectomy. Many patients requiring surgery were treated for submucosal myomas. Most failures occur within 6 months of treatment and are secondary to menorrhagia or prolapse of pedunculated or submucosal myomas. Laparotomy may be complicated by the presence of bowel adhesions to the serosal surface overlying myomas.

### **Surgical Management**

For many women, the lack of prolonged efficacy, desire for fertility, concern regarding potential pregnancy-related complications and attendant side effects result in unacceptable compromises when undergoing medical treatment. Patients with extremely large myomas may find that medical treatment lacks sufficient efficacy in controlling pressure-related symptoms. In these cases, surgery is a viable and potentially curative option.

**Hysterectomy**

Ultimately, hysterectomy provides a permanent cure for fibroid-related symptoms. Whether conducted vaginally, abdominally, or laparoscopically, removal of the uterus resolves bleeding-, pressure-, and pain-related symptomatology. Vaginal hysterectomy should be the primary approach where possible, as it has the lowest morbidity and cost and a relatively rapid recovery time compared with abdominal hysterectomy. For a subtotal hysterectomy, the laparoscopic approach provides significant benefits in terms of recovery. Enlarged uteri may be amenable to vaginal hysterectomy with pretreatment using either GnRH analogs or UAE. Asymptomatic women with myomas should not undergo hysterectomy, as the risk of malignant transformation is 0.3% to 1%, a value less than the risk of morbidity associated with the surgical morbidity of hysterectomy.

In symptomatic women, hysterectomy provides significant relief of symptoms and resolution of anemia. The risk of fibroid growth posthysterectomy is exceedingly low and has only been reported as a metastatic process.<sup>172</sup> The Maine Women's Health study demonstrated that in women with myomas, the most significant factor correlated with positive outcome at 1 year of follow-up was hysterectomy.<sup>173</sup> Satisfaction rates following hysterectomy approximate 90%.<sup>174</sup> Although highly efficacious in the treatment of myomas, hysterectomy has a 3% to 6% morbidity rate. It has been estimated that 1 to 2 per 1000 women undergoing hysterectomy will die of procedural complications.<sup>175</sup> Compared with UAE, patients undergoing hysterectomy had fewer emergency room visits, a decreased rate of minor and moderate complications, but a 5% to 10% incidence of severe complications including deep venous thrombosis, wound infection, need for blood transfusion, and intraperitoneal abscess.<sup>176</sup>

Several studies have examined differences in the route of hysterectomy in women with myomatous uteri. In a randomized, controlled clinical trial comparing total abdominal hysterectomy, vaginal hysterectomy, and laparoscopically assisted vaginal

hysterectomy for myomas greater than 6 cm in size, febrile morbidity was increased significantly in women with abdominal hysterectomy.<sup>177</sup> Operative outcomes from this study are shown in Table 14-10. Blood loss was highest with laparoscopically assisted vaginal hysterectomy, followed by total abdominal hysterectomy, with vaginal hysterectomy showing the least blood loss. Although hospital stays were significantly different, there was little clinical difference in the observed values. The interval from surgery to return to work, however, was significantly longer for abdominal hysterectomies compared with the laparoscopically assisted vaginal hysterectomy or vaginal hysterectomy. Vaginal hysterectomy elicits the least amount of inflammatory reaction as measured by C-reactive protein and interleukin 6 levels, compared with abdominal hysterectomy and total laparoscopic hysterectomy.<sup>178</sup> There does not appear to be any difference in satisfaction or complication rates for total abdominal hysterectomy versus supracervical abdominal hysterectomy.<sup>179</sup>

With delayed child-bearing becoming more common, and medical options available for temporization of fibroid symptoms, the role of hysterectomy in the treatment of fibroids is becoming smaller. However, for women with considerable symptomatology, no desire for future fertility, and acceptance of the potential morbidity associated with hysterectomy, it is the only curative procedure available. Adjunctive use of GnRH agonist or UAE may facilitate the vaginal approach to the myomatous uterus. When vaginal hysterectomy is not possible, total laparoscopic and laparoscopically assisted hysterectomy may provide significant benefits in terms of recovery but carry operator-dependent risks of morbidity that patients must consider prior to electing the route of hysterectomy.

For patients who want to preserve fertility or do not want to have uterine extirpation, four alternative forms of surgical therapy are available: hysteroscopic resection (see Chapters 38 and 39), laparoscopic or hand-assisted laparoscopic myomectomy (see Chapter 37), myomectomy via laparotomy, and myolysis.

**Table 14-10**  
**Comparison of Operative Events Among Women in the Study Groups**

	LAVH (n)	Mean Value	TAH (n)	Mean Value	TVH (n)	Mean Value	P Value
Operation time (min) with second procedure	13	119 ± 20	8	117 ± 32	3	93 ± 15	0.12*
Without second procedure	17	109 ± 22	22	98 ± 16	27	74 ± 23	<0.001*

From Hwang JL, Seow KM, Tsai YL, et al: Comparative study of vaginal, laparoscopically assisted vaginal and abdominal hysterectomies for uterine myoma larger than 6 cm in diameter or uterus weighing at least 450 g: a prospective randomized study. *Acta Obstet Gynecol Scand* 2002;81:1132–1138, with permission.

### Abdominal Myomectomy

For women wishing to preserve the uterus, indications for abdominal myomectomy are similar to those for laparoscopic myomectomy, although because of the increased access provided by laparotomy, multiple fibroids and those that are either large or located in technically challenging locations can generally be resected. Preoperative and intraoperative adjuvant treatments are equally applicable; however, abdominal myomectomy permits minimization of blood loss by temporary mechanical obstruction of the uterine arteries with instruments such as the Bonny clamp.<sup>180</sup> Technically, abdominal and laparoscopic myomectomy procedures are similar, absent the need for laparoscopic instrumentation. Abdominal procedures may be conducted through a Pfannenstiel skin incision, although larger myomas may necessitate vertical skin incisions, with the attendant increase in wound-related morbidity. Uterine incisions should be minimized, since laparotomy often allows for removal of multiple myomas through a single uterine incision.<sup>181</sup> Careful attention to minimization of blood loss, avoidance of tissue trauma, and complete closure of the myoma cavity are the guiding principles of abdominal myomectomy procedures.

Efficacy rates are high with rare cases requiring hysterectomy for intractable bleeding.<sup>182</sup> Buttram and Reiter reviewed five studies and demonstrated an 81% rate of symptom resolution following myomectomy procedures.<sup>2</sup> Recently, Campo et al compared fertility outcomes of patients undergoing both abdominal and laparoscopic myomectomies, in a retrospective cohort evaluation.<sup>183</sup> There was a nonsignificant reduction of nearly 70% in pregnancy loss following abdominal myomectomy and a highly significant 75% reduction in pregnancy loss following laparoscopic myomectomy. Nearly 58% of patients with abdominal myomectomy were able to conceive versus 64% of patients with laparoscopic myomectomy. Eighty percent of patients gave birth successfully, with a cesarean section rate of 50%. Interestingly, these authors noted a 14-fold increase in chance of conception in patients who underwent laparoscopic versus abdominal myomectomy. In their evaluation of 46 separate studies on fertility following myomectomy, Donnez and Jadoul found that pregnancy rates for laparoscopic and abdominal myomectomy patients were 49% and 48%, respectively.<sup>92</sup>

Compared with hysterectomy, abdominal myomectomy demonstrates decreased morbidity.<sup>184</sup> Other sources of morbidity including fever, infection, blood loss, and visceral injury do not significantly differ from those of laparoscopic myomectomy. Adhesion formation rates after abdominal myomectomy may be as high as 90% compared with a lower rate for laparoscopic myomectomy. Leiomyoma recurrence rates following abdominal myomectomy are generally between 15% and 30%. In a randomized, controlled trial comparing abdominal and laparoscopic myomectomy procedures, recurrence rates were 23% and 27%, respectively, with no significant difference detected between the two groups.<sup>185</sup> In Fauconnier's review, excluding studies using ultrasound for diagnosis, recurrence rates were between 5.7% and 11.1%.<sup>186</sup> Inclusion of ultrasound significantly increases the rate of recurrence up to 50%, but many of these myomas may remain asymptomatic. The mean time to recurrence of myomas is 5.6 to 7.6 years following abdominal myomectomy procedures. Studies using life table analysis demonstrated a cumulative risk of 10% at 5 years after

abdominal myomectomy. Hysterectomy rates are similar for both abdominal and laparoscopic approaches, varying in studies from 4.3% to 16.8% for patients who previously underwent myomectomy. These values represent nearly one of every three patients who have recurrence. Predictors of recurrence include uterine size less than 12 weeks of gestational age, history of endometriosis, history of menorrhagia, and parity of one or more.<sup>187</sup>

### Laparoscopic Myolysis

In patients with fibroids not amenable to myomectomy, some authors advocate the use of laparoscopic myolysis. Acceptable candidates for this procedure include those with exceptionally large myomas, multiple myomas, or symptoms of pain or pressure. Myomas are coagulated with laser sources, diathermy, or electrical coagulation, usually starting with the central core followed by application to the entire myoma. Noselle et al treated 48 patients by laparoscopic Nd:YAG laser myolysis and followed patients with ultrasonographic assessment.<sup>188</sup> The authors found that myoma volume progressively decreased by a mean of 4% at 6 weeks postoperatively to a mean reduction of 41% after 6 months. Bipolar myoma coagulation has even higher efficacy with 80% to 90% reduction in uterine and fibroid volume at 6 months and almost universal patient satisfaction levels.<sup>189</sup>

Intraoperative complication rates are low and usually involve hemorrhagic areas within or around the coagulated myoma. Myoma regrowth following myolysis has not been reported. Most studies indicate a 3% to 6% rate of subsequent hysterectomy for persistent symptoms, in accord with reoperation rates following other surgical modalities of leiomyoma management. Although pregnancy has been reported following use of myolytic therapy, complications including uterine rupture also have been noted.<sup>190</sup> Because of its unknown effect on pregnancy, this procedure is not currently recommended for patients wishing to conceive following therapy.

### Alternative Therapies

In an attempt to reduce the complications associated with operative myomectomies, some authors have investigated the utility of performing hysteroscopic global endometrial ablation techniques for the treatment of fibroid-related menorrhagia. In a study of 22 women undergoing hydrothermal endometrial ablation for submucosal fibroids, 54% of patients were amenorrheic, 235 were oligomenorrheic, 14% were eumenorrheic, and only 4.5% (one patient) continued to have menorrhagia, necessitating hysterectomy, after a mean follow-up period of 15.4 months.<sup>191</sup> These results show significant promise, but the modality is unacceptable for patients wishing to conserve fertility. For physicians lacking technical proficiency in hysteroscopic resection techniques, the global ablative technique may be a reliable and effective means of controlling fibroid-related symptoms in selected patients.

## CONTROVERSIES

Epidemiologic studies on fibroids often conflict. Differences in patient populations, diagnostic techniques, and lack of control of confounding variables riddle many of the studies. Although

## General Gynecology

race and hormonal-related factors appear to have significant impact on the incidence of myomas, precise estimates of risk are difficult to ascertain. Moreover, causality or pathophysiologic associations have not been clearly delineated between risk factors and the genesis of uterine leiomyomas.

The effect of myomas on reproductive outcome also requires further investigation. Increasing evidence suggests that submucosal and some intramural fibroids can impair fertility as well as have adverse effects on women undergoing infertility treatment. However, these findings have not been confirmed in large, prospective studies, and the impact of subserosal myomas and smaller intramural fibroids on fertility outcomes is not clear. Moreover, the data regarding fibroids and pregnancy outcomes are mainly derived from retrospective case control studies with limited statistical power. Thus, the value of preconceptional myomectomy in patients with pregnancy loss and even those without symptoms needs further evaluation. Currently, the American College of Obstetricians and Gynecologists recommends that if patients with mild symptoms or reproductive failure undergo therapy, it should be conducted as close to the time of conception as possible owing to the relatively high rate of myoma recurrence over time.<sup>192</sup> Similarly, the association of myomas with recurrent miscarriage has not been assessed prospectively. The authors have reviewed the existing evidence, which indicates that resection of myomas is associated with a reduced miscarriage rate, and agree with Manyonda et al who conclude that from a pragmatic standpoint excision of myomas in patients with recurrent miscarriage not attributable to other factors is a reasonable therapeutic option.<sup>193</sup>

The role of medical therapy in the treatment of myomas is also riddled with numerous unanswered questions. While GnRH agonists have an obvious salutary effect on symptoms and myoma shrinkage, the severity and complexity of associated side effects limits their long-term use. Moreover, little evidence indicates that these agents are useful in patients wishing to subsequently conceive. The utility of preoperative GnRH agonists has not been fully evaluated, since some trials demonstrate potentially increased risks of surgical complexity, longer operative times, and higher recurrence rates in patients pretreated. These potential complications must be weighed against the observed benefits of decreased blood loss and results of some studies that demonstrate reduced operating times. A large, multicenter, randomized, controlled trial assessing the impact of preoperative GnRH analogs on intraoperative and postoperative outcomes would resolve these questions.

The optimal invasive approach is dependent on patient-specific factors. Laparoscopic myomectomy is associated with some improved short-term benefits, but long-term recurrence rates are likely higher than those found with abdominal myomectomy. Uterine artery embolization also has resulted in significant improvements in fibroid symptomatology, but the effects on pregnancy are not well understood. Thus, no single procedure can be considered the gold standard, because patients not wishing to undergo repeat surgical procedures, those who desire to conceive, and those who need rapid relief of symptoms without significant morbidity may each benefit from different procedures. Until the specific benefits, morbidities, and long-term patient and reproductive outcomes have been assessed the authors recommend that physicians review all options with

patients and decide on a course of therapy only after extensive consideration of the risks and benefits of each strategy for each patient.

The quandaries of myoma management are best summarized by Myers et al, who undertook a review of 1084 separate studies on the surgical and nonsurgical management of uterine leiomyomas with outcomes data.<sup>194</sup> Despite the large number of studies evaluated, these authors were unable to conduct any meta-analyses because of the "inconsistency in reporting of severity of symptoms, uterine anatomy, and response to therapy." Two issues thus are paramount in establishing evidence-based guidelines for myoma management: (1) research on myomas must use standardized classification systems, symptom measurement scales, and outcome measures and their respective assessment tools; and (2) greater collaboration between centers is necessary to enable the initiation of adequately powered, large-scale, prospective, randomized controlled trials. Until such circumstances arise, physicians must rely on careful analysis of the current body of evidence and use clinical judgment and skill in the counseling and guidance of patients.

## KEY POINTS

- An ectopic gestation can implant on any surface outside the normal endometrium; however, 95% of ectopic pregnancies occur within the fallopian tube.
- While the incidence of ectopic pregnancy in the United States has plateaued over the last several years, the incidence among minority populations has almost doubled.
- The most common risk factors associated with the development of an ectopic gestation are previous ectopic pregnancy, previous tubal surgery including tubal sterilization, current use of an IUD, and a history of proven pelvic inflammatory disease.
- The patient with an unruptured ectopic pregnancy may be asymptomatic or may appear almost identical to the patient with a threatened abortion.
- Serial quantitative hCG measurements combined with transvaginal ultrasound are the primary modes for excluding a viable intrauterine pregnancy and thus making the diagnosis of ectopic gestation.
- Treatment of the unruptured ectopic pregnancy has moved from surgical toward nonsurgical management over the last two decades, while surgery continues to be the only treatment for the patient with a ruptured ectopic pregnancy.
- Following resolution, the patient continues to have an increased likelihood of a subsequent ectopic pregnancy and an overall decreased risk of a subsequently viable pregnancy.

A pregnancy can occur in either an intrauterine or an extrauterine location. While intrauterine pregnancies can be abnormal (incomplete or missed abortion), an extrauterine (ectopic pregnancy) pregnancy is always abnormal. An ectopic pregnancy occurs when the fertilized ovum implants in a location other than on the normal endometrium lining the endometrial cavity. Ectopic pregnancy appears to be confined to humans, since it has rarely been reported in other mammalian species. The most common site for an ectopic pregnancy is the ampillary segment of the fallopian tube; however, it may occur in other locations (Table 15-1).

## EPIDEMIOLOGY

Ectopic pregnancies are a common occurrence among reproductive-aged women, and the rates have been increasing over the last 30 years. The overall ectopic pregnancy rate is approximately 16 per 1000 pregnancies. Among women aged 35 to 44 years, the rate averages approximately 27 per 1000 pregnancies.

Minority populations have a much higher rate of ectopic pregnancies. The rate for ectopic pregnancies is approximately 21 per 1000 among minorities versus 13 per 1000 in the white population. Women with ectopic pregnancies also have a significant risk for maternal mortality. Teenage women have the highest mortality rates with African American women having a risk five times greater than that of whites. The mortality rate associated with ectopic pregnancies accounts for approximately 15% of the annual maternal deaths in the United States.<sup>1</sup>

Once a woman has had one ectopic pregnancy, she has a 7- to 13-fold increased risk for a subsequent ectopic pregnancy. After an ectopic pregnancy, the following pregnancy has a 50% to 80% chance of being intrauterine and a 10% to 25% chance of again being ectopic, with the remainder of the patients becoming infertile.<sup>2</sup>

## ETIOLOGY AND RISK FACTORS

It is felt that the majority of ectopic pregnancies develop from an underlying tubal factor. The fallopian tubes can become damaged as a result of prior infection, inflammation, or surgery. Table 15-2 provides a listing of the known risks factors for ectopic pregnancy development. Associated risk factors include salpingitis, tubal sterilization, prior reconstructive tubal surgery, partial salpingectomy or congenital anomalies associated with the fallopian tubes. Changing levels of estrogen and progesterone as women age may account for the increased rates of ectopic pregnancies in women over age 35. While the etiology is uncertain, it may be secondary to the effects of estrogen on smooth muscle contractility and progesterone on smooth muscle relaxation.

Many risk factors are associated with development of an ectopic pregnancy; however, a few have been found to significantly increase a woman's risk. Women with a history of proved pelvic inflammatory disease (PID), a prior ectopic pregnancy, current use of an intrauterine contraceptive device (IUD), and previous tubal surgery as a treatment for infertility all have an increased risk for development of an ectopic pregnancy.

One of the major risk factors associated with development of an ectopic pregnancy is a history of a PID. Additional PID episodes may increase the inflammatory response within the pelvis, and subsequently the damage to the fallopian tube and tubal obstruction worsens. Although chlamydia infections may manifest only mild symptoms, there can be significant damage to the fallopian tubes. This may result in many cases being untreated or inadequately treated in the outpatient setting. Women with antichlamydial titers of 1:64 or greater are three times more likely to have an ectopic pregnancy than women with negative titers.<sup>3</sup> With each episode of PID, the rate of tubal obstruction is increased and the first pregnancy after an episode

## General Gynecology

**Table 15-1**  
**Ectopic Pregnancy Locations**

Type of Ectopic Pregnancy	Location
Tubal pregnancy	A pregnancy occurring in the fallopian tube Most commonly found in the ampillary region
Interstitial pregnancy	A pregnancy that implants in the interstitial portion of the fallopian tube
Abdominal pregnancy	Primary: The first and only implantation occurs on a peritoneal surface Secondary: The first implantation begins in the tubal lumen; the pregnancy is later aborted and then reimplants on a peritoneal surface
Cervical pregnancy	The developing ovum implants within the cervical canal
Ligamentous pregnancy	A pregnancy that occurs when a primary ectopic pregnancy erodes into the broad ligament and secondarily implants and develops between the leaves of the broad ligament
Heterotopic pregnancy	Concurrent intrauterine and ectopic pregnancies
Ovarian pregnancy	A pregnancy that develops within the ovarian cortex

of PID has a higher rate for an ectopic gestation at 6% versus 0.9% in the control group of women without prior PID.<sup>4,5</sup>

The type of contraception that a woman is using affects her risk for development of an ectopic pregnancy. IUDs are effective at preventing intra- and extrauterine pregnancies. However, if a woman does conceive with an IUD in place, she is six to ten times more likely to have an ectopic pregnancy than is a woman using no contraception method. The use of other contraceptive methods has also been evaluated. Women have many options such as combined oral contraceptives, progesterone-only hormonal preparations, as well as condom and diaphragm use. Of these, the only method shown to increase the rate for ectopic pregnancies was progesterone-only, by 4% to 10%. Levonorgestrel (Norplant) has shown a 30% increase in the risk of ectopic pregnancy.<sup>6,7</sup> However, this form of birth control is no longer marketed in the United States.

**Table 15-2**  
**Risk Factors for Ectopic Pregnancy**

- History of documented pelvic inflammatory disease/salpingitis
- Tubal sterilization
- Prior reconstructive tubal surgery
- Congenital anomalies of the fallopian tube
- Advanced maternal age
- Prior ectopic pregnancy
- Current use of an intrauterine contraceptive device
- Progestin-only contraceptive method
- Smoking
- Prior pelvic surgery
- Conception with an associated reproductive technology

Tubal sterilization is the most popular form of birth control throughout the world. However, tubal sterilization is not without risks and is associated with the development of future ectopic pregnancies. The use of bipolar electrocautery as the sterilization method is associated with a higher incidence of tubal pregnancies.<sup>8</sup> However, failures resulting in an ectopic pregnancy can occur with all types of sterilization procedures and can occur for many years following the procedure. Because tubal sterilization is such a popular method of sterilization, there is also a high incidence of regret associated with the procedure. As a result, many women are now opting to undergo reversal of the sterilization procedure. Not only do these women have an increase in the risk of developing an ectopic pregnancy secondary to their prior sterilization procedure, but they also are at risk because of the subsequent reanastomosis. The risks vary according to the method of sterilization used, the site of the prior tubal occlusion, the residual tube length after reanastomosis, coexisting disease, and surgical technique. The ectopic pregnancy risks associated with a tube that was cauterized are significantly higher than for a tube that was occluded using the Pomeroy or tubal banding techniques.<sup>9</sup>

Surgical sterilization is not the only tubal surgery that can increase a woman's risk for ectopic pregnancy. Tubal surgery can be performed to relieve an obstruction, lyse adhesions, or treat an existing ectopic pregnancy. Surgery on the tube is felt to place a woman at increased risk for an ectopic pregnancy, but it is unclear whether the increased risk is due to the surgery itself or from the underlying problem that existed prior to the surgery.

Patients who have had prior abdominal surgery are at an increased risk for developing an ectopic pregnancy. Surgery or conditions that result in the development of abdominal/pelvic adhesive disease are felt to place a patient at increased risk for ectopic pregnancy. Spontaneous and elective abortions are not believed to play a significant role in the development of future ectopic pregnancies so long as complications from the procedure do not occur.

The increasing number of women undergoing treatment for infertility is affecting the number of ectopic pregnancies. The majority of women undergoing treatment for infertility are older, and women of increased age are known to be at a greater risk of ectopic pregnancy. Women seeking treatment for infertility also are undergoing sterilization reversal, ovulation induction, and in vitro fertilization. Women undergoing ovulation induction with clomiphene citrate and gonadotropins have been found to be at a greater risk of ectopic pregnancy, even women with normal hysterosalpingography. The increased rate of an ectopic pregnancy with these techniques is between 1.1% and 4.6%.<sup>2</sup> In vitro fertilization is thought to place a woman at greater risk for ectopic pregnancy, owing to either the procedure itself or the underlying pathology resulting in infertility.

Tubal pathology resulting from salpingitis isthmica nodosa (SIN) is felt to place a woman at a greater risk for ectopic pregnancy. SIN is diverticulum of the fallopian tube as the endothelial tissue extends outward into the myosalpinx. It is not known whether the SIN causes ectopic pregnancies or whether its presence in the fallopian tubes of a woman with an ectopic pregnancy is coincidental.

Endometriosis and leiomyomata are two common conditions affecting women of reproductive age. Both conditions can

result in obstruction of the fallopian tubes. However, neither is commonly associated with the development of an ectopic pregnancy.

Smoking is one of the few truly modifiable risk factors associated with the development of an ectopic pregnancy. Women who smoke cigarettes have a two-fold risk for developing an ectopic pregnancy when compared with women who do not smoke. Coste et al suggest that this relationship with smoking may be dose dependent. Women who smoked more than 20 cigarettes per day had a risk 2.5 times greater than nonsmokers; while women smoking between 1 and 10 cigarettes a day had a relative risk of 1.3 for ectopic pregnancy.<sup>10</sup>

## PATHOGENESIS

An ectopic pregnancy is the attempted implantation and development of the fertilized ovum in an extrauterine location. The presence of chorionic villi is pathognomonic for an ectopic pregnancy. The chorionic villi are usually located within the lumen of the fallopian tube; however, they can be found elsewhere in the abdomen. When the ectopic pregnancy is located within the fallopian tube, the tube characteristically exhibits an irregular dilatation and bluish discoloration secondary to the surrounding hematosalpinx.

Patients with an ectopic pregnancy often have associated bleeding. The bleeding is usually extraluminal; however, it can remain confined to the fallopian tube, forming a hematosalpinx. The presence of hemoperitoneum can cause a varying degree of peritoneal irritation and subsequent pain. The hemoperitoneum is usually confined to the cul-de-sac unless rupture of the ectopic pregnancy and fallopian tube has occurred. Ectopic pregnancies can progress to the point of expulsion of the pregnancy out the fimbriated end of the fallopian tube, to rupture of the tube, or to natural involution of the pregnancy. The most common time for rupture of the ectopic pregnancy occurs around the sixth to eighth week of gestation, but is variable.

Histologically, the fallopian tubes may exhibit evidence of chronic salpingitis and/or SIN. The associated inflammation can result in the development of adhesive disease associated with the tubes. Women who have ectopic pregnancies have been found to demonstrate evidence of prior salpingitis.<sup>11</sup>

Histologic findings in the endometrium include the Arias-Sella reaction, which is characterized by localized hyperplasia of endometrial glands that are hypersecretory. The cells have enlarged nuclei that are hyperchromatic and irregular. The Arias-Sella reaction is a nonspecific finding that can be seen in patients with intrauterine pregnancies.

## CLINICAL FEATURES AND DIAGNOSIS

Because ectopic pregnancies are associated with a significant degree of morbidity and mortality, clinicians should have a high degree of suspicion for an ectopic pregnancy. Patients' presentations may range from asymptomatic to experiencing an acute abdomen with hemodynamic instability. The majority of patients with an unruptured ectopic gestation demonstrate vaginal spotting, bleeding, or lower abdominal cramping. While the patient's history and physical examination findings are important, the symptoms and physical examination findings in a patient with an

ectopic pregnancy are sometimes indistinguishable from the patient with an early viable intrauterine pregnancy or threatened abortion. Therefore, the degree of suspicion must be high, especially in areas of high prevalence. Because the goal is to make the diagnosis prior to rupture of the ectopic pregnancy, other diagnostic modalities than the physical examination must be utilized. If the diagnosis is made prior to rupture, morbidity can be reduced and future fertility maximized. Once rupture of the pregnancy has occurred, the goal shifts to stabilizing the patient and achieving hemostasis (Fig. 15-1).

### History

The patient's history is an important component in raising the clinician's awareness of the possibility of an ectopic pregnancy. Many patients will not exhibit clinical symptoms; however, when they do occur they usually involve one or all three of a classic triad. The classic triad consists of amenorrhea, irregular vaginal bleeding, and abdominal pain. This triad is present approximately 50% of the time and increases along with an increasing rate of rupture of the ectopic pregnancy. Abdominal pain is the most common symptom at presentation in the patient with a ruptured ectopic pregnancy and may result after the development of a hemoperitoneum. The severity of the pain can vary widely among patients, and no particular type of abdominal pain is pathognomonic. The pain can occur on only one side or bilaterally. It may be located in the upper or lower abdomen and characterized by being dull, sharp, or crampy in nature. The pain may be constant or intermittent. It can remain localized but more commonly radiates to the shoulders if a hemoperitoneum exists. Patients may also present with syncope or shock.

In addition to the preceding symptoms, patients should be questioned regarding a history of abnormal menses, prior pregnancy outcomes, history of infertility as well as current contraceptive use, specifically regarding progestin-only preparations or an IUD.

### Physical Examination

The physical examination, like the history, is an important component in recognizing and diagnosing an ectopic pregnancy. The clinician should be mindful of the patient's vital signs to evaluate for hemodynamic instability and examine the abdomen and pelvis to evaluate for rupture of the ectopic pregnancy.

Prior to rupture of the ectopic pregnancy, the patient often exhibits nonspecific symptoms. The vital signs are most often normal and the abdomen may be nontender or only mildly tender to palpation. The abdominal examination is usually non-specific, and cervical motion tenderness may or may not exist. An adnexal mass may be present; however, this could represent a functional corpus luteum cyst. As the ectopic pregnancy ruptures and the patient subsequently develops intra-abdominal bleeding, the physical examination findings change as well. The first change usually is the development of tachycardia and, with increasing hemodynamic instability, hypotension. The abdomen becomes distended, and peritoneal signs with tenderness and rebound become evident. At this point patients usually have cervical motion tenderness.

Because the patient's history and physical examination generally do not provide the complete diagnosis, clinicians must be prepared to initiate the appropriate work-up to diagnose

### Nonlaparoscopic algorithm for diagnosis of ectopic pregnancy

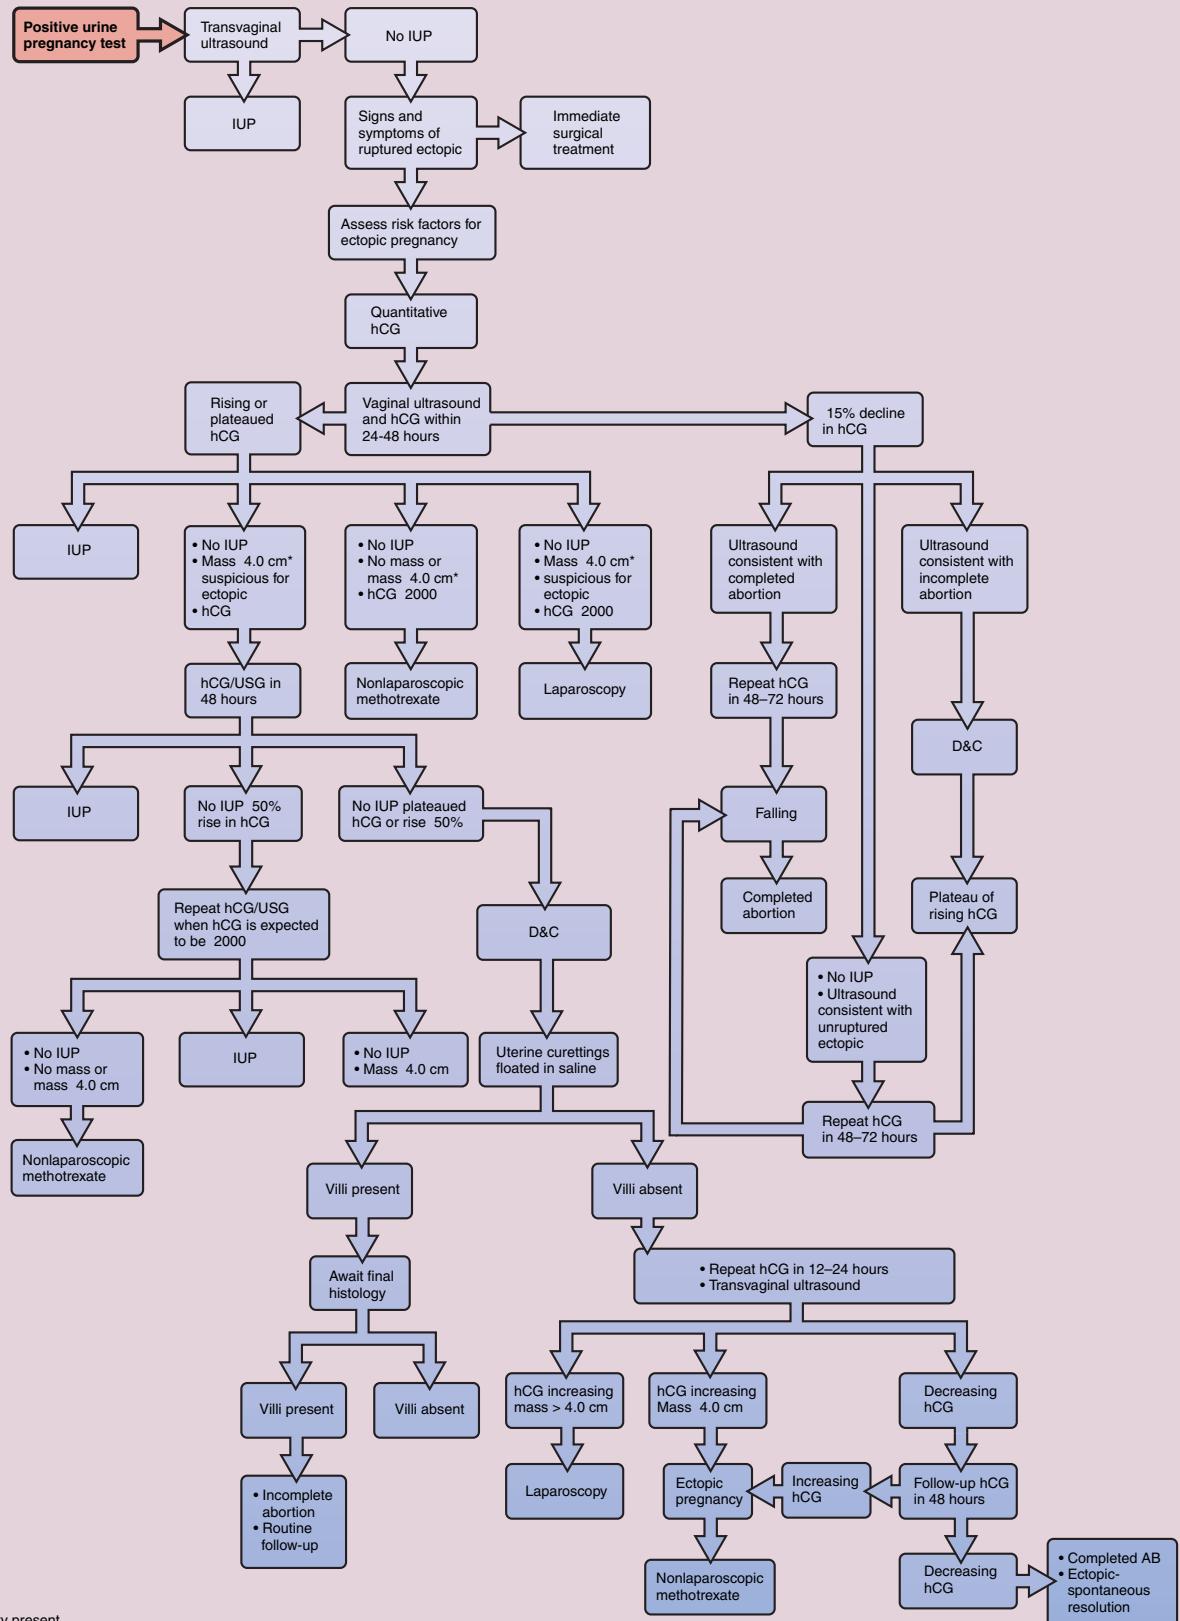

Figure 15-1 Nonlaparoscopic algorithm for diagnosis of ectopic pregnancy.

the ectopic pregnancy. A combination of diagnostic modalities generally is required including measurement of human chorionic gonadotropin (hCG) levels, transvaginal ultrasound, and possibly endometrial curettage and laparoscopy.

## Laboratory Tests

### **Serial Quantitative hCG Measurements**

The history and physical examination are important components of diagnosing an ectopic pregnancy; however, the most important test is the quantitative  $\beta$ -subunit measurement of hCG. The enzyme-linked immunoassay (ELISA) hCG is positive with virtually all ectopic pregnancies because of its sensitivity to 25 mIU/mL. Once a positive pregnancy has been identified, the goal is to determine whether it is intra- or extrauterine.

#### Reference Standards

There are three reference standards for  $\beta$ -hCG measurements. The World Health Organization (WHO) introduced the First International Standard (1st IS) in the 1930s. Testing for hCG and its subunits have improved over the years. The Second International Standard (2nd IS), introduced in 1964, has varying amounts of hCG  $\alpha$  and  $\beta$  subunits. A purified preparation of  $\beta$ -hCG is now available. Originally referred to as the First International Reference Preparation (1st IRP), the test standard is now referred to as the Third International Standard (3rd IS). Although each standard has its own scale, as a general rule, the 2nd IS is about one-half of the 3rd IS. For example, if a level is reported as 500 mIU/mL (2nd IS), it is equivalent to a level of 1000 mIU/mL (3rd IS). The assay standard used must be known in order to correctly interpret hCG results. In several recent articles, attention has been drawn to a problem known as phantom hCG, in which the presence of heterophile antibodies or proteolytic enzymes cause a false-positive hCG result. Because the antibodies are large glycoproteins, significant quantities of the antibody are not excreted in the urine. Thus, in the patient with hCG levels of less than 1000 mIU/mL, a confirmatory positive urine pregnancy test should be obtained prior to instituting treatment.

A single measurement of the hCG level is not helpful in and of itself, especially when the level is below the discriminatory zone for ultrasound visualization. There is a wide range of variability of hCG levels for both intrauterine and ectopic pregnancies, and the location of the pregnancy for a given patient cannot be determined using a single hCG measurement. The single hCG is useful if the test is negative, which essentially excludes the diagnosis of pregnancy. Also, if the hCG level is greater than the discriminatory zone for ultrasonography, the results can be used to aid in the diagnosis of an ectopic pregnancy. If the hCG level is elevated above the discriminatory zone and the ultrasound was inconclusive, the physician would still need to follow serial hCG measurements to differentiate between an ectopic pregnancy and a completed abortion. Thus, in almost all instances, serial hCG measurements are required. The doubling time associated with serum hCG is an important parameter for following an early pregnancy and differentiating a normal from an abnormal pregnancy. A patient's hCG level correlates closely with gestational age early in pregnancy. Within the first 6 weeks of pregnancy, the patient's hCG level increases exponentially.

Kadar and Romero reported that in early gestations the hCG doubles approximately every 1.98 days (95% CL).<sup>12</sup> These hCG levels are useful for diagnosing pregnancy, identifying an abnormal pregnancy at risk for an early abortion or ectopic gestation, and following the resolution of a treated ectopic pregnancy.

Serial measurements of hCG are useful in differentiating a viable intrauterine pregnancy from an ectopic pregnancy. With a viable intrauterine pregnancy, the hCG typically exhibits at least a 66% increase over a 48-hour period (85% CL). However, approximately 15% of viable pregnancies will have less than a 66% increase and the same number of ectopic pregnancies will have more than a 66% increase. Thus, to confirm pregnancy non-viability, an increase of less than 50% over 48 hours should be used in patients with hCG less than 2000 mIU/mL. Patients with a normal intrauterine pregnancy have at least a 50% rise in the hCG level over 48 hours unless the starting level is above 2000 mIU/mL when the rate of rise is more unpredictable. When measurements are repeated in less than 48 hours between samplings, there is even more overlap between normal and abnormal, and so from a clinical perspective the values are not as useful. When serial hCG measurements are followed, the clinical pattern of an hCG that has plateaued (doubling time of  $>7$  days) is the most predictive for an ectopic pregnancy.<sup>13</sup> For falling levels, a 50% decrease in less than 1.4 days is rarely associated with an ectopic pregnancy, whereas a less than 50% decrease over more than 7 days is most predictive of ectopic pregnancy.

If the physician is initially suspicious that a patient has an ectopic pregnancy, an initial ultrasound is obtained. However, if the ultrasound evaluation is indeterminate for either an intrauterine or an ectopic pregnancy, serial hCG levels are obtained. As long as the hCG levels continue to rise appropriately ( $>50\%$  over 48 hours) and the patient is relatively asymptomatic, the physician could follow the patient until the hCG level reaches the transvaginal discriminatory level of 2000 mIU/mL. At this point a repeat vaginal ultrasound should be obtained. If the levels do not rise appropriately, either an ectopic or nonviable intrauterine pregnancy is present. The location of the pregnancy at this point would have to be found surgically; first, with dilation and curettage (D&C), and possibly with laparoscopy depending on the clinical situation.

### **Serum Progesterone Measurement**

Initial progesterone analysis helps differentiate viable from nonviable gestations. In studies by Stovall et al, if the initial progesterone level was 25 ng/mL or greater, the diagnosis of ectopic pregnancy could virtually be excluded with approximately 98% certainty. If the progesterone level was less than 5.0 ng/mL, the diagnosis of a nonviable pregnancy, either intrauterine or ectopic, could be guaranteed with almost 100% sensitivity.<sup>14</sup> The risk of a normal pregnancy with a serum progesterone level below 5.0 ng/mL is approximately 1/1500. For this reason, serum progesterone is not included in the diagnostic algorithm presented here (see Fig. 15-1). The difficulty with progesterone interpretation is when a patient's level is between 5 ng/mL and 25 ng/mL. In this case, the clinician must continue to use hCG, ultrasound, and clinical history for diagnosis.

**Other Markers**

Other maternal serum markers such as estradiol, creatine kinase, pregnancy-associated plasma protein C, relaxin, CA-125, material serum  $\alpha$ -fetoprotein, and C-reactive protein have all been analyzed with regard to ectopic pregnancy. Their clinical reliability has been mixed, and they are not currently used clinically in the management of ectopic pregnancies.

**Ultrasonography**

Ultrasound evaluation of the patient is an important tool in diagnosis. Transvaginal ultrasound is superior to transabdominal ultrasound in visualization of pelvic structures, and an intrauterine gestational sac can be visualized as much as 1 week earlier with transvaginal imaging. However, both have clinical relevance in the complete evaluation of a patient with an expected ectopic pregnancy. Figure 15-2 demonstrates a right tubal ectopic pregnancy as visualized on ultrasound.

The ultrasound results obtained should be correlated with the patient's  $\beta$ -hCG level, which is termed the discriminatory zone. The discriminatory zone is the hCG level above which the ultrasonographer should be able to visualize normal intrauterine pregnancies. With abdominal ultrasonography viable intrauterine pregnancies should be seen above hCG levels of 6500 mIU/mL as opposed to 1500 to 2000 mIU/mL transvaginally. If the hCG is 6500 mIU/mL or greater for an abdominal ultrasound and 2000 mIU/mL or greater for a vaginal ultrasound and a pregnancy is not visualized, it is either a failed intrauterine pregnancy or an ectopic pregnancy. The difficulty with utilizing the discriminatory zone for analysis is that there is no discriminatory zone associated with an ectopic pregnancy. An ectopic pregnancy can exist with either a high or low hCG level. A word of caution is warranted, even in those patients with an hCG titer above the discriminatory zone for an intrauterine pregnancy. In the stable patient, the hCG titer and ultrasound should be repeated prior to instituting treatment. In other words, unless cardiac activity is seen in the ectopic pregnancy or the clinical situation dictates more immediate management, the ultrasound and hCG findings are confirmed by repeat testing.

With ultrasound, early findings indicative of an intrauterine pregnancy are the presence of a small, fluid-filled space and the gestational sac with a surrounding echogenic ring. The gestational sac typically has an eccentric uterine location. The gestational

sac can be visualized at 4 weeks postconception vaginally versus 5 weeks abdominally. In an intrauterine pregnancy, the sac grows followed by the presence of a yolk sac and subsequently an embryo with cardiac activity.

A normal gestational sac is often confused with a pseudosac. The pseudosac is probably due to bleeding from the decidua into the endometrial cavity. Investigators have wondered whether the presence of pseudosac is indicative of an ectopic pregnancy; in a recent study of 77 patients it was felt that the presence of the pseudosac could not be used reliably. Ahmed et al found that the presence of the pseudosac was not indicative of an ectopic pregnancy because an intrauterine pregnancy failure could not be differentiated from an ectopic pregnancy using ultrasonography.<sup>15</sup>

It has long been believed that the presence of a double decidual sac sign (DDSS) is the best method to determine if a sac present is a true gestational sac or a pseudosac. The DDSS is thought to be a layer of decidua surrounding the chorionic sac. Its presence is felt to be indicative of an intrauterine pregnancy, and the clinician's confidence can increase when the yolk sac has been seen on ultrasound. The yolk sac is usually visible with abdominal ultrasound when the gestational sac reaches a size of 2.0 cm and 0.6 to 0.8 mm vaginally. When cardiac activity is seen within the uterine cavity, definitive evidence of an intrauterine pregnancy exists.

When a gestational sac with fetal pole and cardiac activity is present within the adnexa, the clinician can be relatively confident that an ectopic pregnancy exists. However, ultrasonography of the adnexa is not particularly sensitive in diagnosing ectopic pregnancies.

If, after ultrasonography is used to aid in diagnosis, the uterus is found to be empty and the hCG level is below the discriminatory zone, the clinician must consider the differential diagnosis of: an early normal intrauterine pregnancy, an abnormal intrauterine gestation, miscarriage, ectopic pregnancy, and even the nonpregnant state.

In this situation, further diagnostic tests such as a follow-up laboratory studies, repeat ultrasounds, D&C, and laparoscopy can all be useful.

**Dilation and Curettage**

D&C should be performed once the pregnancy has been determined to be nonviable or its exact location cannot be verified ultrasonographically. Care must be taken to not perform D&C in the presence of a viable intrauterine pregnancy; therefore, D&C should be performed when the ultrasound is inconclusive above the level of the discriminatory zone and hCG levels have plateaued or are rising suboptimally. The physician can immediately examine the specimen removed at the time of the endometrial curettage. The specimen can be placed in normal saline and examined. Chorionic villi exhibit a lacy, frond-like appearance and float on the saline. This technique has sensitivity and specificity of greater than 95%. The specimen also should be examined by a pathologist for the presence of chorionic villi and a serum hCG level obtained.

If the follow-up hCG levels decrease by 15% or more in the initial 12-hour period after the D&C, a completed abortion is suspected. However, if the follow-up hCG levels plateau or rise, the diagnosis of an ectopic pregnancy has been made.<sup>14</sup>

Figure 15-2 Right tubal ectopic pregnancy, visualized by ultrasound.

### Culdocentesis

The practice of culdocentesis has declined in popularity for the diagnosis of ectopic pregnancies with the advent of transvaginal ultrasonography and serial hCG measurements. In culdocentesis the posterior fornix of the vagina is visualized by means of a speculum. The posterior cul-de-sac is then entered with a spinal needle and the contents are aspirated with a syringe. With a positive test—the presence of nonclotting blood—a ruptured ectopic pregnancy may exist. If serous fluid is aspirated, the test is thought to be negative. Culdocentesis is considered non-diagnostic if clotted blood or no fluid is aspirated. The problem associated with culdocentesis is that the majority of patients with an ectopic pregnancy will have a positive test, yet the majority of these patients will not have a ruptured ectopic pregnancy.

Historically, if the culdocentesis results were positive, surgery was performed for a presumed diagnosis of ruptured tubal pregnancy. However, the results of culdocentesis do not always correlate with the status of the pregnancy. Although approximately 70% to 90% of patients with an ectopic pregnancy have a hemoperitoneum demonstrated by culdocentesis, only 50% of patients have a ruptured tube. Furthermore, approximately 6% of women with positive culdocentesis results do not have an ectopic gestation at the time of laparotomy. Non-diagnostic fluid occurs in 10% to 20% of patients with ectopic pregnancy and therefore is not definitive.

### Laparoscopy

The gold standard for diagnosing an ectopic pregnancy has long been laparoscopy. Laparoscopy allows for visualization of the pelvis, fallopian tubes, and ovaries (Fig. 15-3). Disadvantages of laparoscopy are that the patient has to undergo a surgical procedure with its inherent risks, including anesthesia, and that small ectopic pregnancies may be missed. Since many ectopic pregnancies occur in normal fallopian tubes, if surgery can be avoided, the fallopian tube has been spared, which may increase a patient's future fertility. A distinct advantage of laparoscopy is that diagnosis and treatment can occur in the same setting.

At the time of laparoscopy, with the presence of a tubal ectopic pregnancy, the tubal architecture is usually distorted. If

Figure 15-3 Right tubal ectopic pregnancy, visualized by laparoscopy.

the patient has experienced prior PID or tubal damage resulting in adhesive disease, the assessment of the fallopian tubes may be compromised.

### Diagnostic Algorithm: A Combination of Assessment Techniques

This diagnostic algorithm (see Fig. 15-1) was found to be 100% accurate in a randomized clinical trial.<sup>14,16</sup> Serial hCG levels are used to assess the viability of a pregnancy, correlate the given transvaginal ultrasound findings, and determine whether the hCG titer increases or falls following suction curettage in those patients who require curettage before beginning medical therapy for an ectopic pregnancy.

Transvaginal ultrasound is an important diagnostic tool in the algorithm. If the patient is found to have an intrauterine sac or pregnancy, ectopic pregnancy can be excluded with a reasonable degree of certainty. If the patient's hCG is greater than the discriminatory level and no intrauterine gestational sac is visualized, the patient is considered to have an ectopic pregnancy. If cardiac activity is found in an extrauterine location, most specifically the adnexa, the diagnosis of ectopic pregnancy is confirmed. With the sensitivity of ultrasound, masses greater than 1 cm can be identified. When the size of the ectopic pregnancy reaches 3.5 to 4.0 cm, depending on the presence of fetal cardiac activity, surgical treatment becomes the preferred method of treatment.

Endometrial curettage is used to distinguish between a non-viable intrauterine pregnancy and an ectopic pregnancy. Suction curettage is performed when a patient experiences an inappropriate rise in the hCG level of less than 50% over 48 hours and an hCG level of 2000 or greater with an indeterminate ultrasound. With D&C the clinician can avoid using methotrexate for medical management in patients with an abnormal intrauterine gestation that can effectively be diagnosed via uterine evacuation. The only real drawback to curettage is the presence of a heterotopic gestation or missing an extremely early nonviable intrauterine gestation.

### TREATMENT

Medical and surgical options exist for the treatment of ectopic pregnancy. Both methods are effective, and the individual patient's clinical scenario including the site and size of the ectopic pregnancy should determine her treatment.

#### Surgical Treatment

Surgical treatment has been the gold standard for treatment of ectopic pregnancy. Experts are unsure which operative treatment is best, and the surgical options range from salpingo-oophorectomy, salpingectomy, segmental resection, and salpingostomy. Salpingo-oophorectomy was once considered appropriate because it was theorized that this technique would eliminate transperitoneal migration of the ovum or zygote, which was thought to predispose to recurrent ectopic pregnancy. Ovary removal results in all ovulations occurring on the side with the remaining normal fallopian tube. Subsequent studies have not confirmed that ipsilateral oophorectomy increases the likelihood of conceiving an intrauterine pregnancy; therefore, this practice is not recommended.

## General Gynecology

The most widely accepted method for surgical treatment in a patient who has not experienced rupture of the ectopic pregnancy and who desires future fertility is salpingostomy. The fallopian tube is opened along the antimesenteric border, and the products of conception are removed (see Chapter 37). A fine incision should be utilized and carried out with the needle tip bovine cautery, scalpel, scissors, or laser. The surgery can be done either through a laparotomy or laparoscopically. When patients undergoing salpingectomy and salpingostomy were followed, no difference was found in future fertility rates.<sup>17</sup> The patients who had a history of infertility were more likely to have an ectopic pregnancy following salpingostomy. Therefore, consideration should be given in this patient group to salpingectomy in order to reduce their risk for ectopic pregnancy. However, the status of the contralateral tube must be considered when this decision is made.

There is also debate over whether the patient requiring surgery should be treated with a laparotomy or laparoscopically. The primary treatments of salpingectomy, salpingostomy, and segmental resection can be accomplished via both techniques. The hemodynamic stability of the patient and the comfort level of the surgeon are the primary factors that determine the surgical approach. Typically, laparotomy is indicated if the patient becomes hemodynamically unstable. Rupture of the ectopic pregnancy does not necessitate laparotomy. Laparotomy is typically chosen if the patient has an abdominal or ovarian pregnancy.

Studies have shown that laparoscopy and laparotomy are both safe and effective treatment measures. However, laparoscopy is more economical secondary to reduced costs and shorter hospitalizations. Laparoscopically treated patients also have a shorter time for recovery and convalescence and reduced post-operative pain requirements. It has also been concluded that laparoscopy results in the formation of fewer adhesions post-operatively and less blood loss. For these reasons, many physicians consider laparoscopy the preferred method of surgical treatment for ectopic pregnancies.<sup>18</sup> Future pregnancy rates are similar in patients treated by both laparotomy and laparoscopy.

### Medical Treatment

The most popular current medical treatment for ectopic pregnancy is methotrexate although other agents such as potassium chloride (KCl), hyperosmolar glucose, prostaglandins, and RU-486 have been studied. The routes of treatment vary from systemic administration—intravenous, intramuscular, and oral—to local administration—laparoscopically guided direct injections, transvaginal ultrasound directed injections, and retrograde fallopian tube treatments.

#### Methotrexate

Methotrexate is the most popular form of medical treatment for women with unruptured ectopic pregnancies. Methotrexate is a folic acid analog and functions by inhibiting dihydrofolate reductase. With the synthesis of folate disrupted, the synthesis of DNA is prevented. Methotrexate is also used for the treatment of gestational trophoblastic disease. The most common side effects are leukopenia, thrombocytopenia, bone marrow aplasia, ulcerative stomatitis, diarrhea, and hemorrhagic enteritis. Other less common side effects include alopecia, dermatitis, elevated

liver function tests, and pneumonitis. These side effects are more common at the higher therapeutic doses associated with chemotherapy and are not associated with the lower dosing regimens necessary to treat ectopic pregnancies. A patient who requires multiple doses for treatment of ectopic pregnancy is more prone to develop the minor side effects. The incidence of these side effects can be reduced with the administration of citrovorum factor.

Stovall et al studied the use of multidose (Table 15-3) intramuscular methotrexate (1 mg/kg/day) followed by citrovorum factor (0.1 mg/kg/day). One hundred patients received injections on alternate days with a success rate of 96%.<sup>19,20</sup> This treatment regimen was continued until the hCG level began to decline by at least 15% between two consecutive hCG levels. Citrovorum factor was given on the day following the methotrexate injection even if the patient required no further methotrexate injections. Once the treatment was discontinued, the patient's hCG levels were measured until they became negative. A second treatment course of methotrexate was given only if the patient's hCG levels plateaued or began to rise. In this study 96 patients were treated effectively. Seventeen received one methotrexate/citrovorum injection while 19 patients received four doses. Four of 100 patients ultimately required surgical management secondary to rupture. Each of these four patients differed with respect to ectopic pregnancy size, hCG level, and time of rupture. Five patients had ectopic pregnancies with cardiac activity, and four of the five (80%) were treated successfully.

In an effort to reduce the side effects associated with methotrexate, a single-dose protocol was devised. Initially, 31 patients were treated with a single dose of methotrexate (50 mg/m<sup>2</sup>). Citrovorum factor was eliminated. Approximately 97% of the treated patients (29/30) were treated successfully.

**Table 15-3**  
**Multidose Methotrexate-Citrovorum Protocol for Unruptured Ectopic Pregnancy**

Day	Therapy
1	CBC, SGOT, BUN, creatinine, $\beta$ -hCG, blood type and Rh, MTX
2	CF, $\beta$ -hCG
3	MTX, $\beta$ -hCG
4	CF, $\beta$ -hCG
5	MTX, $\beta$ -hCG
6	CF, $\beta$ -hCG
7	MTX, $\beta$ -hCG
8	CF, $\beta$ -hCG, CBC, SGOT, BUN, creatinine
>8	Weekly $\beta$ -hCG until <10 mIU/mL

BUN, blood urea nitrogen; CBC, complete blood count with differential and platelet count; CF, intramuscular citrovorum factor 0.1 mg/kg; hCG, human chorionic gonadotropin; MTX, intramuscular methotrexate 1.0 mg/kg; SGOT, serum glutamic–oxaloacetic transaminase.

Notes: (1) Methotrexate/citrovorum is given until there is a 15% decline in two consecutive hCG titers; (2) any time methotrexate is given, citrovorum is given on the following day; (3) patients with a hematocrit <35% are given oral iron therapy; (4) patients are told to refrain from alcohol, folic acid-containing vitamins, and sexual intercourse during the treatment period; (5) oral or barrier contraceptives are used until the hysterosalpingogram is completed; (6) hysterosalpingogram is requested on days 6–9 after the second menstrual cycle.

**Table 15-4****Single-Dose Methotrexate Protocol for Ectopic Pregnancy**

Day	Therapy
0	D&C, hCG
1	CBC, SGOT, BUN, creatinine, blood type and Rh, methotrexate 50 mg/m <sup>2</sup> IM
4	hCG
7	hCG

BUN, blood urea nitrogen; CBC, complete blood count; D&C, dilation and curettage; hCG, human chorionic gonadotropin; SGOT, serum glutamic–oxaloacetic transaminase.

Notes: (1) Treatment is never begun based on a single hCG titer unless cardiac activity is visualized on transvaginal scan in the ectopic pregnancy. (2) If <15% decline in hCG level between days 4 and 7, give second dose of methotrexate 50 mg/m<sup>2</sup> on day 7. (3) If >15% decline in hCG level between days 4 and 7, follow weekly until hCG <10 mIU/mL. (4) In patients not requiring D&C (hCG > 2000 mIU/mL and no gestational sac on transvaginal ultrasonography), days 0 and 1 are combined.

Currently, 600 patients have been treated with this protocol with an overall success rate of 93% (Table 15-4). A major advantage of this treatment regimen is that no patients experienced methotrexate-related side effects. In addition, the single-dose treatment protocol is less expensive than the multidose protocol, has increased patient acceptance/compliance secondary to decreased patient monitoring during therapy, with similar treatment results and prospects for future fertility.

Most clinicians who oppose the use of methotrexate do so owing to the potential side effects. The majority of patients who experience side effects were treated with the intravenous form of the medication, with higher doses or for longer period of time. When the single-dose regimen was utilized, the incidence of side effects was less than 1%, while the failure rate was similar to that of conservative forms of laparoscopic surgery.

**Treatment Initiation**

Before methotrexate therapy can be initiated, the physician must confirm that the patient is a good candidate for therapy (Table 15-5), that the pretreatment check-in has been completed (Table 15-6), and that the patient has been given the appropriate instructions (Table 15-7). This is essential to maximize the safety of the therapy and decrease the chance that a patient with an

**Table 15-6****Initiation of Methotrexate: Physician Checklist**

- Obtain hCG level
- Perform transvaginal ultrasound within 48 hours
- Perform endometrial curettage if hCG level <2000 mIU/mL
- Obtain normal liver function (SGOT), normal renal function (BUN, creatinine), and normal CBC (WBC >2000/mL and platelet count >100,000)
- Administer Rh<sub>s</sub>(D) immune globulin if patient is Rh-negative
- Identify unruptured ectopic pregnancy <3.5 cm
- Obtain informed consent
- Prescribe FeSO<sub>4</sub> 325 mg PO bid if hematocrit <30%
- Schedule follow-up appointment on days 4, 6, and 7

BUN, blood urea nitrogen; CBC, complete blood count; hCG, human chorionic gonadotropin; SGOT, serum glutamic–oxaloacetic transaminase; WBC, white blood cell.

early intrauterine or nonviable intrauterine gestation will receive methotrexate. Good candidates for therapy are patients who (1) have a rising or plateaued hCG level after salpingostomy; (2) who have a rising or plateaued hCG level at least 12 to 24 hours following a diagnostic D&C; and (3) who are without an intrauterine gestational sac or fluid collection by transvaginal ultrasound, have an abnormally rising hCG level below 2000, have an ectopic mass of 3.5 cm or less with fetal cardiac activity or 4.0 cm and less without fetal cardiac activity.

**Follow-up**

Once methotrexate has been administered, the patient is sent home for follow-up as an outpatient. During the initial treatment phase, the frequency of follow-up is determined based on whether the multidose (see Table 15-3) or the single-dose (see Table 15-4) protocol is being followed. Serial hCG measurements, usually weekly, are obtained until negative. Following the initial treatment, patients are instructed to monitor their pain and to call in if there is any increase in pain. If the pain is prolonged or severe, the hematocrit is evaluated and a transvaginal ultrasound should be obtained. If a drop of greater than 3% to 4% occurs in the hematocrit or if the patient becomes unstable, the physician should suspect a tubal rupture. Transvaginal ultrasound may be helpful if an increase in abdominal free fluid is noted; however, a small amount of physiologic fluid may be present within the pelvis. Although there is no scientific base for doing so, the authors ask patients to refrain from becoming pregnant for 2 months after methotrexate treatment is completed.

**Table 15-5**  
**Candidates for Methotrexate Treatment of Ectopic Pregnancy**

- An hCG level is present and plateaued or rising after salpingostomy or salpingectomy
- A rising or plateaued hCG level is present at least 12–24 hours after suction curettage (needed if hCG is <2000 mIU/mL)
- No intrauterine gestational sac or fluid collection is detected by transvaginal ultrasound,\* hCG level is >2000 mIU/mL, and an ectopic pregnancy mass ≤3.5 cm is demonstrated with cardiac activity or ≤4.0 cm without cardiac activity

\*The ultrasound finding must be interpreted with caution because most unruptured ectopic pregnancies will be accompanied by fluid in the cul-de-sac.

**Table 15-7****Initiation of Methotrexate: Patient Instruction**

- Refrain from alcohol use, multivitamins containing folic acid, and sexual intercourse until hCG level is negative
- Call your physician if you experience prolonged or heavy vaginal bleeding, or if pain is prolonged or severe (lower abdomen and pelvic pain is normal during the first 10–14 days of treatment).
- Use oral contraception or barrier contraceptive methods
- Know that ~5% of women experience unsuccessful methotrexate treatment and require surgery

### Other Modalities

The primary alternative treatment modality—salpingocentesis—includes the injection of various substances into the ectopic pregnancy either transvaginally utilizing ultrasound guidance, transcervically via tubal cannulation, or laparoscopically. Agents such as KCl, methotrexate, prostaglandins, and hyperosmolar glucose are used.<sup>21</sup> The advantages of this treatment are that it is a one-time, localized treatment that can avoid most of the systemic side effects associated with methotrexate.

## CLINICAL COURSE, PROGRESSION, AND ECTOPIC PREGNANCY TYPES

### Spontaneous Resolution

Not all ectopic pregnancies require medical or surgical management. Some resolve by resorption or by a tubal abortion. Some investigators feel that expectant management may be appropriate for the management of early ectopic pregnancies. Following serum hCG levels until resorption or tubal abortion occurs has been advocated. Some authors feel that expectant management is the best way to preserve future fertility; however, this is controversial. Falling hCG levels are the most reliable indicator of success, but the physician should be mindful that rupture can occur even with a falling or low  $\beta$ -hCG level. Expectant management should be attempted only in extremely compliant patients.<sup>22</sup>

### Persistent Ectopic Pregnancy

A persistent ectopic pregnancy is present when a patient has already undergone a conservative form of surgery such as salpingostomy or fimbrial expression and viable trophoblastic tissue remains. The persistent trophoblastic tissue is usually located in the medial segment of the fallopian tube; however, it can be located on the peritoneal surface as well.<sup>23</sup>

The incidence of persistent ectopic pregnancies is increasing as the incidence of tubal conservation surgery is increasing. The persistent ectopic pregnancy is suspected and later diagnosed as the  $\beta$ -hCG levels remain elevated following conservative surgery.

The risk factors for development of a persistent ectopic pregnancy vary from the type of initial surgical procedure, initial hCG level, duration of amenorrhea, and size of the ectopic pregnancy.

The treatment of a persistent ectopic pregnancy is similar to the treatment of the initial ectopic pregnancy; either medical or surgical. Methotrexate can be used as a medical treatment for patients who are hemodynamically stable. Many feel that methotrexate is the treatment of choice, since the trophoblastic tissue may have been spread to multiple locations during the initial surgical procedure. If follow-up surgery is indicated, repeat salpingostomy can be performed; however, salpingectomy is more commonly performed.

### Chronic Ectopic Pregnancy

Chronic ectopic pregnancy occurs as a result of expectant medical management or occasionally following salpingostomy. In the course of the treatment, if the ectopic pregnancy does not completely resorb, chorionic villi will still be present. Because of the persistent chorionic villi, the patient may develop bleeding

into the wall of the fallopian tube. As a result, the tube distends slowly and does not rupture. Patients usually have symptoms of pain and vaginal bleeding. On examination the majority of patients have a pelvic mass. The treatment for a chronic ectopic pregnancy is surgery with removal of the affected fallopian tube.

### Nontubal Ectopic Pregnancies

#### Cervical Pregnancy

The rates associated with a cervical pregnancy have been reported to range from 1 in 2400 to 1 in 50,000 in the United States. The differential diagnosis initially must include cervical cancer, presence of a cervical fibroid, trophoblastic tumor, and abnormalities of placental location such as a placenta previa or low-lying placenta. Patients are at risk of developing a cervical pregnancy if they have undergone a prior elective abortion, developed Asherman's syndrome, had a prior cesarean delivery, been exposed to diethylstilbestrol, developed leiomyomata, or undergone in vitro fertilization.<sup>24</sup>

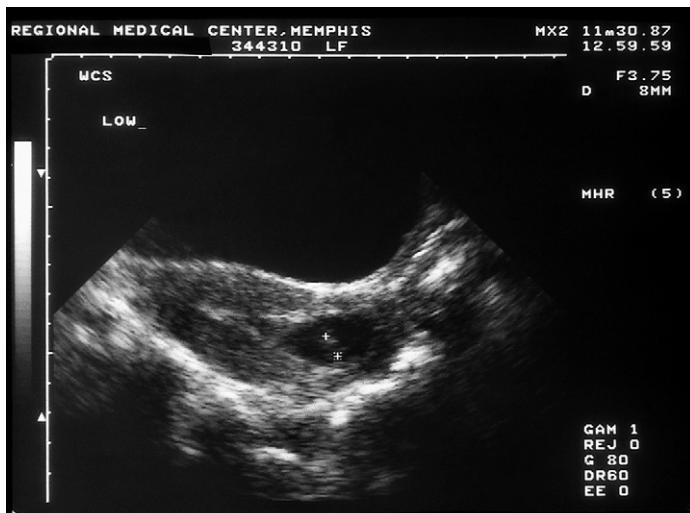

Clinical criteria that should alert the physician to the possibility of a cervical pregnancy include smaller size of the surrounding uterus than of the distended cervix, the presence of a closed internal os, no chorionic tissue found on curettage of the endometrial cavity, and dilation of the external os sooner than would be expected in the presence of a spontaneous miscarriage.

Utilization of ultrasound is useful in diagnosis of a cervical pregnancy. Ultrasound diagnostic criteria of a cervical pregnancy (Table 15-8) consist of the presence of an echo-free uterine cavity, decidual transformation of the endometrium, a diffuse uterine wall structure in an hourglass shape, enlargement and ballooning of the cervical canal, a closed internal cervical os with a gestational sac and placental tissue within the cervical canal (Fig. 15-4).

When a cervical pregnancy is diagnosed, the patient can be treated medically with methotrexate or surgically. If surgical treatment is to be performed, the patient should give consent for a D&C with the possibility of blood transfusion and even hysterectomy. Typed and cross-matched blood should be available prior to initiation of the procedure. If bleeding does occur at the time of diagnosis or treatment, it may range from light to heavy. Attempts to control the bleeding can be accomplished through various techniques such as uterine packing, lateral cervical suture placement in an attempt to ligate the lateral cervical vessels, placement of a cerclage, or insertion of a 30-mL Foley catheter into the cervix for tamponade. If these measures

**Table 15-8**  
**Ultrasound Criteria for Diagnosis of Cervical Pregnancy**

- Echo-free uterine cavity or the presence of a pseudogestational sac only
- Decidual transformation of the endometrium with dense echo structure
- Diffuse uterine wall structure
- Hourglass uterine shape
- Ballooned cervical canal
- Gestational sac in the endocervix
- Placental tissue in the cervical canal
- Closed internal os

**Figure 15-4 Cervical pregnancy, visualized by ultrasound.**

are unsuccessful, embolization of the bleeding vessels can be attempted. If the patient requires laparotomy, the uterine arteries can be ligated. If all these methods are unsuccessful, the patient requires hysterectomy.

#### Ovarian Pregnancy

The most common site for a nontubal ectopic pregnancy is the ovary. Ovarian pregnancy represents 0.5% to 1.0% of all ectopic pregnancies, and the incidence varies from 1 in 7000 to 1 in 40000.<sup>25</sup> The primary difference between a tubal ectopic pregnancy and an ovarian pregnancy is that an ovarian pregnancy is not associated with PID or infertility. The primary risk factor associated with the development of an ovarian pregnancy is concurrent use of an IUD. Patients with an ovarian ectopic pregnancy have similar symptoms to those of other ectopic pregnancies.

Ovarian pregnancy may be misdiagnosed as a ruptured corpus luteum cyst, and ultrasonography may aid in the diagnosis. The primary criteria for diagnosis of an ovarian pregnancy (Table 15-9) are that the fallopian tube on the affected side must be intact, the fetal sac must replace the position of the ovary, and the ovary must remain attached to the uterus by the ovarian ligament. Finally, ovarian tissue must be located within the wall of the gestational sac.

Historically, the treatment for an ovarian pregnancy was oophorectomy; however, the current trend is to perform an ovarian cystectomy. If medical treatment is an option, methotrexate therapy could also be attempted.

**Table 15-9**  
**Spiegelberg's Criteria for Diagnosis of Ovarian Pregnancy**

- The fallopian tube on the affected side must be intact
- The fetal sac must occupy the position of the ovary
- The ovary must be connected to the uterus by the ovarian ligament
- Ovarian tissue must be located in the sac wall

**Table 15-10**  
**Studdiford's Criteria for Diagnosis of Primary Abdominal Pregnancy**

- Presence of a pregnancy related exclusively to the peritoneal surface and early enough to eliminate the possibility of secondary implantation after primary tubal nidation
- Presence of normal tubes and ovaries with no evidence of recent or past pregnancy
- No evidence of uteroplacental fistula

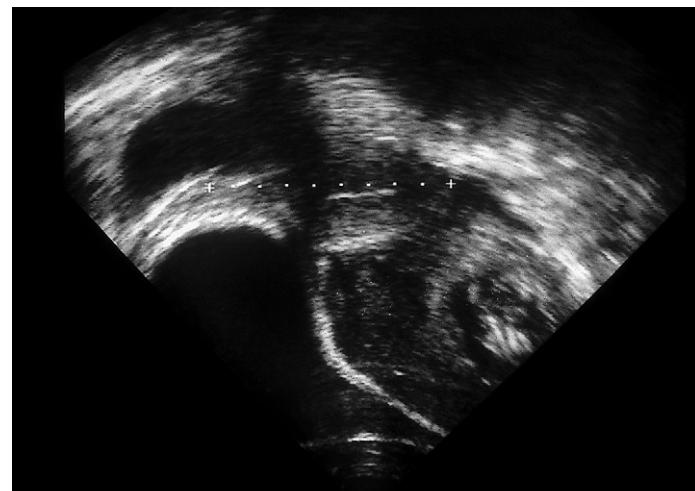

#### Abdominal Pregnancy

Abdominal pregnancies occur with a frequency of approximately 1 in 372 to 1 in 9714 live births in the United States.<sup>26</sup> Abdominal pregnancies are classified as either primary or secondary, with secondary being the most common.

A primary abdominal pregnancy (Table 15-10) occurs in the presence of normal fallopian tubes and ovaries without evidence of a prior pregnancy. With a primary pregnancy there is also no evidence of uteroplacental fistula. A primary pregnancy must be related exclusively to the peritoneal surface. Secondary abdominal pregnancies usually develop as a result of a tubal abortion, tubal rupture, or uterine rupture with intra-abdominal implantation.

Abdominal pregnancies carry a significant risk of maternal morbidity and mortality. The risk of mortality associated with an abdominal pregnancy is approximately eight times greater than for ectopic pregnancy and 90 times greater than for intrauterine gestation. Few abdominal pregnancies are carried to term. If they are, these pregnancies are associated with significant perinatal morbidity, mortality, and congenital anomalies.

Patients with an abdominal pregnancy in the first and second trimesters often have symptoms similar to those of a tubal ectopic pregnancy. Ultrasonography is helpful in establishing the diagnosis (Fig. 15-5). As a patient achieves an advanced gestational age, she may have vague complaints. She may feel misplaced fetal movements in the upper abdomen or extremely painful fetal movements. On physical examination, the patient

**Figure 15-5 Abdominal pregnancy, visualized by ultrasound.**

## General Gynecology

will often have persistent abnormal fetal lies, abdominal tenderness, a displaced cervix, easily palpated fetal parts, and a uterus that is palpated separately from the fetus. If there are no uterine contractions with pitocin infusion, the diagnosis is often suspected.

Once an abdominal pregnancy is suspected, the patient should be treated with surgery. The placenta should be removed only if its vascular supply can be identified and ligated. Many patients require abdominal packing, which is left in place and removed after 24 to 48 hours. If the vascular supply to the placenta is not identifiable, it should be left in place and the umbilical cord ligated at the base. The involution of the placenta can be followed with serial ultrasound images and serial  $\beta$ -hCG levels. Patients should be monitored for the development of a bowel obstruction, fistula formation, and sepsis as the placental tissue degenerates. In this situation, methotrexate is contraindicated, since it leads to rapid tissue necrosis, subsequently causing a high rate of complications such as sepsis and death.<sup>27</sup>

### **Interstitial Pregnancy**

Interstitial pregnancies present later than typical ectopic pregnancies and represent 1% of all ectopic pregnancies. These pregnancies are associated with a higher rate of maternal mortality than are typical ectopic pregnancies secondary to the increased rate of uterine rupture. The treatment is to attempt to achieve hemostasis and perform a cornual resection either through laparotomy or laparoscopy.

### **Interligamentous Pregnancy**

The development of an interligamentous pregnancy is a rare occurrence in the development of ectopic gestations, but there have been reported cases of live births from an interligamentous pregnancy. It is believed that an interligamentous pregnancy develops as the trophoblastic tissue penetrates the tubal serosa into the mesosalpinx with further implantation between the leaves of the broad ligament. It can also occur if a fistula is present between the uterine cavity and the retroperitoneal space of the broad ligament. Complications arise as the placenta can be firmly adherent to the adjacent pelvic organs and side walls. As is the case with an abdominal pregnancy, the placenta should be removed if possible; however, if the placenta cannot be removed with good hemostasis, it should be left in place and allowed to resorb.

### **Heterotopic Pregnancy**

A heterotopic pregnancy is the presence of both an intrauterine and an ectopic pregnancy. Patients having undergone ovulation induction with clomiphene citrate and gonadotropins, or in vitro fertilization, are at a greater risk for a heterotopic pregnancy. The ectopic pregnancy may be missed as the ultrasonographer focuses on the intrauterine gestation. Serial  $\beta$ -hCG levels are usually not useful secondary to the normal intrauterine gestation causing a normal doubling time.

The treatment for a heterotopic pregnancy is surgical management of the ectopic pregnancy with expectant management of the intrauterine gestation. Heterotopic pregnancies have been successfully treated with KCl and hyperosmolar glucose solutions injected directly into the ectopic pregnancy either laparoscopically or transvaginally.<sup>21</sup>

### **Multiple Ectopic Pregnancies**

Multiple ectopic pregnancies occur rarely, with approximately 250 case reports for twin ectopic gestations.<sup>28</sup> The majority of multiple ectopic pregnancies are twin tubal pregnancies; however, there have been reports of ovarian, interstitial, and abdominal pregnancies. Management of multiple ectopic pregnancies is similar to that of single ectopic pregnancies and depends on patient stability and location of the pregnancies.

### **Pregnancy After Hysterectomy**

Hysterectomy is expected to eliminate the risk of an ectopic pregnancy; however, the situation has been reported.<sup>29</sup> A patient undergoing hysterectomy could have a luteal-phase pregnancy at the time of the initial surgery and subsequently have an ectopic pregnancy within the remaining fallopian tube. Additionally, in a patient with a vaginal wall defect or supracervical hysterectomy, sperm could gain intra-abdominal access to the peritoneal cavity and fertilize an egg, resulting in an ectopic pregnancy.

## KEY POINTS

- Vulvar diseases are underdiagnosed and underrecognized disorders that may require a multidisciplinary approach to treatment.
- Disorders of the vulva can be categorized into infectious, inflammatory, neoplastic, and neuropathic.
- A careful history and complete dermatologic examination can establish the diagnosis.
- Biopsy of vulvar lesions remains the standard for diagnostic confirmation.

## NORMAL VULVA

The vulva is a convergence of the integumentary, genital, and urinary systems. The vulvar boundaries are the genitocrural folds laterally, the vestibule medially, the mons pubis anteriorly, and the perineal posterior border. The major vulvar areas include the labia majora, labia minora, clitoris, vestibule, and hymen. The external border of the vestibule is Hart's line, which is a subtle skin demarcation on the inner labia minora.

### Anatomic Variants

There are many anatomic variants of the normal vulva, including labial asymmetry (Fig. 16-1). One of the most commonly misinterpreted normal vulvar variants is vestibular papillae (Fig. 16-2), which is estimated to exist in 44% of premenopausal women and 8% of postmenopausal women.<sup>1</sup> These symmetric flesh-colored or pink projections are asymptomatic. They may be mistaken for condylomata accuminata, but the regularity and symmetry of the papillae help distinguish them from human papilloma virus (HPV)-related changes.

Over time, an individual's vulvar appearance may change. In menopause, atrophy may produce thinning of the labia minora.

Unlike skin on other surfaces, the vulva is exposed to constant moisture and pressure due to its anatomic position and its covering by restrictive, occlusive clothing.

Distinctions between normal and abnormal changes in the vulva are sometimes difficult to discern. Accurate diagnosis requires an understanding of the complex interaction of skin occlusion from clothing, anatomic variance, and physiologic processes of the vulva.

## EVALUATION OF VULVAR DISEASE

### Prevalence

Vulvar disorders are common complaints in gynecology, primary care, and dermatology practices. Because patients present to a

variety of practitioners, the prevalence of many vulvar diseases is unknown. Most reports on the prevalence of vulvar disorders are based on information derived from genital dermatology clinics, but these numbers may not adequately represent the prevalence in the general population.

### Classification Guidelines

Benign vulvar disorders fall into the following main categories: infectious, inflammatory, neoplastic, and neuropathic etiologies. Much of our knowledge about treatment of vulvar diseases is supported by Level III evidence. Few randomized trials are available to shape our therapeutic decisions. Some of the challenges in developing a consensus for treatment exist in regard to terminology. Because a number of different health care providers treat vulvar disease and each discipline has its own categorization to identify vulvar disorders, a multidisciplinary approach to the study of vulvar disease, vulvology, has been proposed.<sup>2</sup> The International Society for the Study of Vulvovaginal Disease (ISSVD) has established classification guidelines. This terminology is reviewed and updated periodically. ISSVD terminology for vulvar nonneoplastic disease includes the categories found in Table 16-1.<sup>3,4</sup>

### Patient History

A systematic, detailed approach to the evaluation of vulvar complaints is optimal. The clinician should begin with an extensive exploration of the chief complaint. Patients may not be exact in their description of the problem. The nature and timing of symptoms should be as accurate as possible, and the quality of discomfort should be delineated, with distinctions made between itching, burning, sharp pain, and dull ache. The interview should also focus on any inciting events or topical product use. Patients should be questioned about hygiene practices, including bubble baths and douching. Currently, douching is not recommended for routine hygiene, but the practice continues.<sup>5</sup>

Patients should provide a detailed list of any over-the-counter products or prescription medications used in the genital region. According to one observational study conducted in Finland, 76% of women complaining of chronic vulvovaginal symptoms were confident in their own self-diagnosis and used at least one over-the-counter preparation for self-treatment without consulting a health care provider.<sup>6</sup> Physicians surveyed in the same study estimate adverse events related to patient self-medication in 74% to 95% of patients seen in follow-up. Level III evidence indicates that the most commonly noted problems with self-treatment are misdiagnosis and delay in receiving adequate therapy.<sup>6</sup>

A detailed problem list, including a history of systemic dermatologic disorders, should be compiled. Any disorder of the

**Figure 16-1 Asymmetry of the labia minora is a common normal vulvar variant.**

skin can affect the vulva. Disorders of mucous membranes, such as lichen planus, can also be found in the vulva and vagina. One case series of 37 female patients with lichen planus indicated that vulvar involvement is present in 19 (51%) of the patients treated for extragenital lichen planus.<sup>7</sup>

Acquisition of the past medical history should also include any history of a self-limited disorder that could predispose a patient to long-term sequelae as well as chronic disorders or trauma that may increase the likelihood of vulvar disease (Table 16-2). For example, chronic postherpetic neuralgia can develop in patients with a history of genital herpes. Patients with diabetes may have more severe candidal infection of the vulva. Patients with a history of neurologic trauma or generalized chronic pain disorders may be at increased risk for vulvar pain syndromes. Level III

evidence compiled from a survey of patients with vulvodynia revealed that 55% of 300 women also had other chronic health conditions.<sup>8</sup> These disorders included pain syndromes such as chronic fatigue, endometriosis, fibromyalgia, interstitial cystitis, irritable bowel syndrome, depression, low back pain, and migraine headaches. Due to the complexity of disorders associated with vulvar disease, interdisciplinary collaboration may be essential for diagnosis and treatment.

**Physical Examination**

The physical examination should begin with a clinical inspection of the skin on the entire body. Inspection of the mouth and vagina may be helpful because some conditions can lead to erosions of the mucous membranes. Other body surfaces including the trunk and extremities may have easily recognized lesions that may also be found on the vulva but with an altered appearance.

**Lesion Characteristics**

A vulvologist is akin to an art historian in some key ways. Both use the power of recognition for identification. Lesion characteristics

**Figure 16-2 Vulvar papillae may be found on the labia minora.** The symmetric distribution and frondlike individual projections help distinguish them from HPV lesions.

help support the diagnosis. Types of lesions include the macule, papule, plaque, vesicle, ulcer, nodule, and tumor. Lesions may be flesh colored, erythematous, hyperpigmented, hypopigmented, or variegated. Categorizing the vulvar appearance into these descriptions facilitates the diagnostic process. The presence of one or multiple lesions can define the disorder. On inspection of the vulva, the absence of lesions may also give clues to neuropathic origins of disease.

Physical examination of the external genitalia should focus on important vulvar landmarks. Distortion of the normal vulvar anatomy gives clues to the diagnosis. For example, patients who present with labial thinning may have symptoms related to vulvovaginal atrophy. Lichen planus or lichen sclerosus may present with labial agglutination or clitoral phimosis.

Mapping of pain symptoms may be helpful. Some conditions such as vestibulodynia may present with pain confined to the vulvar vestibule. Several techniques are used to map vulvar pain.

A cotton-tipped applicator can be used to delineate point tenderness. Although this is the most common technique for assessing vulvar pain, this method is subjective and it is not quantified or always reproducible. A vulvar algometer, a noninvasive tool for the measurement of vulvar pain, has been implemented in some studies in an attempt to quantify vulvar pain.<sup>9</sup>

### Associated Signs

Vaginal discharge may be obtained and examined for pH and wet preparation. A maturation index can confirm the diagnosis of vulvovaginal atrophy. Scrapings of the vulvar skin can also be examined microscopically for fungal infection. If the patient has had recurring symptoms, a vaginal culture may reveal resistant fungal organisms. A bacterial culture can reveal *Streptococcus agalactiae* overgrowth. Herpes simplex virus (HSV) cultures should be obtained in any patient who presents with vulvar vesicles or ulcers. Serologic tests such as those for HSV antibody, human immunodeficiency virus antibody, and antinuclear antibodies can support the vulvar diagnosis.

### Diagnosis

Ultimately a biopsy confirms the diagnosis of most vulvar disorders. A magnified view of the vulva with either a magnifying lens or a colposcope can target the biopsy site, and a dermatopathologist may be consulted to confirm histopathologic diagnoses. Specialized testing, including direct immunofluorescence studies of vulvar biopsies, requires special handling of the tissue.

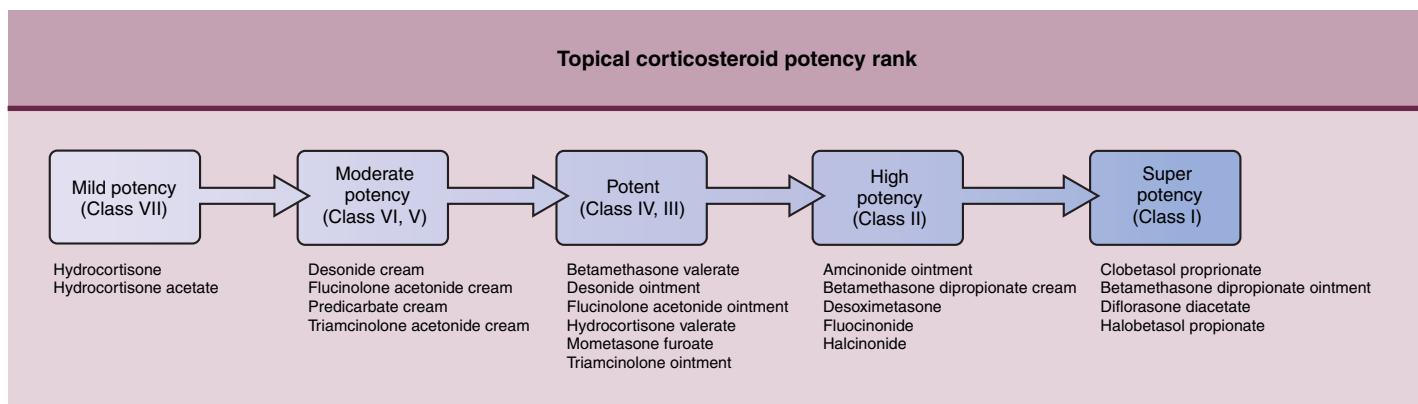

### Treatment Options

Topical corticosteroids are the mainstay of therapy for many vulvar disorders. Steroids reduce inflammation, but the local immunosuppressive effect of steroids on the skin may worsen a pre-existing vulvar infection. Bacterial, viral, or fungal infections should be excluded before initiating treatment. Topical steroids are categorized into seven classes based on potency, and many steroid options exist within each class. Class I steroids are in the ultrapotent category. Class VII steroids are the mildest topical steroid preparations. A practitioner usually uses a few steroids in each general potency group (Fig. 16-3).

Topical steroids exist in a variety of preparations, including creams, lotions, and ointments. In general creams and lotions are easier to apply; however, they contain more allergens and preservatives than ointments and so stinging may occur on skin contact. Ointment-based steroids are more occlusive; therefore, they have a longer-lasting, more potent effect on the skin.

### Steroid Side Effects

It is important to remember that the stronger the steroid, the more likely it is to produce side effects. Systemic absorption of ultrapotent steroids such as 0.05% clobetasol propionate can be significant, with the risk of hypothalamic-pituitary axis suppression. Aseptic necrosis of the femoral head has been reported. Additionally, long-term use may result in skin atrophy and striae. Steroid rebound dermatitis can occur when long-term high-potency steroid use is discontinued; therefore, this class of steroids should be used with caution. Limits should be set on the amount and duration of use. The potent steroid should be tapered to a milder class or discontinued as soon as a response is obtained.

**Figure 16-3 Topical corticosteroid potency rankings.****Immune Modulators**

A new class of topical preparations is now available for use in vulvar conditions. Tacrolimus and pimecrolimus are nonsteroidal drugs that reduce inflammation by inhibiting T-lymphocyte activation. This class of drugs is currently only approved by the Food and Drug Administration for atopic dermatitis, but it has been used for treatment of other vulvar disorders.

Other immunomodulators include imiquimod cream, which augments the immune response. Primarily used in the treatment of HPV, it is applied three times per week, and a response should be noted within 16 weeks. The side effects of imiquimod include skin irritation, which may prohibit its use in some patients. Case reports suggest that imiquimod may be used in vulvar intraepithelial neoplasia. One report even noted utility in recurrent Paget's disease, once an associated malignancy has been excluded.

**VULVAR DISORDERS****Infection**

Vulvar infections include a wide variety of disorders. These disorders will be reviewed in detail in Chapter 18 and include vulvar candidiasis.

**Candida**

Vulvar candidiasis can have a variety of presentations. Vulvar pruritus, erythema with satellite papules, fissures, or vaginal discharge are common signs and symptoms. In the acute setting, *Candida albicans* accounts for the majority of fungal infections. Chronic or recurrent infections may be associated with the more resistant non-*albicans* species. Cyclic vulvovaginitis, a recurring entity characterized by intermittent postovulatory vulvar discomfort and a sensation of labial swelling, has been linked to infection and hypersensitivity to fungus. In a retrospective review of 40 cases of cyclic vulvitis, 61.5% of patients had positive fungal cultures.<sup>10</sup> Only 54% of the positive cultures revealed *C. albicans*. *Candida glabrata* was the most common non-*albicans* species isolated. Fungal cultures may be useful because non-*albicans* candidiasis may be more difficult to diagnose and treat. In general, cultures for bacteria have limited value because a wide variety of organisms are considered part of the normal flora.

**Human Papillomavirus**

Human papillomavirus may present with vulvovaginal condyloma acuminata. The verrucoid appearance of these lesions aids in identification of the disorder. If vulvar intraepithelial neoplasia or squamous cell carcinoma is suspected, a biopsy should be performed.

**Herpes Simplex Virus**

Herpes simplex virus should be included in the differential diagnosis of anyone who presents with vulvar vesicles or ulcers. HSV-1 or -2 can be confirmed by viral culture. Direct fluorescent antibody testing can yield results in the same day. Serologic testing for HSV proves a history of the infection but is not site specific. Serum antibody testing is mainly useful in ruling out a history of infection with a negative result. HSV vesicles can be found on the vulva or on other body surfaces (Figs. 16-4 and 16-5).

**Figure 16-4 Vulvar herpes simplex virus.** The initial vesicular lesions have ruptured to reveal round coalescent erosions.

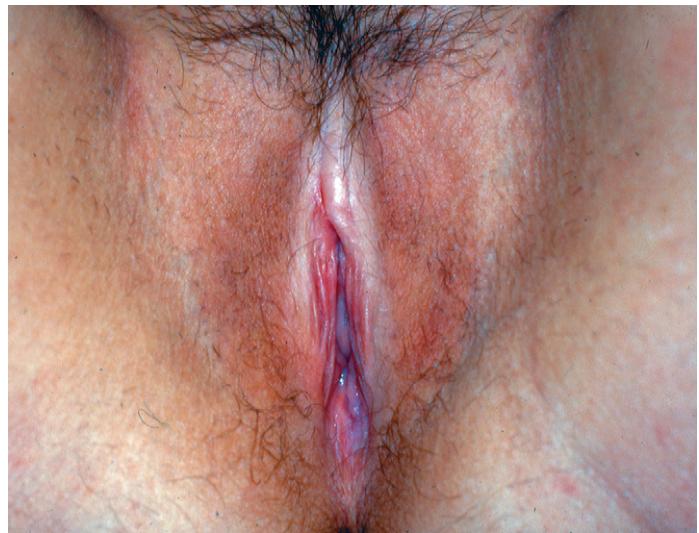

**Figure 16-5 Facial herpes simplex virus.**

### Benign Dermatoses

Nonmalignant vulvar dermatoses can be subdivided into three categories: non-neoplastic epithelial disorders, tumors, and intraepithelial neoplasias. Clinically these lesions can be categorized by appearance based on color, pattern, and location (Table 16-3; Figs. 16-6 through 16-18).

Table 16-3 Characterization of Vulvar Lesions by Appearance		
Lesion Characteristics	Examples	Illustrations
<b>Color</b>		
White lesions	Lichen sclerosus (LS), squamous hyperplasia, vulvar intraepithelial neoplasia (VIN), vitiligo	LS (Fig. 16-6)
Red lesions	Vestibulodynia, vulvar candidiasis, lichen planus (LP), VIN	Candidiasis (Fig. 16-7)
Brown lesions	VIN, nevi, acanthosis nigricans	VIN (Fig. 16-8)
<b>Pattern</b>		
Macule	Vitiligo, melanosis, HPV, VIN	Melanosis (Fig. 16-9)
Papule	Skin tag, nevus, molluscum contagiosum, seborrheic keratosis	Seborrheic keratosis (Fig. 16-10)
Plaque	Eczema, Paget's disease, psoriasis, HPV, VIN	Paget's disease (Fig. 16-11)
Verrucae	HPV, verrucous xanthoma	HPV (Fig. 16-12)
Vesicles	HSV, varicella	Varicella (Fig. 16-13)
Cyst	Bartholin cyst, Skene's duct cyst, keratinous cysts	Skene's duct cyst (Fig. 16-14)
Ulcer	Behçet's disease, HSV, Crohn's disease, LGV, syphilis, chancroid	HSV (Fig. 16-15)
Tumor	Fibroma, hemangioma, lipoma, VIN	Lipoma (Fig. 16-16)
<b>Location</b>		
Vulvodynia subsets	Vestibulodynia Pudendal neuralgia, generalized vulvodynia	(Fig. 16-17) (Fig. 16-18)

**Figure 16-6 Vulvar lichen sclerosus.** Skin pallor may be noted on the labia in a keyhole distribution or may be noted around the labial and anal areas in a figure-of-eight distribution.

### Non-neoplastic Epithelial Disorders

Any disorder that can involve the skin can exist in the vulva. Given the moist environment of the vulva, lesions may appear altered compared to other skin. An example is psoriasis, which usually presents as erythematous plaques with silvery white scales, but on the vulva often appears as red plaques without scales (Fig. 16-19). Depending on the pigmentation of the affected individual, lesions may also vary. Vulvar disorders in individuals with dark skin may have a different appearance than the same types of lesions in a woman with less pigmented skin.

### Contact Dermatitis

Contact dermatitis is an inflammatory skin reaction to an irritant or allergen. The skin barrier of the vulva is more susceptible to irritation than skin in other anatomic sites due to constant moisture, occlusion, and frictional forces. Vulvar irritants may

**Figure 16-7 Vulvar candidiasis.** Erythematous patches on the vulva and intertriginous areas may be surrounded by satellite papular lesions.

**Figure 16-8 Vulvar intraepithelial neoplasia.** Vulvar intraepithelial lesions may be hyperpigmented and eroded.

range from caustic agents such as 5-fluorouracil to more typical irritants such as perfumed soaps and detergents.<sup>11</sup> Vulvar exposures and hygiene practices such as overzealous cleansing, piercing of genitalia, and wearing constrictive, synthetic undergarments and clothing can exacerbate the condition.

Allergic contact dermatitis is an immune-mediated response to an allergen in a previously exposed and sensitized individual.<sup>12</sup> Both irritant and allergic contact dermatitis may present with vulvar erythema, edema, itching, stinging, or burning sensations (Fig. 16-20).

History is an important key to identifying the type of dermatitis and the causative agent. Patch testing may be helpful

**Figure 16-10 Seborrheic keratosis.** These hyperpigmented lesions vary in size and may be single or multiple. The oily, “stuck on” appearance helps distinguish this lesion from other dermatoses.

in distinguishing an allergen. According to Level III evidence compiled from a vulvar clinic in 2000, 20% to 30% of patients had dermatitis, with 26% associated with positive patch tests.<sup>13</sup> Treatment should focus on identifying and eliminating the causative agent. Short-term use of anti-inflammatory agents such as a midpotency to ultrapotency topical corticosteroid may be useful in controlling pruritus. Contact dermatitis is usually self-limited if the inciting factors are removed.

#### **Lichen Simplex Chronicus**

Lichen simplex chronicus is one of the most common vulvar dermatoses. Lichen simplex chronicus is the vulvar manifestation of a chronic dermatitis. The hallmark of lichen simplex chronicus

**Figure 16-9 Vulvar melanosis.** This benign change is more commonly seen on the labia minora of postmenopausal women.

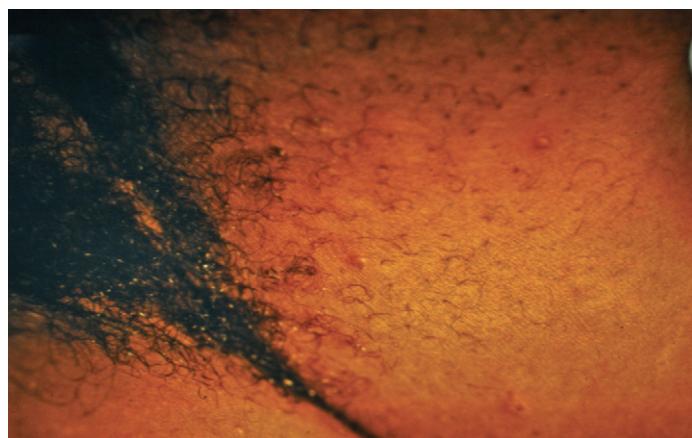

**Figure 16-11 Paget's disease of the vulva.** This plaque has a velvet-like appearance. Affected patients typically present with chronic pruritus that may be misdiagnosed as candidiasis.

**Figure 16-12 Human papillomavirus.** Condylomata accuminata can be single or confluent verrucoid lesions.

is pruritus. Patients may complain of intense itching with temporary relief with scratching. Indeed the itch-scratch cycle is the perpetuating force with lichen simplex chronicus.

A careful history regarding vulvar hygiene is an important key to resolution of symptoms. Patients must be interviewed about the use of topical agents because seemingly benign things such as soaps, feminine hygiene products, and bubble bath may be the inciting irritants. Clinical evaluation should be performed to assess for infection and other dermatoses. In addition to lichen simplex chronicus, the differential diagnosis for these patients includes any dermatosis that may present with pruritus, including lichen sclerosus, atopic dermatitis, and psoriasis. Inspection of the skin may reveal lichenification or thickening of the labia minora and the labia majora (Fig. 16-21). Within the thickened whitish or grayish plaques, normal skin markings may be accentuated (Fig. 16-22). If a patient scratches excessively,

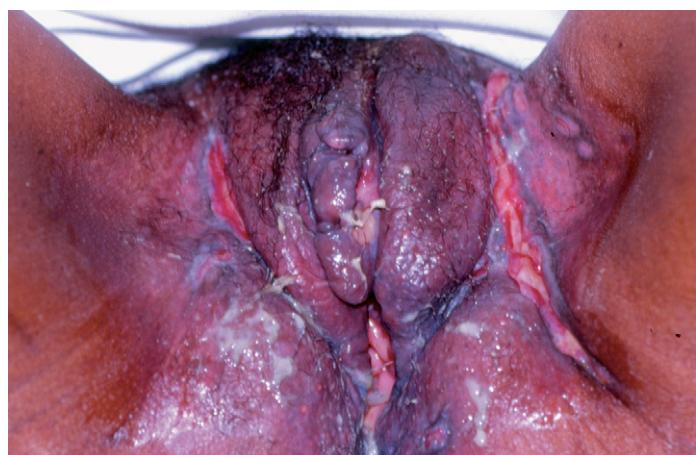

**Figure 16-13 Vulvar vesicles.** Vesicles on the vulva are fragile and easily rupture. This patient was diagnosed with varicella.

**Figure 16-14 Skene's gland cyst.**

linear excoriations may be found (Fig. 16-23). Vulvar biopsy may be indicated to confirm the diagnosis. Hyperkeratosis and acanthosis may also be noted.

Tests to ascertain inciting factors include cutaneous and vaginal swabs with microscopic evaluation for fungal infection. If a longstanding history of lichen simplex chronicus is present, further evaluation is warranted. Culture for *non-albicans* candidiasis should be obtained. If perianal pruritus is also noted, parasitic examination of the stool for pinworms should be considered. Level III evidence supports patch testing to identify allergens if there is a history of prolonged use of topical irritants or topical treatments. In one case series, 48% of women diagnosed with lichen simplex chronicus tested positive for allergens, and 27% of these allergens were found to be relevant to the pathology.<sup>13</sup> Although rare, corticosteroid allergy has been reported.<sup>14</sup>

**Figure 16-15 Hidradenitis suppurativa.** This condition may present with ulceration, sinus tracts, and abscess formation.

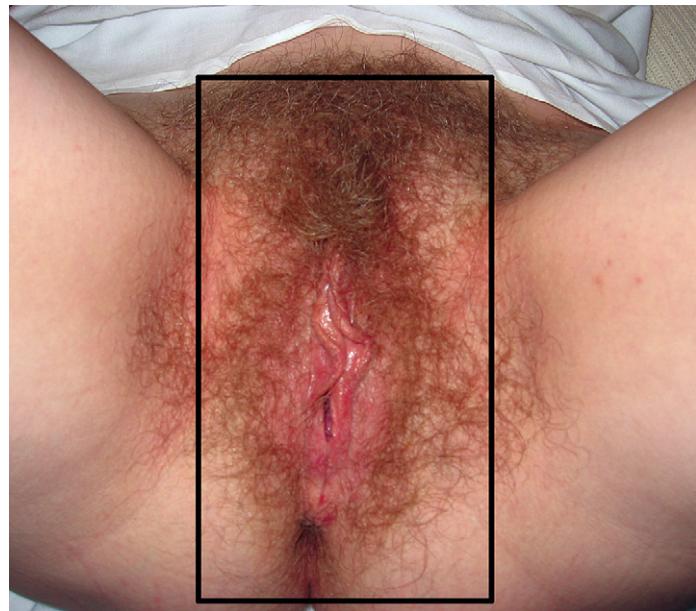

**Figure 16-16 Vulvar lipoma.**

Identification of the etiologic factor, avoidance of skin irritants, and cessation of the itch-scratch cycle are the simplified keys to resolution of this dermatosis. Breaking the itch-scratch cycle is the challenge. Often a medium- to high-potency topical corticosteroid must be applied to the affected skin. Oral anti-histamines may be used to treat intense pruritic symptoms. The sedative properties of some antihistamines may be preferable for suppression of nocturnal exacerbations. In extreme cases, a short course of oral corticosteroids may be indicated.

#### Lichen Sclerosus

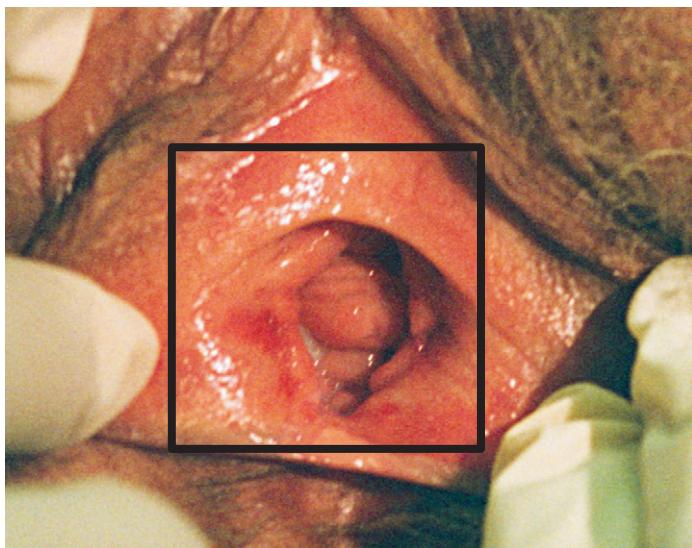

Lichen sclerosus is a chronic dermatosis that may present with vulvar pruritus. Lichen sclerosus was previously considered a disorder of hypoestrogenic girls and women. Currently, many

**Figure 16-18 Generalized vulvodynia and pudendal neuralgia present with a wide distribution of vulvar pain.**

cases of lichen sclerosus are first identified in women of reproductive age. The pathogenesis of lichen sclerosus is unknown. Reports of multiple members of a family being affected suggest a genetic link. Patients with lichen sclerosus may also have hypothyroidism, indicating a possible autoimmune association.<sup>15</sup>

Examination reveals a pale parchment-like appearing of the labia (Fig. 16-24). Labial agglutination may also be present in longstanding dermatoses. Lichen sclerosus may increase the fragility of the vulvar skin; therefore, fissures and ecchymosis may develop (Fig. 16-25). Lichen sclerosus can also present with white plaques on other body surfaces (Fig. 16-26).

**Figure 16-17 Vestibulodynia.** Patients have point tenderness confined to the vulvar vestibule. The inner border of the vestibule is the hymen/hymenal tags. The outer border is Hart's line, a demarcation on the medial labia minora.

**Figure 16-19 Vulvar psoriasis.** Psoriasis on the vulva has a bright red appearance. Due to the moist environment of the vulva, it lacks the silvery scale that is typical of psoriasis on other skin surfaces.

**Figure 16-20 Dermatitis.** Erythema and pruritus are common manifestations of dermatitis.

Treatment protocols for lichen sclerosus have evolved over time. Initially this condition was treated with testosterone preparations. A randomized, controlled study of testosterone versus a petrolatum base (placebo) revealed that the hormone is no more potent in treatment of lichen sclerosus than the petrolatum ointment in which it is prepared.<sup>16</sup> In a study of 79 women with lichen sclerosus, each patient was randomized into a topical therapy group of testosterone (2%), progesterone (2%), clobetasol propionate (0.05%), or a cream-based preparation. After 3 months of treatment, remission was noted in 20% of the testosterone-treated group, 10% in the progesterone-treated group, 75% in the clobetasol propionate group, and 10.5% in the group treated with the cream-based preparation. Histologic improvement of the lichen sclerosus was found only

**Figure 16-22 Lichen simplex chronicus.** Edematous changes may produce exaggerated skin markings.

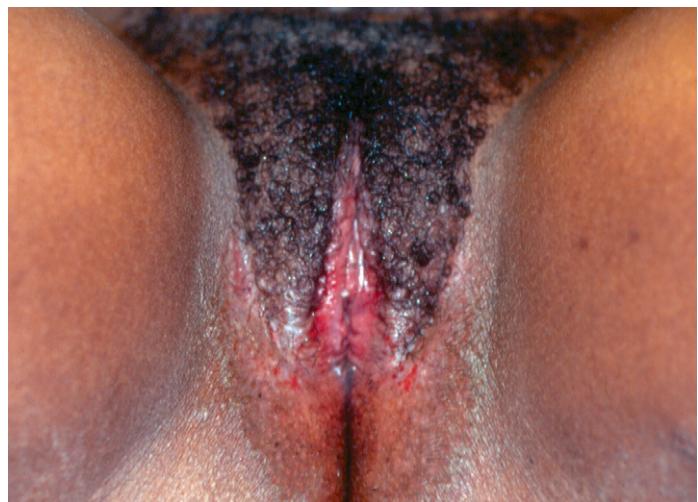

in the clobetasol propionate–treated group.<sup>17</sup> Ultrapotent topical corticosteroids such as 0.05% clobetasol propionate are now standard therapy for lichen sclerosus. Improvement of symptoms is usually noted within the first month of use. Daily treatment should be limited given potential side effects of long-term ultrapotent steroid use. Small case series also suggest the utility of tacrolimus and pimecrolimus for the treatment of lichen sclerosus.<sup>18-20</sup> Surgical excision is not advocated because lichen sclerosus can recur in the surrounding vulvar skin.

If left untreated, lichen sclerosus can be a progressive disorder. Loss of normal vulvar architecture may occur due to scarring. Introital narrowing and dyspareunia may result.

Lichen sclerosus can be associated with vulvar carcinoma. In a cohort study of 20 months' duration, squamous cell carcinoma resulted in 3 of 211 patients with lichen sclerosus.<sup>21</sup> Lichen sclerosus has been found in skin adjacent to squamous cell carcinoma at the time of excision. A retrospective review of

**Figure 16-21 Lichen simplex chronicus.** Patients with this chronic condition may have hyperpigmented, lichenified skin.

**Figure 16-23 Linear excoriations.** Patients with chronic dermatitis may develop linear erosions from persistent scratching.

**Figure 16-24 Lichen sclerosus.** The pallor of lichen sclerosus presents a striking contrast in a dark-skinned patient.

72 cases of non-HPV-related squamous cell carcinoma found 25 cases associated with lichen sclerosus.<sup>22</sup> Because vulvar carcinoma arises in only a small fraction of the many women affected by the dermatosis, lichen sclerosus is not a direct precursor for the disease. Other contributing factors remain undetermined. Regular evaluation of the skin should be performed to detect malignant changes. A biopsy should be performed on hyperkeratotic or ulcerated lesions when malignancy is suspected.

#### Lichen Planus

Vulvar lichen planus is an uncommon but chronic, debilitating condition that is often misdiagnosed initially.<sup>23</sup> The etiology of lichen planus is unknown, but a cell-mediated autoimmune reaction is suspected. The difficulty in diagnosis of lichen planus

**Figure 16-26 Lichen sclerosus on the eyelid.** Lichen sclerosus can affect other skin surfaces.

may be related to the variable symptoms, appearance, and anatomic sites of presentation. Patients with vulvar lichen planus complain of burning, irritation, or itching. The three types of vulvar lichen planus are hypertrophic, papular, and erosive disease. The hypertrophic form may reveal subtle thickening on examination; itching may be reported by the patient. The papular form reveals raised lesions that may be pruritic or asymptomatic. The erosive form reveals denuded surfaces with ill-demarcated borders on exam and usually presents with complaints of a burning sensation (Fig. 16-27). Pain with urination may be reported if the urine irritates eroded vulvar skin.

Erosive lichen planus can also affect mucous membranes. Vaginal erosions may yield an inflammatory vaginal discharge. This discharge may be characterized by an alkaline pH, lack of maturation (parabasal cells on wet prep), replacement of lactobacilli with cocci, and many inflammatory cells (mainly eosinophils).<sup>24</sup> Exogenous lesions may include oral lichen planus, which may appear as erosion or a reticulate pattern known as *Wickham's striae*. Violaceous papules may also be

**Figure 16-25 Lichen sclerosus.** Skin fragility may lead to fissures, tears, petechiae, and ecchymosis.

**Figure 16-27 Erosive vulvar lichen planus.**

**Figure 16-28** **Vaginal erosive lichen planus.** This lesion developed after hysterectomy along the vaginal vault scar.

found on the extremities and trunk. Lichen planus may exhibit the Koebner response; it tends to develop at sites of friction or scars. It may even develop at the vaginal cuff suture line after hysterectomy (Fig. 16-28).

Treatment usually consists of mid-potency to high-potency topical steroids. An ointment may produce less burning than a cream preparation when applied to eroded skin. Initial therapy for an advanced case may consist of clobetasol propionate applied sparingly once or twice per day for the first month. The patient should be reevaluated monthly until the condition improves. The topical steroid should be tapered, either by decreasing the frequency of application or by decreasing the potency of the preparation. One case series reports 81% subjective improvement in patients with vulvovaginal lesions treated with 25 mg intravaginal hydrocortisone suppositories.<sup>25</sup> Foam steroid preparations can also be used in the vagina. Severe cases of lichen planus may be treated with a short course of oral steroids. Small case series suggest that tacrolimus may be beneficial in the treatment of recalcitrant vulvar lichen planus.<sup>26,27</sup> If untreated, the hypertrophic and papular types of lichen planus may be self-limited, but the erosive form has a progressive course. Distortion of labial architecture, with loss of the labia minora and midline labial agglutination can be seen. Narrowing of the introitus with scarring and shortening of the vagina may result in dyspareunia.

### Vulvodynia

Although the symptom of vulvar pain has always existed, the identification of the disorder is still undergoing classification. The recognition of vulvar pain in the literature has certainly lagged behind the existence of the disorder, but as awareness of vulvodynia increases, new light has been shed on the disorder.

Vulvar pain can be divided into identifiable disorders, neuropathic disease, or idiopathic causes (Fig. 16-29).

*Vulvodynia*, defined as chronic vulvar pain existing in the absence of an underlying recognizable disease,<sup>28</sup> has long been

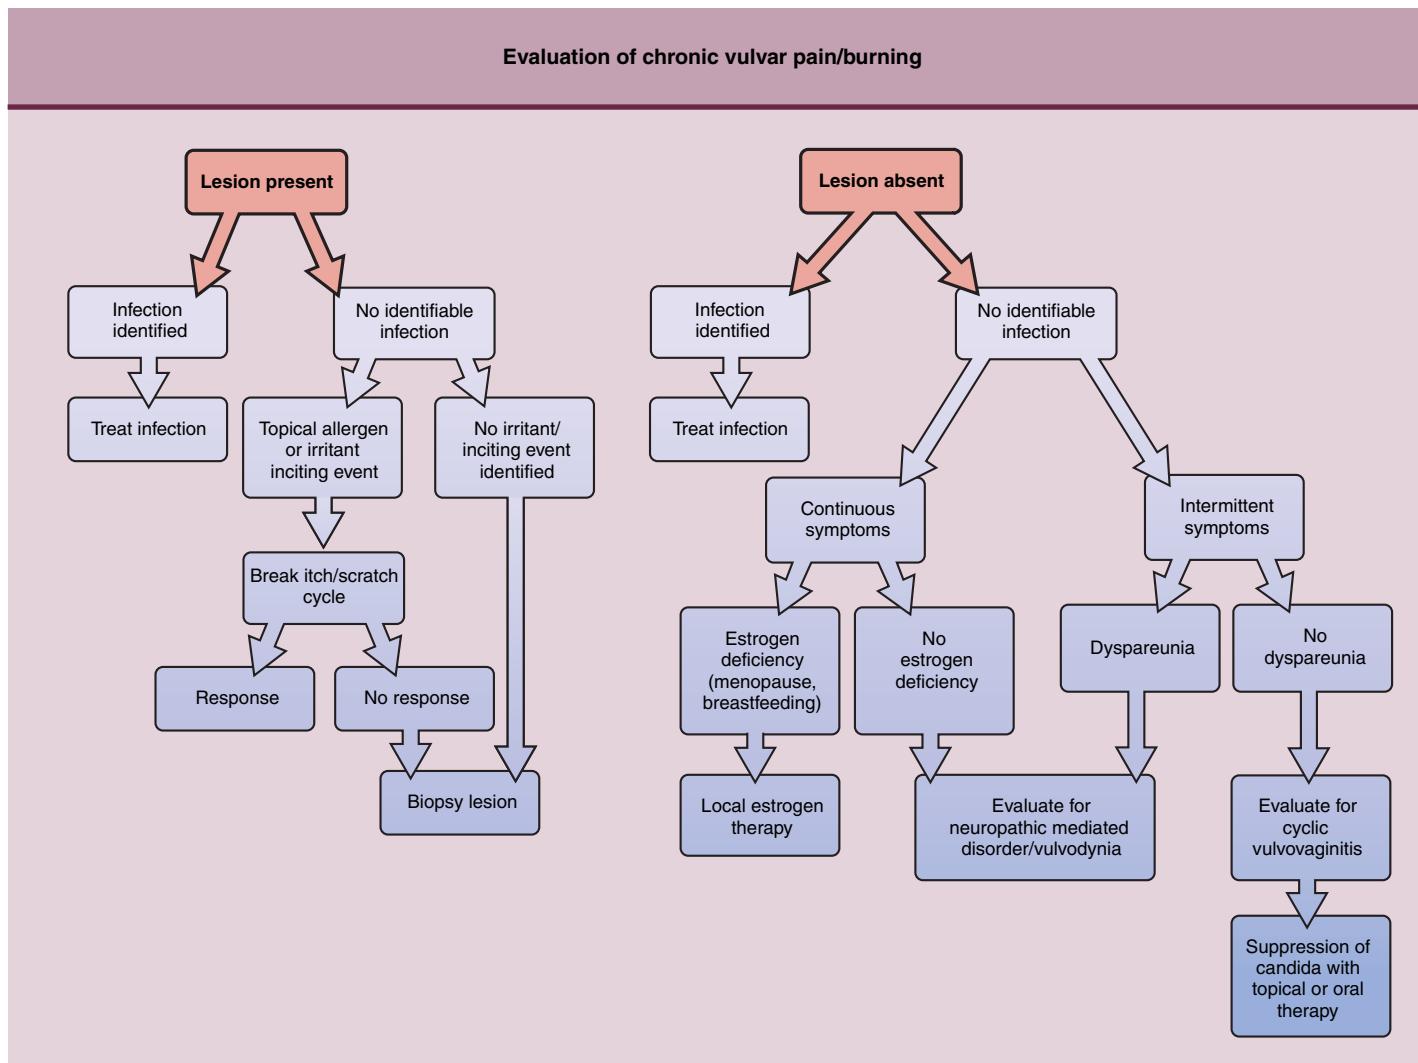

considered a clinical entity. The chronicity of the disorder usually is at least 3 months' duration. In 1976, this disorder was initially recognized as the *burning vulva syndrome*. Debate over vulvodynia as a symptom versus a disease continues.

Various terminology has evolved to characterize this entity, including recently defining the distinct terms *dysesthetic vulvodynia* and *vestibulitis*. In 2003, at the 17th World Congress, the ISSVD updated the terminology.<sup>28</sup> *Vulvodynia* remains the preferred term, with subsets of generalized, localized, or mixed groups. Further subclassification of these groups includes spontaneous or provoked pain with reference to anatomic sites (Fig. 16-30).

*Vestibulitis*, a subset of vulvodynia, was originally defined as a triad of severe pain on vestibular touch or attempted vaginal entry, tenderness to pressure localized within the vulvar vestibule, and physical findings confined to vestibular erythema of various degrees.<sup>29</sup> The popular term *vestibulitis* has been deemed a misnomer by the ISSVD because local inflammation, as implied by its suffix, has not been the defining histologic picture. The term has been officially replaced by the term *provoked vestibulodynia*. Modifications to terminology may continue as new information about the disorder is discovered. Pain rather than pruritus is the hallmark of this entity.

Early studies of vulvodynia described the disease as an entity of non-Hispanic white women. Interestingly, in a population-based cross-sectional survey conducted in the Boston area of 3358 women age 18 to 64, Hispanic women were at greatest risk of unexplained chronic vulvar pain. African American and white women had similar risk of unexplained vulvar pain, but Hispanic women were 80% more likely than white women to report chronic vulvar pain.<sup>30</sup> Although the exact incidence of vulvodynia is unknown, this study estimated the lifetime cumulative incidence at 16% in women age 18 to 64. Researchers extrapolated these figures to estimate that approximately 14 million U.S. women may experience vulvodynia.<sup>30</sup>

Several etiologies of vulvodynia have been postulated, including embryologic abnormalities, increased urinary oxalate

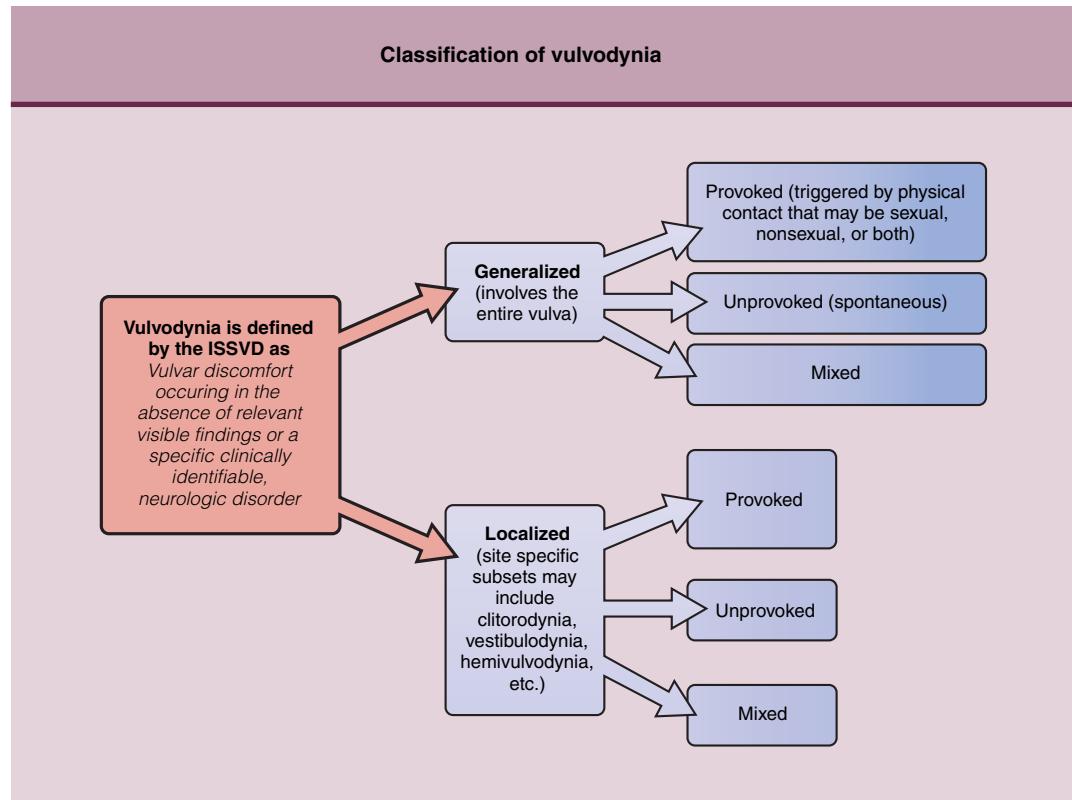

**Figure 16-29 Evaluation of chronic vulvar pain and burning.**

levels, genetic or immune factors, hormonal factors, inflammation, infection, and neuropathic changes.<sup>31</sup> The etiology of the disorder may be multifactorial; no one cause has been isolated. Other causes of vulvar burning or pain should be excluded, including monilial infection, postherpetic neuralgia, dermatitis, vulvovaginal atrophy, lichen sclerosus, erosive lichen planus, and other dermatoses. Early researchers postulated a link between HPV and vulvodynia, but this association has been discredited by a number of studies. Biopsy has limited usefulness, except to exclude other causes. The histopathologic characteristics described in the literature are varied. Inflammation of the vestibule may exist,<sup>32–34</sup> but there is controversy over whether it is definitive.<sup>35</sup> Proliferation of intraepithelial nerve fibers has been noted in patients with vestibulodynia,<sup>36,37</sup> but the significance of this finding is also unclear.

Patients with generalized unprovoked vulvar pain should be assessed for pudendal neuralgia and other disorders in the complex regional pain syndrome. Tricyclic antidepressant

therapy has been a widely used pharmacologic approach to treatment.<sup>38</sup> The use of tricyclic antidepressants is based originally on their use in the treatment of postherpetic neuralgia. In both entities, an inciting event may lead to allodynia. Unlike postherpetic neuralgia, the inciting event in vulvodynia is often unknown. Other pharmacologic therapeutic regimens include the use of gabapentin, topical lidocaine ointment and vulvar injections of steroids and anesthetic agents. Nonpharmacologic agents include physical therapy with rehabilitation of the pelvic floor musculature and biofeedback exercises. Less information is available about acupuncture, dietary restrictions, vitamin supplementation, and other alternative therapies. Surgical excision of the vestibule with advancement of vaginal mucosa should only be considered when conservative options have been exhausted. Treatment options must be individualized because varied responses are reported and few prospective trials have been performed to validate the effectiveness of most therapeutic protocols.

# Chapter 17

# Preoperative Evaluation and Postoperative Management

Daniel L. Clarke-Pearson, MD, Monique A. Spillman, MD, PhD,  
Christopher V. Lutman, MD, and Paula S. Lee, MD, MPH

## KEY POINTS

- Multimodality postoperative pain management usually is optimized by a combination of opioids and nonsteroidal anti-inflammatory drugs (NSAIDs).
- Perioperative antibiotic prophylaxis is effective in reducing postoperative infection in most major abdominal and vaginal procedures.
- The use of low-dose heparin, low-molecular-weight heparins, and external pneumatic compression significantly reduces venous thromboembolic complications in moderate- and high-risk surgery patients.
- Red blood cell transfusion should not be dictated by a single hemoglobin value but rather by the patient's risk of developing complications of inadequate oxygenation.
- Obese patients are at high risk for postoperative complications including obesity hypoventilation syndrome, prolonged mechanical ventilation, aspiration, wound infection and dehiscence, and venous thromboembolism.
- Perioperative care of patients with coronary artery disease is based on maximizing delivery of oxygen to the myocardium as well as decreasing myocardial oxygen utilization.

The successful outcome of gynecologic surgery is based on thorough evaluation, careful preoperative preparation, and attentive postoperative care. Approaches to the general perioperative management of patients undergoing major gynecologic surgery with specific medical problems that could complicate the surgical outcome are discussed in this chapter.

## MEDICAL HISTORY AND PHYSICAL EXAMINATION

Gynecologic surgery should be undertaken only after obtaining a thorough understanding of a patient's medical history and performing a complete physical examination.

The detailed medical history will identify any medical illnesses that might be aggravated by surgery or anesthesia. Coronary artery disease and pulmonary diseases are the most common sources of postoperative complications.

Medications currently being taken (including nonprescription drugs) as well as those discontinued within the month prior to surgery should be recorded. In addition, the use of "alternative

therapies," herbs, and vitamins should be elicited. Specific instructions must be given to the patient regarding the need to discontinue any medications prior to surgery (e.g., aspirin, antiplatelet agents) as well as those medications that should be continued (e.g., cardiac or antihypertensive medications).

The patient should be questioned regarding known allergies to medications (e.g., sulfa and penicillin), foods, or environmental agents. A history of sensitivity to shellfish may be the only clue of iodine sensitivity, which can be fatal if intravenous (IV) contrast is used without corticosteroid preparation.

Previous surgical procedures and the patient's course following those surgical procedures should be reviewed to identify previous complications that might be avoided. The patient should be asked about specific complications, such as excessive bleeding, wound infection, deep vein thrombosis, peritonitis, and bowel obstruction. A history of pelvic surgery should alert the gynecologist to the possibility of distorted surgical anatomy and possible preexisting injury to adjacent organ systems such as small bowel adhesions or ureteral stenosis from previous periureteral scarring. In such cases it may be prudent to identify any preexisting abnormality by performing an intravenous pyelogram (IVP) or computed tomography (CT) scan. Many patients may not be entirely clear about the extent of the previous surgical procedure or the details of intraoperative findings. Operative notes from previous operations can be obtained and reviewed.

Family history may identify familial traits that might complicate planned surgery. A family history of excessive intraoperative or postoperative bleeding, venous thromboembolism, malignant hyperthermia, and other potentially inherited conditions should be sought.

A review of systems should be detailed to identify any coexisting medical or surgical conditions. Inquiry about gastrointestinal and urologic function is particularly important prior to undertaking pelvic surgery, since many gynecologic diseases also involve adjacent nongynecologic viscera.

Although many women undergoing gynecologic surgical procedures are otherwise healthy, with disease identified only on pelvic examination, other major organ systems should not be neglected in the physical examination. Identification of abnormalities such as a heart murmur or pulmonary compromise should lead the surgeon to obtain additional testing and consultation in order to minimize intraoperative and postoperative complications.

### Laboratory Evaluation

The selection of appropriate preoperative laboratory studies depends on the extent of the anticipated surgical procedure and the patient's medical status.

For patients undergoing general anesthesia, a blood count including hematocrit, white cell count, and platelet count should be obtained routinely. (For low-risk laparoscopy procedures even a hematocrit may be unnecessary.)

Serum chemistries and liver function testing results are rarely abnormal in the asymptomatic patient who has no significant medical history and who is not taking medications.

Coagulation studies are of little value unless the patient has a significant medical history.<sup>1</sup>

In women under 50 years of age, chest radiography and electrocardiography are of low yield in identifying asymptomatic cardiopulmonary disease and thus are not necessary.<sup>2,3</sup>

Radiographic evaluation of adjacent organ systems should be undertaken in individual cases as follows:

- Intravenous pyelography is helpful to delineate ureteral patency and course, especially in the presence of a pelvic mass, gynecologic cancer, or congenital müllerian anomaly. However, an IVP is not of value in the evaluation of most patients undergoing pelvic surgery.<sup>4</sup>
- A barium enema or upper gastrointestinal series with small bowel assessment may be of value in evaluating some patients before pelvic surgery. Because of the proximity of the female genital tract to the lower gastrointestinal tract, the rectum and sigmoid colon may be involved with benign (endometriosis or pelvic inflammatory disease) or malignant gynecologic conditions. Conversely, a pelvic mass could have a gastrointestinal origin such as a diverticular abscess or Crohn's disease. Clearly, any patient with gastrointestinal symptoms should be further evaluated.
- Other imaging studies, including ultrasound, CT scanning, or magnetic resonance imaging (MRI), may be useful in selected patients.

### PREOPERATIVE DISCUSSION AND INFORMED CONSENT

The goals of the preoperative discussion are to detail issues relevant to the surgery, its expected outcome, and risks and is the basis for obtaining signed informed consent.<sup>5</sup> Informed consent is an educational process for the patient and her family and fulfills the physician's need to convey information in understandable terms. The following items (Table 17-1) should be discussed, and after each item, the patient and family should be invited to ask questions.

1. A discussion of the nature and the extent of the disease process should include an explanation in lay terms of the significance of the disease. Printed materials, computer-based learning programs, and videotapes may assist in this process.
2. The goals of surgery should be discussed in detail. Some gynecologic surgical procedures are performed purely for diagnostic purposes (e.g., dilation and curettage, cold knife conization, diagnostic laparoscopy) although most are aimed at correcting a specific disease process. The extent

**Table 17-1**  
**Key Topics of Preoperative Informed Consent Discussion**

1. Nature and extent of the disease process
2. Extent of the actual operation proposed and the potential modifications of the operation, depending on intraoperative findings
3. Anticipated benefits of the operation, with a conservative estimate of successful outcome
4. Risks and potential complications of the surgery
5. Alternative methods of therapy and the risks and results of those alternative methods of therapy
6. Likely results if the patient is not treated

of the surgery should be outlined, including which organs will be removed. Most patients like to be informed about the type of surgical incision and the estimated duration of anesthesia.

3. The expected outcome of the surgical procedure should be explained. If the procedure is being performed for diagnostic purposes, the outcome will depend on surgical or pathologic findings that are not known before surgery. When treating anatomic deformity or disease, the expected success of the operation should be discussed, as well as the potential for failure (i.e., failure of tubal sterilization or the possibility that stress urinary incontinence may not be alleviated). When treating cancer, the possibility of finding more advanced disease and the potential need for adjunctive therapy (e.g., postoperative radiation therapy or chemotherapy) should be mentioned. Other issues of importance to the patient include loss of fertility or loss of ovarian function. These issues should be raised by the physician to ensure that the patient adequately understands the pathophysiology that may result from the surgery and to allow her to express her feelings regarding these emotionally charged issues. Unanticipated findings at the time of surgery should also be mentioned. For example, if the ovaries are unexpectedly found to be diseased, the best surgical judgment may be to remove them.
4. The risks and potential complications of the surgical procedure should be discussed with the patient, including the most frequent complications of the particular surgical procedure. For most major gynecologic surgery, the risks include intraoperative and postoperative hemorrhage, postoperative infection, venous thrombosis, injury to adjacent viscera, and wound complications. If the patient has a preexisting medical problem, additional risks should be reviewed.
5. The usual postoperative course should be discussed in enough detail to allow the patient to understand what to expect in the days following surgery. Information regarding the need for a suprapubic catheter or prolonged central venous monitoring helps the patient accept her postoperative course and avoids surprises that may be disconcerting. The expected duration of the recovery period, both in and out of the hospital, should be outlined.
6. Alternative methods of therapy should be discussed including medical management or other surgical approaches. The patient should also have an understanding of the outcome of the disease if nothing is done.

## PERIOPERATIVE PAIN MANAGEMENT

Current therapeutic strategies for perioperative pain control are largely dependent on opioid analgesics and NSAIDs. Multi-modal therapy is recommended in postoperative surgical patients to reduce opioid consumption by coadministration of NSAIDs. This may reduce the side effects of opioid use such as respiratory depression, central nervous system depression and sedation, nausea, vomiting, diminished gastrointestinal motility, and pruritus.

Nonselective NSAIDs inhibit both cyclooxygenase (COX)-1 and COX-2. Potential adverse effects associated with the use of NSAIDs include an increased risk of renal compromise, gastrointestinal side effects, hypersensitivity reactions, and bleeding. The anti-inflammatory and analgesic effects are produced by COX-2 inhibition, whereas gastrointestinal toxicity and platelet dysfunction are caused by COX-1 inhibition. With the development of COX-2 selective inhibitors, several randomized control studies involving both minor and major abdominal surgeries have shown a benefit of preoperative COX-2 selective inhibitor use to reduce acute postoperative pain and perioperative opioid use.<sup>6-8</sup> However, the use of IV NSAIDs such as ketorolac, which has an analgesic potency comparable to morphine, may be more effective than the orally administered COX-2 selective inhibitors.<sup>9</sup> Rofecoxib has been withdrawn from the marketplace after concerns about myocardial risk.

The use of patient-controlled analgesia (PCA) devices shortens the time between the onset of pain and the administration of pain medication, provides more continuous access to analgesics, and allows for an overall steadier state of pain control. Anesthetics and narcotics administered either in the epidural space or intrathecally have greater efficacy than is provided by IV PCA techniques. Epidural analgesia has been shown to be associated with improved pulmonary function postoperatively, a lower incidence of pulmonary complications, a decrease in postoperative venous thromboembolic events, fewer gastrointestinal side effects, a lower incidence of central nervous system depression, and shorter convalescence.<sup>10</sup> Severe respiratory depression is the most serious potential complication, occurring in less than 1% of patients.

## ANTIMICROBIAL PROPHYLAXIS

Gynecologic procedures often involve breaching of the reproductive and gastrointestinal tracts. These locations harbor endogenous flora that are capable of causing polymicrobial infections in the postoperative period. Despite advances in aseptic technique and drug development, bacterial contamination of the operative site and postoperative infections are an inevitable part of the practice of gynecologic surgery.

Infections in the skin or pelvis that result from gynecologic surgery (i.e., parametritis, cuff cellulitis, pelvic abscess) are typically polymicrobial. These infections are complex and often involve gram-negative rods, gram-positive cocci, and anaerobes. Antibiotic prophylaxis should be sufficiently broad as to cover these potential pathogens.<sup>11</sup>

As the number and virulence of bacteria increase within a surgical site, the risk for postoperative infection increases.

Excessive tissue injury and foreign material, such as suture and drains, may further increase the risk for infection. Antibiotic prophylaxis is given to the gynecologic surgery patient with the belief that antibiotics can enhance the immune mechanisms in the host tissues that would resist such infections by killing bacteria that inoculate the surgical site at the time of surgery.<sup>12</sup>

The timing of antimicrobial prophylaxis is important. There is a relatively narrow window of opportunity for affecting outcomes.<sup>13</sup> In the United States, it is customary to give antimicrobial prophylaxis shortly before or during the induction of anesthesia. Data have revealed that a delay of 3 or more hours between the time of bacterial inoculation (i.e., skin incision) and administration of antibiotics may result in ineffective prophylaxis. Evidence indicates that for prophylaxis, one dose of antibiotic is appropriate. When the surgical procedure is longer than one to two times the half-life of the drug or blood loss is greater than 1.5 L, the data suggest that additional intraoperative doses of antibiotics maintain adequate levels of drug in serum and tissues. There are no data to support the continuation of prophylactic antimicrobial agents into the postoperative period for routine gynecologic procedures.

The cephalosporins have emerged as the most important class of antimicrobial agents for antimicrobial prophylaxis. These drugs have a broad spectrum and relatively low incidence of adverse reactions. Cefazolin (1 g) appears to be most widely used by gynecologic surgeons in the United States because of its relatively low cost and long half-life. Other cephalosporins, such as cefoxitin, cefotaxime, and cefotetan, are also widely used for prophylaxis. These agents appear to have a broader spectrum of activity against anaerobic bacteria. Most data do not indicate a clinically relevant distinction between cefazolin and the other agents; however, data have emerged from randomized controlled trials indicating that cefotetan and cefotaxime are superior to cefazolin in women undergoing abdominal hysterectomy.<sup>14</sup>

Women undergoing gynecologic surgery who are given antimicrobial prophylaxis may have adverse reactions to this treatment. A single dose of broad-spectrum antibiotic can result in pseudomembranous colitis, caused by *Clostridium difficile*. Diarrhea may develop in as many as 15% of hospitalized patients treated with  $\beta$ -lactam antibiotics. In patients receiving clindamycin, the rate of diarrhea is nearly 30%. These gastrointestinal complications from antibiotics may cause serious morbidity in the surgical patient, and the surgeon should be familiar with recognizing and managing these problems.<sup>15</sup> Anaphylaxis is the greatest life-threatening complication from antibiotic use.

Anaphylactic reactions to penicillins occur in 0.2% courses of treatment. The fatality rate is 0.0001%. Data indicate that it is generally safe to administer cephalosporins to women who report a history of adverse reactions to penicillins. The incidence of adverse reactions (i.e., skin flushing, itching) in women with a history of penicillin allergy who are given cephalosporins is 1% to 10%. The incidence of anaphylaxis in this setting is less than 0.02%.<sup>16</sup>

Not all gynecologic surgery patients need to receive prophylactic antibiotics. The surgeon should choose agents to cover procedures based on available data, thereby avoiding the potential for adverse reactions and minimizing the frivolous use of antibiotics, which may contribute to increased rates of antimicrobial resistance. In patients reporting adverse reactions to

## General Gynecology

Table 17-2 Antimicrobial Prophylaxis for Gynecologic Surgical Procedures	
Procedure	Drug
Hysterectomy (vaginal/abdominal)	1–2 g IV cefazolin, 2 g IV cefoxitin, 1–2 g IV cefotetan, 1 g IV ceftotaxime
Hysterosalpingogram	100 mg doxycycline PO bid for 5 days
Abortion/dilation and curettage	100 mg doxycycline PO 1 hour before procedure, then 200 mg PO after the procedure
Cervical conization	No clear recommendations; doxycycline suggested by some authors
Colporrhaphy	No clear recommendations; cephalosporins suggested by some authors
Laparoscopy (clean)	None
Laparotomy (clean)	None
Hysteroscopy	None

the above agents, the surgeon should choose other drugs or combinations that will provide adequate prophylactic coverage. For example, metronidazole and levofloxacin or clindamycin and gentamycin are two alternative broad-spectrum prophylactic regimens in hysterectomy patients that cover anaerobes, gram-positive cocci and gram-negative rods.<sup>17</sup> Some commonly used regimens are listed in Table 17-2.

### Spontaneous Bacterial Endocarditis Prophylaxis

Often, the gynecologic surgeon encounters the issue of endocarditis prophylaxis. Most commonly, a woman will report a history of a murmur or mitral valve prolapse to the surgeon during the preoperative interview. Data clearly indicate that surgeons and dentists in the United States overtreat these women with prophylactic antibiotics meant to prevent endocarditis. The majority of patients who report these cardiac issues are at no increased risk for endocarditis. For example, most patients with mitral valve prolapse or benign murmurs do not require endocarditis prophylaxis at the time of gynecologic surgery. A thorough history and physical examination, coupled with a preoperative echocardiogram and consultation with a cardiologist, will provide detailed assessment of endocarditis risk in these patients.

The American Heart Association (AHA) has published guidelines for physicians and dentists to use in selecting patients and procedures for endocarditis prophylaxis. If the surgeon is uncertain, consultation with a cardiologist is most appropriate. If it appears that the patient would benefit from endocarditis prophylaxis, based on the cardiac lesion and the procedure she will undergo, then the risk is stratified as high or moderate. High-risk patients receive ampicillin or vancomycin *plus* gentamycin in a multidose regimen; moderate-risk patients receive amoxicillin or ampicillin or vancomycin in a single-dose regimen. Low-risk patients require no prophylaxis regardless of the procedure.

Antibiotics administered to prevent surgical site infection are not sufficient for endocarditis prophylaxis; however, some experts feel that antibiotics given for endocarditis prophylaxis

may provide adequate coverage against postoperative infections. This claim may be suspect, however, in the gynecologic surgery patient. Some regimens (e.g., single-dose oral amoxicillin) prescribed for endocarditis prophylaxis in some patients may not provide adequate coverage for flora (gram-negative rods and anaerobes) found in the reproductive or gastrointestinal tracts. The reader is referred to the AHA guidelines for detailed dosing and schedule information on the topic of endocarditis prophylaxis<sup>18</sup> (Table 17-3).

### Bowel Preparation

The structures of the female genital tract lie in close proximity to the small bowel, large bowel, and veriform appendix. Pathologic conditions such as endometriosis, pelvic inflammatory disease, adnexal cysts, leiomyomata, inflammatory bowel disease, cancer, and prior surgery often give rise to adhesions between genital and gastrointestinal structures. Given the anatomic proximity of these structures and the frequency of involvement between them, the gynecologic surgeon must have an understanding of the available data regarding preoperative bowel preparation.

General surgeons, gynecologists, and gynecologic oncologists often point to numerous potential benefits of mechanical bowel preparation before abdominal or pelvic operations. These include removal of feces, facilitation of intraoperative palpation, ease of packing for pelvic surgery, lowering of the bacterial load, and reduction in spillage or contamination. These are reasonable benefits; however, mechanical bowel preparation is potentially harmful to patients. Patient discomfort, noncompliance, electrolyte abnormalities, and dehydration before major surgery are frequently reported.<sup>19</sup>

Mechanical bowel preparation prior to pelvic surgery can be completed with the use of several commercially available products. Magnesium citrate, polyethylene glycol, and sodium phosphate are each effective in mechanically cleansing the bowel. Effective mechanical cleansing of the gastrointestinal tract can be achieved by combining the agent of choice with a clear liquid diet for 24 hours prior to surgery. Although numerous options for mechanical bowel preparation exist, a randomized trial comparing polyethylene glycol and sodium phosphate found that sodium phosphate was more effective, less expensive, and better tolerated.<sup>20</sup>

Table 17-3 Antimicrobial Prophylaxis for Endocarditis	
Patient Description	Drug
Patients at “high risk” for endocarditis	Ampicillin plus gentamicin
Patients at “high risk” for endocarditis and allergic to penicillins	Vancomycin plus gentamicin
Patients at “moderate risk” for endocarditis	Amoxicillin or ampicillin
Patients at “moderate risk” for endocarditis and allergic to penicillins	Vancomycin
Patients at “negligible risk” for endocarditis (e.g., mitral valve prolapse without regurgitation)	No antibiotics needed

Despite dogma, prospective studies have failed to prove the benefit of mechanical bowel preparation. The available prospective data have not shown a decreased risk of wound or abdominal infections.<sup>21</sup> The incidence of anastomotic breakdown was not lowered in patients undergoing preoperative mechanical bowel preparation. These reports have not typically controlled for surgical indications, actual procedures, or other associated comorbidities, so the astute pelvic surgeon will exercise caution interpreting these data. Until these data mature and more randomized, controlled studies are available, it appears prudent to recommend mechanical bowel preparation for patients undergoing pelvic surgery at risk for gastrointestinal complications.

The role for perioperative antibiotics in patients undergoing abdominal or pelvic operations anticipated to involve the gastrointestinal tract remains controversial. A variety of perioperative antibiotic regimens have been proposed and defended. The use of oral, parenteral, and combination prophylaxis is described widely in the literature. The typical oral regimen involves the preoperative administration of neomycin, erythromycin, or metronidazole. Various doses and combinations exist in the literature. The lack of solid data and the increased incidence of preoperative gastrointestinal distress (e.g., nausea and vomiting) seen in patients treated with these preoperative oral antibiotics raise questions about their utility and advisability.

Perioperative parenteral antibiotics are used widely in patients undergoing abdominal operations. A single dose of a broad-spectrum agent (i.e., one that covers anaerobes, gram-positive cocci, and gram-negative rods) given 30 to 60 minutes prior to the operation will provide adequate antibacterial prophylaxis for patients undergoing gastrointestinal operations. Parenteral antibiotics appear to be an adequate substitute for preoperative oral antibiotics. If a lengthy operation is encountered (greater than twice the half-life of the antibiotic) or if blood loss (greater than 1 L) is encountered, the surgeon should consider ordering one or two additional doses of parenteral antibiotics during or after the operation.<sup>22</sup>

## POSTOPERATIVE COMPLICATIONS

### Thromboembolism and Pulmonary Embolism

#### Risk Factors

Deep venous thrombosis (DVT) and pulmonary embolism, although largely preventable, are significant postoperative complications. The magnitude of this problem is relevant to the gynecologist, since 40% of all deaths following gynecologic surgery are directly attributed to pulmonary emboli<sup>23</sup> and they are the most frequent cause of postoperative death in patients with uterine or cervical carcinoma.<sup>24</sup>

The causal factors of DVT were first proposed by Virchow in 1858 and include a hypercoagulable state, venous stasis, and vessel endothelial injury. Risk factors include major surgery; advanced age; nonwhite race; malignancy; history of DVT, lower extremity edema, or venous stasis changes; presence of varicose veins; being overweight; a history of radiation therapy; and hypercoagulable states, such as factor V Leiden; pregnancy; and use of oral contraceptives, estrogens, or tamoxifen. Intraoperative factors associated with postoperative DVT include increased anesthesia time, increased blood loss, and the need for

**Table 17-4**  
**Thromboembolism Risk Stratification**

Low risk
Minor surgery No other risk factors*
Moderate risk
Age >40 years and major surgery Other risk factors* and major surgery
High risk
Age >60 years and major surgery Cancer History of DVT or PE Thrombophilia
Highest risk
Age >60 and cancer or history of venous thromboembolism

DVT, deep venous thrombosis; PE, pulmonary embolism.  
\*Risk factors: obesity; varicose veins; history of DVT or PE; current estrogen, tamoxifen, or oral contraceptive use.

transfusion in the operating room. It is important to recognize these risk factors (Table 17-4) to provide the appropriate level of DVT prophylaxis.<sup>25,26</sup>

#### Thromboembolism Prophylaxis

A number of prophylactic methods have been shown to significantly reduce the incidence of DVT, and a few studies have demonstrated a reduction in fatal pulmonary emboli. The ideal prophylactic method would be effective, free of significant side effects, well accepted by the patient and nursing staff, widely applicable to most patients, and inexpensive.

#### Low-Dose Heparin

The use of small doses of subcutaneously administered heparin for the prevention of DVT and pulmonary embolism is the most widely studied of all prophylactic methods. More than 25 controlled trials have demonstrated that heparin given subcutaneously 2 hours preoperatively and every 8 to 12 hours postoperatively is effective in reducing the incidence of DVT. The value of low-dose heparin in preventing fatal pulmonary emboli was established by a randomized, controlled, multicenter international trial that demonstrated a significant reduction in fatal postoperative pulmonary emboli in general surgery patients receiving low-dose heparin every 8 hours postoperatively.<sup>27</sup> Trials of low-dose heparin in gynecologic surgery patients have shown a significant reduction in postoperative DVT.

Although low-dose heparin is considered to have no measurable effect on coagulation, most large series have noted an increase in the bleeding complication rate, especially a higher incidence of wound hematoma.<sup>28</sup> Although relatively rare, thrombocytopenia is associated with low-dose heparin use and has been found in 6% of patients after gynecologic surgery.<sup>28</sup> If patients remain on low-dose heparin for greater than 4 days it is reasonable to check the platelet count to assess the possibility of occurrence of heparin-induced thrombocytopenia.

## General Gynecology

### Low-Molecular-Weight Heparins

Low-molecular-weight heparins (LMWHs) are fragments of heparin that vary in size from 4500 to 6500 Da. When compared with unfractionated heparin, LMWHs have more anti-Xa and less antithrombin activity, leading to less effect on partial thromboplastin time and possibly to fewer bleeding complications.<sup>29</sup> An increased half-life of 4 hours leads to increased bioavailability when compared with unfractionated heparin. The increase in half-life of LMWHs also allows the convenience of once a day dosing.

Randomized controlled trials have compared LMWH with unfractionated heparin in patients undergoing gynecologic surgery. In all studies, there was a similar incidence of DVT. Bleeding complications<sup>30</sup> were also similar. A meta-analysis of general and gynecologic surgery patients from 32 trials likewise indicated that daily LMWH administration is as effective as unfractionated heparin in DVT prophylaxis with no difference in hemorrhagic complications.

### Mechanical Methods

Stasis in leg veins has been clearly demonstrated while the patient is undergoing surgery and continues postoperatively for varying lengths of time. Stasis occurring in the capacitance veins of the calf during surgery, plus the hypercoagulable state induced by surgery, are the prime factors contributing to the development of acute postoperative DVT. Prospective studies of the natural history of postoperative DVT have shown that the calf veins are the predominant site of thrombi and that most thrombi develop within 24 hours of surgery.<sup>31</sup>

Although probably of only modest benefit, reduction of stasis by short preoperative hospital stays and early postoperative ambulation should be encouraged for all patients. Elevation of the foot of the bed, raising the calf above heart level, allows gravity to drain the calf veins and should further reduce stasis.

**Elastic Stocking.** Controlled studies of graduated pressure stockings are limited but suggest modest benefit when they are carefully fitted.<sup>32</sup> Poorly fitted stockings may be hazardous to some patients, who develop a tourniquet effect at the knee or midthigh.<sup>24</sup> Variations in human anatomy do not allow perfect fit of all patients to available stocking sizes. The simplicity of elastic stockings and the absence of significant side effects are probably the two most important reasons that they are often included in routine postoperative care.

**External Pneumatic Compression.** The largest body of literature dealing with the reduction of postoperative venous stasis deals with intermittent external compression of the leg by pneumatically inflated sleeves placed around the calf or leg during intraoperative and postoperative periods. Various pneumatic compression devices and leg sleeve designs are available, and the current literature does not demonstrate superiority of one system over another. Calf compression during and after gynecologic surgery significantly reduces the incidence of DVT on a level similar to that of low-dose heparin. In addition to increasing venous flow and pulsatile emptying of the calf veins, external pneumatic compression also appears to augment endogenous fibrinolysis, which may result in lysis of very early thrombi before they become clinically significant.<sup>33</sup>

The duration of postoperative external pneumatic compression differs in various trials. External pneumatic compression may be

effective when used in the operating room and for the first 24 hours postoperatively<sup>33,34</sup> in patients with benign conditions who will ambulate on the first postoperative day.

External pneumatic compression used in patients undergoing major surgery for gynecologic malignancy reduces the incidence of postoperative venous thromboembolic complications by nearly threefold,<sup>35</sup> but only if calf compression is applied intraoperatively and for the first 5 postoperative days.<sup>36</sup> Patients with gynecologic malignancies may remain at risk because of stasis and hypercoagulable states for a longer period than general surgical patients and therefore appear to benefit from longer use of external pneumatic compression.

External pneumatic leg compression has no significant side effects or risks and is considered slightly more cost-effective than pharmacologic methods of prophylaxis.<sup>37</sup>

### Management of Postoperative Deep Venous Thrombosis

Because pulmonary embolism is the leading cause of death following gynecologic surgical procedures, identification of high-risk patients and the use of prophylactic DVT regimens are an essential part of management.<sup>23,24,38</sup> In addition, the early recognition of DVT and pulmonary embolism and immediate treatment are critical. Most pulmonary emboli arise from the deep venous system of the leg although following gynecologic surgery, the pelvic veins are a known source of fatal pulmonary emboli as well.

The signs and symptoms of DVT of the lower extremities include pain, edema, erythema, and prominent vascular pattern of the superficial veins. These signs and symptoms are relatively nonspecific; 50% to 80% of patients with these symptoms will not actually have DVT.<sup>39</sup> Conversely, approximately 80% of patients with symptomatic pulmonary emboli have no signs or symptoms of thrombosis in the lower extremities.<sup>40</sup> Because of the lack of specificity when signs and symptoms are recognized, additional diagnostic tests should be performed to establish the diagnosis of DVT.

### Doppler Ultrasound

B-mode duplex Doppler imaging is currently the most common technique for the diagnosis of symptomatic DVT, especially when it arises in the proximal lower extremity. With duplex Doppler imaging, the femoral vein can be visualized and clots may be seen directly.<sup>41</sup> Compression of the vein with the ultrasound probe tip allows assessment of venous collapsibility; the presence of a thrombus diminishes vein wall collapsibility. Doppler imaging is less accurate when evaluating the calf venous system and pelvic veins.

### Venography

Although venography has been the “gold standard” for diagnosis of DVT, other diagnostic studies are accurate when performed by a skilled technologist and, in most patients, may replace the need for routine contrast venography. Venography is moderately uncomfortable, requires the injection of a contrast material that may cause allergic reaction or renal injury, and may result in phlebitis in approximately 5% of patients.<sup>42</sup>

### Magnetic Resonance Venography

Magnetic resonance venography (MRV) has a sensitivity and specificity comparable to venography. In addition, MRV may

## Preoperative Evaluation and Postoperative Management

detect thrombi in pelvic veins that are not imaged by venography.<sup>43</sup> The primary drawbacks to MRV are the time involved in examining the lower extremity and pelvis and the expense of this technology.

The treatment of postoperative DVT requires the immediate institution of anticoagulant therapy. Treatment may be with either unfractionated heparin or LMWHs, followed by 6 months of oral anticoagulant therapy with warfarin.

### **Unfractionated Heparin**

After DVT is diagnosed, unfractionated heparin should be initiated to prevent proximal propagation of the thrombus and allow physiologic thrombolytic pathways to dissolve the clot. After an initial bolus of 5000 units intravenously, continuous infusion of 30,000 units per day should be implemented and dosage adjusted to maintain activated partial thromboplastin time (APTT) level at a therapeutic level 1.5 to 2.5 times the control value. Patients having subtherapeutic APTT levels in the first 24 hours have a risk of recurrent thromboembolism 15 times the risk of patients with appropriate levels. Patients, therefore, should be managed aggressively using IV heparin to achieve prompt anticoagulation. Oral anticoagulant (warfarin) should be started on the first day of heparin infusion. The international normalized ratio (INR) should be monitored daily until a therapeutic level is achieved (INR 2.0 to 3.0). The change in INR resulting from warfarin administration often precedes the anticoagulant effect by approximately 2 days, during which time low protein C levels are associated with a transient hypercoagulable state. Therefore, heparin should be administered until the INR has been maintained in a therapeutic range for at least 2 days, confirming proper warfarin dose. IV heparin may be discontinued in 5 days if an adequate INR level has been established.

### **Low-Molecular-Weight Heparin**

LMWHs are effective in the treatment of venous thromboembolism and have a cost-effective advantage over IV heparin because they can be administered in the outpatient setting. The dosages used in treatment of thromboembolism are unique and weight adjusted according to each LMWH preparation. Because LMWHs have a minimal effect on APTT, serial laboratory monitoring of PTT levels is not necessary. Similarly, monitoring of anti-Xa activity (except in difficult cases) has not been shown to be of significant benefit in a dose adjustment of LMWH. The increased bioavailability associated with LMWH allows for twice-a-day dosing, potentially making outpatient management for a subset of patients an option. A meta-analysis involving more than 1000 patients from 19 trials suggests that LMWH is more effective, safer, and less costly than unfractionated heparin in preventing recurrent thromboembolism.

### **Management of Pulmonary Embolism**

Many signs and symptoms of pulmonary embolism are associated with other, more commonly occurring pulmonary complications following surgery. The classic findings of pleuritic chest pain, hemoptysis, shortness of breath, tachycardia, and tachypnea should alert the physician to the possibility of a pulmonary embolism. Many times, however, the signs are more subtle and may be suggested only by persistent tachycardia or a slight

elevation in the respiratory rate. Patients suspected of pulmonary embolism should be evaluated initially by chest radiography, electrocardiography, and arterial blood gas assessment. Any evidence of abnormality should be further evaluated by ventilation-perfusion lung scan or a spiral CT scan of the chest. Unfortunately, a high percentage of lung scans may be interpreted as "indeterminate." In this setting, careful clinical evaluation and judgment are required to decide whether pulmonary arteriography should be obtained to document or exclude the presence of a pulmonary embolism.

### **Treatment**

1. Immediate anticoagulant therapy, identical to that for the treatment of DVT, should be initiated.
2. Respiratory support, including oxygen and bronchodilators and an intensive care setting, may be necessary.
3. Although massive pulmonary emboli are usually quickly fatal, pulmonary embolectomy has been performed successfully on rare occasions.
4. Pulmonary artery catheterization with the administration of thrombolytic agents bears further evaluation and may be important in patients with massive pulmonary embolism.
5. Vena cava interruption may be necessary in situations in which anticoagulant therapy is ineffective in the prevention of repeat thrombosis and repeat embolization from the lower extremities or pelvis. A vena cava umbrella or filter may be inserted percutaneously above the level of the thrombosis and caudad to the renal veins.
6. In most cases, however, anticoagulant therapy is sufficient to prevent repeat thrombosis and embolism and to allow the patient's endogenous thrombolytic mechanisms to lyse the pulmonary embolus.

## **BLOOD COMPONENT THERAPY**

Most hematologic problems observed in the postoperative period are related to perioperative bleeding and blood component replacement. Adherence to proper indications for blood component therapy is necessary to avoid potential adverse effects and costs of transfusion. Adverse effects include most commonly nonhemolytic transfusion reactions, rarely hemolytic reactions from incompatible blood, and exposure to infectious diseases including bacterial contamination.

Red blood cell transfusions should not be dictated by a single hemoglobin value but rather by the patient's risk of developing complications due to inadequate oxygenation. Red blood cell transfusion is rarely indicated in hemoglobin concentrations greater than 10 g/dL and is almost always indicated when it is less than 6 g/dL. The determination of whether intermediate hemoglobin concentrations (6 to 10 g/dL) require transfusion should be dependent on clinical assessment. Autologous blood donation has been advocated as a safer alternative for the patient; however, preoperative autologous blood donation is not cost-effective, especially in low-transfusion-risk operations.<sup>44</sup> Furthermore, having preoperative autologous blood may lead to more liberal blood transfusion, iatrogenic anemia, volume overload, and other risks such as hemolytic reactions due to clerical

## General Gynecology

errors and bacterial contamination.<sup>45</sup> The National Heart, Lung, and Blood Institute Expert Panel does not recommend collection of autologous blood for procedures with a likelihood of transfusion less than 10%, such as uncomplicated abdominal and vaginal hysterectomies.<sup>46</sup>

Replacement of platelets and clotting factors in patients with massive transfusion and microvascular bleeding is dependent on clinical and surgical assessments. Guidelines are provided by the American Society of Anesthesiologists task force.<sup>47</sup> Platelet transfusion is rarely indicated for counts greater than 100,000/ $\mu$ L and usually indicated for counts <50,000/ $\mu$ L. With intermediate platelet counts of 50,000/ $\mu$ L to 100,000/ $\mu$ L, transfusion should be based on the risk of bleeding. Fresh-frozen plasma therapy is indicated in massively transfused patients with microvascular bleeding or hemorrhage if the prothrombin or APTT values exceed 1.5 times the normal values. Cryoprecipitate transfusions are recommended for prophylaxis in nonbleeding perioperative patients with fibrinogen deficiencies or von Willebrand's disease refractory to desmopressin, bleeding patients with von Willebrand's disease, and correction of microvascular bleeding in massively transfused patients with fibrinogen concentrations less than 80 to 100 mg/dL.

## MANAGEMENT OF MEDICAL DISORDERS

### Inherited Disorders of Coagulation and Menorrhagia

Menorrhagia is a common gynecologic complaint in reproductive aged women. A specific cause for menorrhagia is identified in less than 50% of affected women.<sup>48</sup> Many of these women are referred for surgical intervention and require a thorough preoperative evaluation for possible inherited disorders of coagulation, such as factor VIII (hemophilia) and factor IX (Christmas disease) deficiencies and von Willebrand's disease. Von Willebrand's disease is a common hereditary bleeding disorder with prevalence in the general population of 0.8% to 1.3%,<sup>49</sup> but in women with menorrhagia, its prevalence is 10% to 18%.<sup>49</sup> Identified women can be treated effectively with desmopressin nasal spray, thus improving quality of life and preventing unnecessary surgical intervention. In addition, unanticipated and excessive bleeding during surgery can be avoided with prophylactic treatment.

A careful medical history identifying a long history of menorrhagia; bleeding after dental procedures, operations, or childbirth; easy bruising; and mucosal bleeding may predict an increased risk of a bleeding disorder. However, women with von Willebrand's disease may present only with easy bruising.<sup>50</sup> In the absence of a genetic diagnosis, the diagnosis of von Willebrand's disease is difficult and involves a combination of clinical and laboratory assessments including von Willebrand factor antigen and von Willebrand factor (vWF) functional activity or ristocetin cofactor assay. Physiologic fluctuations occur with vWF levels, requiring repeated testing and consultation or referral to a hematologist. Nevertheless, it is recommended that women with menorrhagia without obvious uterine or endometrial abnormalities should be routinely screened for inherited bleeding disorders, especially von Willebrand's disease, before undergoing invasive procedures.

### Diabetes

#### **Preoperative Assessment and Optimization of Management**

According to the American Diabetes Association, 9.3 million American women, or 8.7% of all women older than 20 years have diabetes.<sup>51</sup> The risk is increased 2.4 fold in African American, Hispanic, Native American, and Asian/Pacific Islander women. Prevalence rates of diabetes are 4.7% in non-Hispanic white women, 12.6% of non-Hispanic African American women, and 11.3% in Mexican American women.<sup>52</sup>

In older classification systems, diabetes was classified as childhood or adult-onset diabetes. These classifications have been supplanted by the terminology of insulin-dependent diabetes mellitus (IDDM, type 1) and non-insulin-dependent diabetes mellitus (NIDDM, type 2) with the recognition that either type can occur in any age group. From a practical point of view, patients with NIDDM are managed with oral hypoglycemic agents and those with IDDM require insulin.

Preoperative assessment of patients with diabetes requires knowledge of the patient's routine glucose management regimen, including finger-stick testing regimens and medications.<sup>53</sup> The presence of symptoms of hyperglycemia and hypoglycemia should be documented. Complications of diabetes should also be noted, including nephropathy, neuropathy, and retinopathy. A serum HgbA1<sub>c</sub> level should be obtained for independent assessment of long-term blood sugar control in known diabetic patients.

The current recommendations for making a diagnosis of diabetes include the following<sup>54</sup>: (1) random nonfasting blood glucose greater than 200 mg/dL with symptoms of diabetes (polyuria, polydipsia, unexplained weight loss), or (2) fasting plasma glucose greater than 126 mg/dL, or (3) 2-hour post-75 g glucose load with a serum glucose greater than 200 mg/dL. To confirm the diagnosis, one of the above criteria must be verified on a subsequent day. It is imperative that diabetes be controlled before proceeding to the operating room. Referral to internal medicine or endocrine physicians and dietitians is appropriate prior to elective gynecologic surgery.

Diabetic patients are at higher risk of other comorbidities, including coronary heart disease and silent cardiac ischemia, which are discussed in other sections of this chapter.

#### **Perioperative and Postoperative Management**

Ideally, surgery on the diabetic patient should be accomplished early in the operative day. Type 2 diet-controlled diabetics can safely receive IV fluids that do not contain dextrose, and they should be provided a sliding scale insulin regimen for postoperative management. Type 2 diabetics on oral hypoglycemic regimens should not take their oral hypoglycemic medicines on the morning of surgery. Postoperatively, a sliding scale insulin regimen can be instituted until oral intake is sufficient to resume hypoglycemic medicines.

Type 1 diabetics who require insulin need special consideration. The general heuristic procedure is that one third to one half of the morning NPH insulin should be taken on the day of surgery. The patient will require dextrose-containing IV fluids. For particularly long or complex surgeries, intraoperative assessment of blood glucose levels and administration of subcutaneous or IV insulin may be instituted by the anesthesiologist.

Postoperatively, the hormonal regulation of blood glucose is altered. Insulin production is decreased, and ACTH and

glucagon production are increased. The countervailing hormones drive blood sugar levels higher. Insulin must be provided in the postoperative setting to obtain control of blood glucose with a goal of 120 to 200 mg/dL. In the DIGAMI study,<sup>55</sup> tight control of blood glucose contributed to a decreased overall mortality in post-myocardial infarction patients. Elevated postoperative insulin levels contribute to increased risk of infection and delayed wound healing.

At a minimum, blood glucose levels should be obtained every 6 hours in the patient without significant oral intake. Initially, sliding scale insulin may be administered. If sliding scale subcutaneous insulin does not achieve adequate blood glucose control, or if the patient will be receiving corticosteroids, an IV insulin drip should be considered.

For patients with IDDM and elevated blood glucose postoperatively, close monitoring of urine for ketones must be instituted to avoid diabetic ketoacidosis (DKA). If ketones are detected, assessment of serum electrolytes is warranted. The first signs and symptoms of impending DKA may be a drop in serum bicarbonate level and increased respiratory rate. The diagnosis of DKA mandates a search for the predisposing factor, including occult infections of the operative site, wound, urinary tract, respiratory tract, or blood.

Once oral intake has been reliably established, the patient may be gradually switched to the preoperative regimen. Caution must be used in restarting metformin in the setting of significant renal insufficiency, hepatic impairment, or congestive heart failure. Metformin may increase the risk of lactic acidosis. In addition, metformin should be held for 24 to 48 hours before and after the patient has received a CT scan to reduce the likelihood of renal insufficiency developing after contrast dye load.

## Obesity

### **Incidence and Definition**

Obesity is the new scourge of the American public. Centers for Disease Control and Prevention (CDC) statistics from the year 2000 indicate that 30% of U.S. adults greater than 20 years old are obese—an astounding 59 million adults! If these statistics are expanded to include overweight as well as obese persons, 64% of the U.S. adult population is facing a significant medical problem.<sup>56</sup>

Obesity is defined by the body mass index (BMI). BMI is calculated by dividing the weight in kilograms by the height in centimeters squared. Alternatively, the body weight in pounds is multiplied by 704 and then divided by the height in inches squared. Current American Gastroenterology Association Guidelines<sup>57</sup> use BMI to define classes of obesity. A BMI of 25 to 29.9 is defined as overweight; BMI 30 to 34.9, class I obesity; BMI 35 to 39.9, class II obesity; and BMI over 40 is extreme class III obesity. In practical terms, a 5 ft. 4 in. American woman who is 30 pounds overweight will have a BMI greater than 30, placing her in obesity class I.

### **Preoperative Planning**

A gynecologic surgeon with an obese patient faces obstacles in both surgical performance and postoperative care. Preoperative imaging may be complicated by lack of a size-appropriate CT or MRI scanner and limitations of ultrasound probe depth penetration. Vaginal ultrasound may offer more detailed infor-

mation than abdominal ultrasound. Obese patients may have multiple medical comorbidities, including diabetes, coronary heart disease, obesity hypoventilation syndrome, and hypertension. Preoperative clearance in consultation with internal medicine, endocrine, and anesthesia colleagues is imperative to optimize preoperative function and postoperative control.

The most important decisions facing the gynecologic surgeon are the timing of the operation and the possibility of referral to a more experienced consultant. Decision to proceed to the operating room should be accompanied by extensive discussion. Part of the preoperative counseling of an obese patient must include the increased risk of operative injury to adjacent structures, wound dehiscence or infection with prolonged wound healing,<sup>58</sup> severe sepsis syndrome, skin ulcers, venous thromboembolism, and increased risk of medical and anesthetic complications, including prolonged intubation. A study of abdominal and vaginal hysterectomy in obese and normal-weight patients found that the obese patients required a longer operating time for both procedures and had greater blood loss during vaginal hysterectomy but otherwise tolerated the procedure as well as the normal-weight patients.<sup>59</sup> Similar results were found with radical hysterectomy for cervical cancer in obese versus normal-weight women, where outcomes were the same but operating time and blood loss were increased in the obese patients.<sup>60</sup> The surgeon should plan ahead with requests for a weight-appropriate operating room bed, extra-long or bariatric surgical instruments, deep retractors, extra assistants, and possibly panniculectomy.<sup>61,62</sup>

Intubation may be exceedingly difficult in the morbidly obese patient.<sup>63</sup> These patients have a decreased functional residual capacity, decreased expiratory reserve volume, decreased compliance of the chest wall, and chronic abnormalities of room air blood gases. The lack of normal anatomic markers, redundant neck folds, small oropharynx, and a poor Mallampati class<sup>64</sup> also increase the risk of failed intubation. Experienced anesthesiologists with availability of fiberoptic intubation or other advanced techniques may increase the safety of the anesthetic induction. Consideration may be given to awake intubation.

### **Postoperative Complications and Management**

Control of the airway continues as the critical element in the immediate postoperative period.<sup>63</sup> Extubation may not be prudent or possible at the end of the case. If the initial intubation was difficult, tracheal edema may have developed, enveloping the endotracheal tube. Alternatively, the patient may not have the physical capacity to compensate for excess chest wall weight. Many obese patients suffer from the obesity hypoventilation syndrome (OHS), which increases their baseline hypercarbia and may delay extubation. Transfer to a surgical intensive care unit with mechanical ventilation and serial arterial blood sampling will aid in timing of extubation. Postoperative reduction in vital capacity is related more to the degree of obesity than to the site of surgery.<sup>65</sup>

Extubation may also be delayed by intraoperative anesthetic agents that suppress respiratory drive.<sup>66</sup> For this reason, preoperative placement of a regional anesthesia modality such as an epidural may lessen the amount of IV anesthetic agents used and assist with postoperative extubation. Analgesic and anesthetic

## General Gynecology

agents that are fat soluble will continue to slowly release from fat stores for a period time after the operation is finished. Even after extubation, ventilation of the obese patient during sleep may be aided by the use of noninvasive positive pressure ventilation units, particularly if the patient has a history of sleep apnea and uses a continuous positive airway pressure (CPAP) machine at home. Respiratory therapists can be of assistance in patient instruction and management of CPAP machinery in addition to other respiratory toilet.

Postextubation management must heed the higher risk of aspiration<sup>67</sup> in the obese patient. These patients have increased gastric residual volumes, a higher rate of gastroesophageal reflux disease (GERD), and increased intra-abdominal pressure from mass effect. Neutralization of the stomach contents with a proton pump inhibitor can minimize the chemical burn potential of aspirated stomach contents. Gastrointestinal motility agents such as metoclopramide may decrease residual volume by increasing intestinal transit.

Venous access poses another problem.<sup>63</sup> Extreme obesity obliterates anatomic landmarks and makes insertion of peripheral lines, as well as central lines, problematic. Adjunctive visualization technology such as Doppler ultrasound or fluoroscopy increases the accuracy and safety of line placement. Arterial line placement facilitates monitoring of pressures and blood gas parameters. Ideally, central venous lines and arterial lines should be placed intraoperatively by the anesthesia team to insure adequate access in the postoperative period. The intraoperative placement of central lines should be verified for position postoperatively by chest radiography in the post-anesthesia care unit.

Medication administration must take into account total body weight as well as ideal body weight.<sup>63</sup> Certain medications are dosed on ideal body weight (corticosteroids, penicillin, cephalosporins, β-blockers). Others are dosed on total body weight (heparin), and still others based on a calculated "dosing weight" (aminoglycosides, fluoroquinolones, vancomycin). An inpatient pharmacist should be consulted for assistance with proper dosing and monitoring of pharmacotherapy.

### Cardiac Complications

The risk of perioperative cardiac complications such as myocardial infarction in patients with no prior history of coronary artery disease is less than 1%. In contrast, the risk of perioperative infarction is doubled in patients with known or suspected coronary disease. When these complications occur, subsequent cardiac mortality is high. The goal of perioperative cardiac evaluation is to lower perioperative morbidity and mortality by identifying high-risk patients and performing tests that may modify perioperative management and improve long-term benefit.

The history and physical examination of the patient remain the key factors of preoperative risk assessment. A number of risk indices have been developed on the basis of multivariate analysis. The largest and most current scheme of clinical risk assessment for noncardiac surgery is the revised cardiac risk index.<sup>68</sup> The risk of major cardiac events (myocardial infarction, cardiac arrest, pulmonary edema, and complete heart block) range from 0.5% to 9.1% based on the number of risk factors (Table 17-5). Risk factors include high-risk surgical procedures

**Table 17-5**  
**Major Cardiac Event Rates by Revised Cardiac Risk Index**

Class	Events/Patients (No.)	Event Rate (95% CI), (%)
I (0 risk factors)	2/488	0.4 (0.05–1.5)
II (1 risk factor)	5/567	0.9 (0.3–2.1)
III (2 risk factors)	17/258	6.6 (3.9–10.3)
IV (≥3 risk factors)	12/109	11.0 (5.8–18.4)

From Lee T, Marcantonio E, Mangione C, et al: Derivation and prospective validation of a simple index for prediction of cardiac risk of major noncardiac surgery. Circulation 1999; 100:1043–1049.

(intraperitoneal, intrathoracic, or suprainguinal vascular reconstruction), history of ischemic heart disease (excluding prior revascularization), history of congestive heart failure, history of transient ischemic attack or stroke, preoperative insulin therapy, and preoperative serum creatinine levels greater than 2.0 mg/dL.

The American College of Cardiology/American Heart Association Practice Guidelines stratify risk assessment into three major categories: (1) clinical predictors, (2) functional capacity, and (3) surgery-specific risk. Clinical predictors of increased perioperative cardiac risk are major, intermediate, and minor factors (Table 17-6). Poor functional capacity is the inability to perform activities that require at least four metabolic equivalents, such as climbing a flight of stairs or walking up a hill. Patients with poor functional capacity have higher perioperative risks, and self-reported exercise tolerance can be used to predict perioperative risk.<sup>69</sup> Surgery-specific risk is sub-classified as high risk (emergency major surgery, aortic or vascular procedures, and prolonged surgeries associated with large fluid shifts or blood loss), intermediate risk (other intra-peritoneal procedures), and low risk (endoscopies, breast surgery, and superficial procedures). The updated Guidelines<sup>70</sup> present a detailed algorithm that incorporates these factors to guide clinicians to proceed directly to surgery, obtain non-invasive testing, consider coronary angiography, or consider delay of surgery and risk factor modification (Fig. 17-1).

Preoperative testing should be used discriminately in intermediate-risk patients. Controversy exists concerning the accuracy of these tests to provide prognostic information beyond that which is obtained from clinical risk stratification for non-vascular procedures. Stress tests such as exercise electrocardiography, dipyridamole-thallium scintigraphy, and dobutamine echocardiography may provide information on ischemic threshold, maximal tolerated heart rate, and localization and amount of threatened myocardium. Echocardiography can be performed to assess left ventricular dysfunction in patients with current or poorly controlled heart failure, and in valvular heart disease. Coronary angiography should only be considered in patients who have an indication for angiography independent of the planned surgery, such as patients with acute coronary syndromes, unstable angina, angina refractory to medical therapy, or high-risk results on noninvasive testing.

Although the pathophysiologic mechanisms are complex, the causes of myocardial ischemia and infarction are related to

<b>Table 17-6</b> <b>Clinical Predictors of Increased Perioperative Cardiovascular Risk (Myocardial Infarction, Heart Failure, and Death)</b>	
<b>Major</b>	
Unstable coronary syndromes	
Acute or recent myocardial infarction (MI)*	
Unstable or severe angina	
Decompensated heart failure	
Significant arrhythmia	
High-grade atrioventricular block	
Symptomatic ventricular arrhythmias in the presence of underlying heart disease	
Supraventricular arrhythmias with uncontrolled ventricular rate	
Severe valvular disease	
<b>Intermediate</b>	
Mild angina	
Previous myocardial infarction (>1 month before planned surgery)	
Compensated or prior heart failure	
Diabetes mellitus	
Renal insufficiency	
<b>Minor</b>	
Advanced age	
Abnormal electrocardiogram (ECG; left ventricular hypertrophy, left bundle branch block, ST-T abnormalities)	
Rhythm other than sinus	
Low functional capacity	
History of stroke	
Uncontrolled systemic hypertension	

\*Recent MI defined as >7 days but ≤30 days; acute MI is within 7 days. If a recent stress test does not indicate residual myocardium at risk, the likelihood of reinfarction after noncardiac surgery is low. It appears reasonable to wait 4 to 6 weeks after MI to perform elective surgery.

From American College of Cardiology/American Heart Association: Guideline update for perioperative cardiovascular evaluation for noncardiac surgery. Executive Summary. Circulation 2002;105:1257–1267.

increases in myocardial oxygen demand coupled with decreased myocardial oxygen supply, alterations in coagulation that may precipitate thrombosis, and changes in vascular tone and endothelial function.<sup>71</sup> Postoperative ischemic events peak on the second and third postoperative days, whereas tachycardia is maximal during days 1 and 2. Conditions leading to decreased myocardial oxygen supply include hypotension, anemia, and hypoxia. Myocardial oxygen consumption may be increased by hypothermia, tachycardia, and hypertension, which occur with stress responses to intubation and emergence from anesthesia, pain, and shifts in intravascular volume.

Perioperative care of patients with coronary artery disease is based on maximizing delivery of oxygen to the myocardium as well as decreasing myocardial oxygen utilization. Patients benefit from maintenance of normothermia, supplemental oxygen, correction of anemia, and effective pain management. In high-risk patients, close hemodynamic monitoring is integral to perioperative management and may require surveillance in an intensive care setting postoperatively. The value of pulmonary artery catheters in high-risk surgical patients is controversial. A randomized, controlled trial of patients undergoing urgent or elective major noncardiac surgery found neither benefit nor harm with pulmonary artery catheters.<sup>72</sup> In this randomized trial, pulmonary catheter use did not decrease perioperative

morbidity or mortality and should no longer be recommended as a risk-reduction strategy in high-risk surgical patients.

Diagnosis of perioperative myocardial infarction includes clinical symptoms, postoperative electrocardiographic changes, and elevation of myocardium-specific enzymes. Electrocardiograms obtained at baseline, immediately after surgery, and on the first 2 days postoperatively appear to be cost effective in patients with known or suspected coronary artery disease undergoing high-risk procedures.<sup>73</sup> Measurement of cardiac enzymes should be reserved for patients at high risk and those with clinical, electrocardiographic, or hemodynamic evidence of cardiovascular dysfunction.

A meta-analysis of six prospective randomized studies has shown that β-blocker therapy reduces the incidence of perioperative cardiac complications in patients undergoing noncardiac surgery.<sup>74</sup> The authors suggest a clinical algorithm that recommends perioperative β-blocker therapy for patients with at least one major or two minor risk factors as defined by the revised cardiac risk index.<sup>68</sup> The timing and optimal duration of β-blocker therapy are uncertain. Current evidence suggests initiating therapy at least 1 week prior to surgery and continuing throughout the hospitalization. For patients receiving β-blockade therapy prior to surgery, therapy should be continued immediately in the perioperative period.

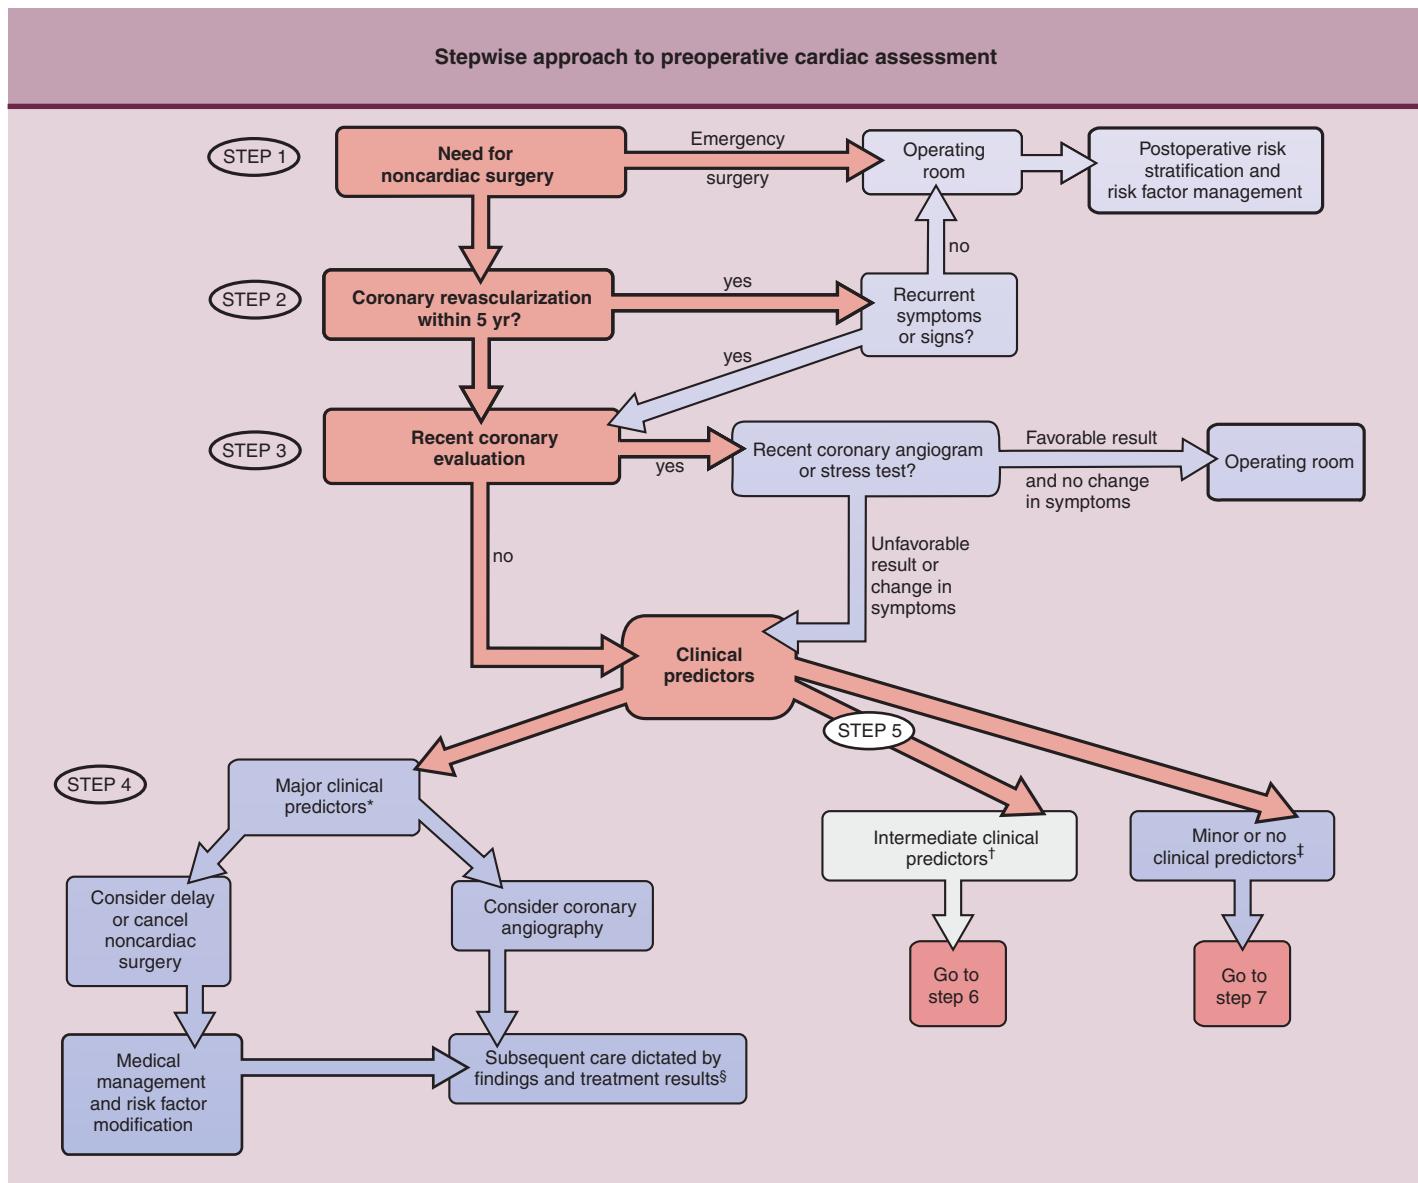

## Pulmonary Complications

### Preoperative Predictors and Testing

Postoperative pulmonary complications occur in 2% to 80% of cases, depending on the exact definition utilized and the study population.<sup>75</sup> Pulmonary complications can include atelectasis, infection, prolonged mechanical ventilation, bronchospasm, exacerbation of chronic lung disease, pulmonary edema, and pulmonary embolism.<sup>75,76</sup> A previous history of chronic obstructive pulmonary disease (COPD) places the patient at the highest risk of postoperative pulmonary complications, with a relative risk (RR) of 2.7 to 6.0. A previous history of asthma does not significantly raise postoperative pulmonary complication risks unless the patient's peak flow is less than 80% of predicted values. Tobacco smoking in the 2 months prior to surgery increases the odds ratio of pulmonary complications to 2.3.

Many clinical studies using multivariate regression analyses have attempted to define patient risk factors that are strong predictors of postoperative pulmonary complications. Definite risk factors for postoperative pulmonary complications include the following<sup>77</sup>: upper abdominal, thoracic, or abdominal aortic aneurysm surgery; surgical procedure time greater than 3 hours; poor functional status; ASA (American Society of Anesthesiologists) class greater than 2; previous COPD; smoking within 2 months of surgery; and use of pancuronium as an anesthesia agent. Probable risk factors for postoperative complications include general (as opposed to regional) anesthesia, PaCO<sub>2</sub> greater than 45 mm Hg, and emergency surgery. Possible risk factors are upper respiratory infection, an abnormal preoperative chest radiograph, and age greater than 70 years.

Patients with COPD must have their pulmonary function maximized preoperatively with regimens that may include inhaled agents such as ipratropium bromide and albuterol as well as systemic and inhaled corticosteroids. Smoking cessation should be urged, possibly with a nicotine replacement regimen.

**Figure 17-1 Stepwise approach to preoperative cardiac assessment.** CHF, congestive heart failure; ECG, electrocardiogram; MET, metabolic equivalent; MI, myocardial infarction. \*Major clinical predictors: unstable coronary syndromes; decompensated CHF; significant arrhythmias; severe vascular disease. †Intermediate clinical predictors: mild angina pectoris; prior MI; compensated or prior CHF; diabetes mellitus; renal insufficiency. ‡Minor clinical predictors: advanced age; abnormal ECG; rhythm other than sinus; low functional capacity; history of stroke; uncontrolled systemic hypertension. §Subsequent care may include cancellation or delay of surgery, coronary revascularization followed by noncardiac surgery, or intensified care.

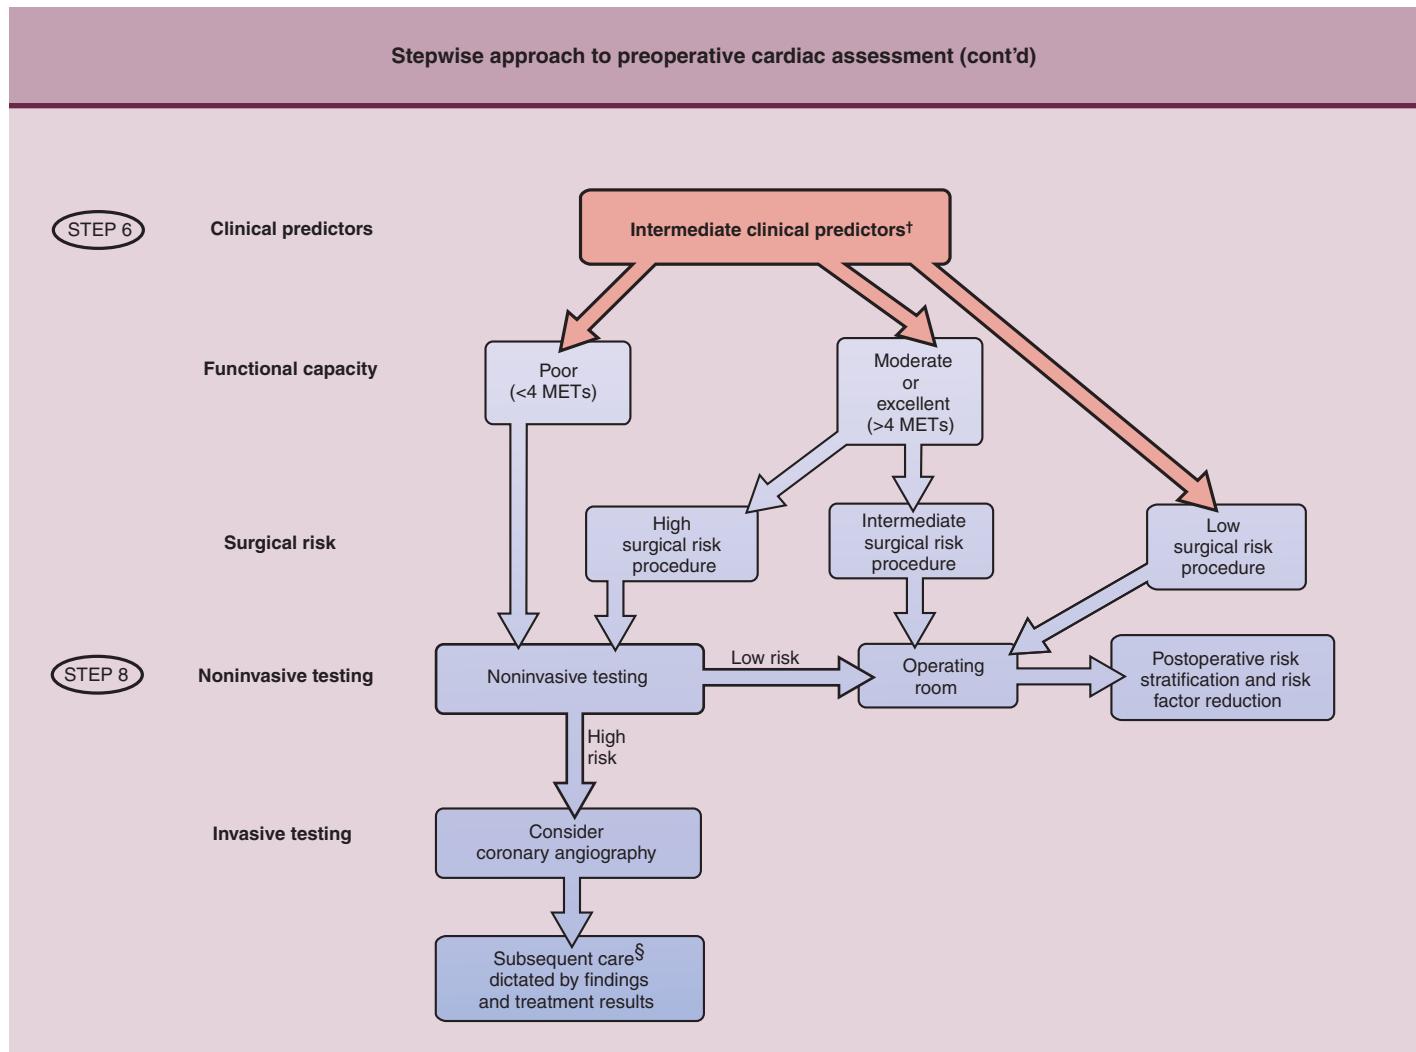

Routine treatment with antibiotics is not necessary; however, the presence of purulent sputum should initiate antibiotic treatment.

The optimal tests to assess preoperative pulmonary function and surgical risk are controversial. A chest radiograph is indicated for all patients older than 60 years and for those patients in whom metastatic malignancy is a concern. Obtaining pulmonary function tests preoperatively remains controversial. Pulmonary function tests are indicated in smokers in whom COPD has not yet been diagnosed. Often, a careful physical examination can reveal as much about pulmonary function as formal spirometry.

Auscultation for adventitious respiratory sounds and assessment of the ratio of inspiration time to expiration time may give clues to the need for more formal testing.

#### Postoperative Complications

The most common complication facing postoperative gynecologic surgery patients is atelectasis. Large vertical midline incisions are associated with the most pulmonary dysfunction owing to decreased vital capacity and decreased functional residual capacity. Lower abdominal and laparoscopy incisions produce much less pulmonary dysfunction. A second predisposing factor

**Figure 17-1, cont'd. Stepwise approach to preoperative cardiac assessment.** CHF, congestive heart failure; ECG, electrocardiogram; MET, metabolic equivalent; MI, myocardial infarction. \*Major clinical predictors: unstable coronary syndromes; decompensated CHF; significant arrhythmias; severe vascular disease. <sup>†</sup>Intermediate clinical predictors: mild angina pectoris; prior MI; compensated or prior CHF; diabetes mellitus; renal insufficiency. <sup>‡</sup>Minor clinical predictors: advanced age; abnormal ECG; rhythm other than sinus; low functional capacity; history of stroke; uncontrolled systemic hypertension. <sup>§</sup>Subsequent care may include cancellation or delay of surgery, coronary revascularization followed by noncardiac surgery, or intensified care.

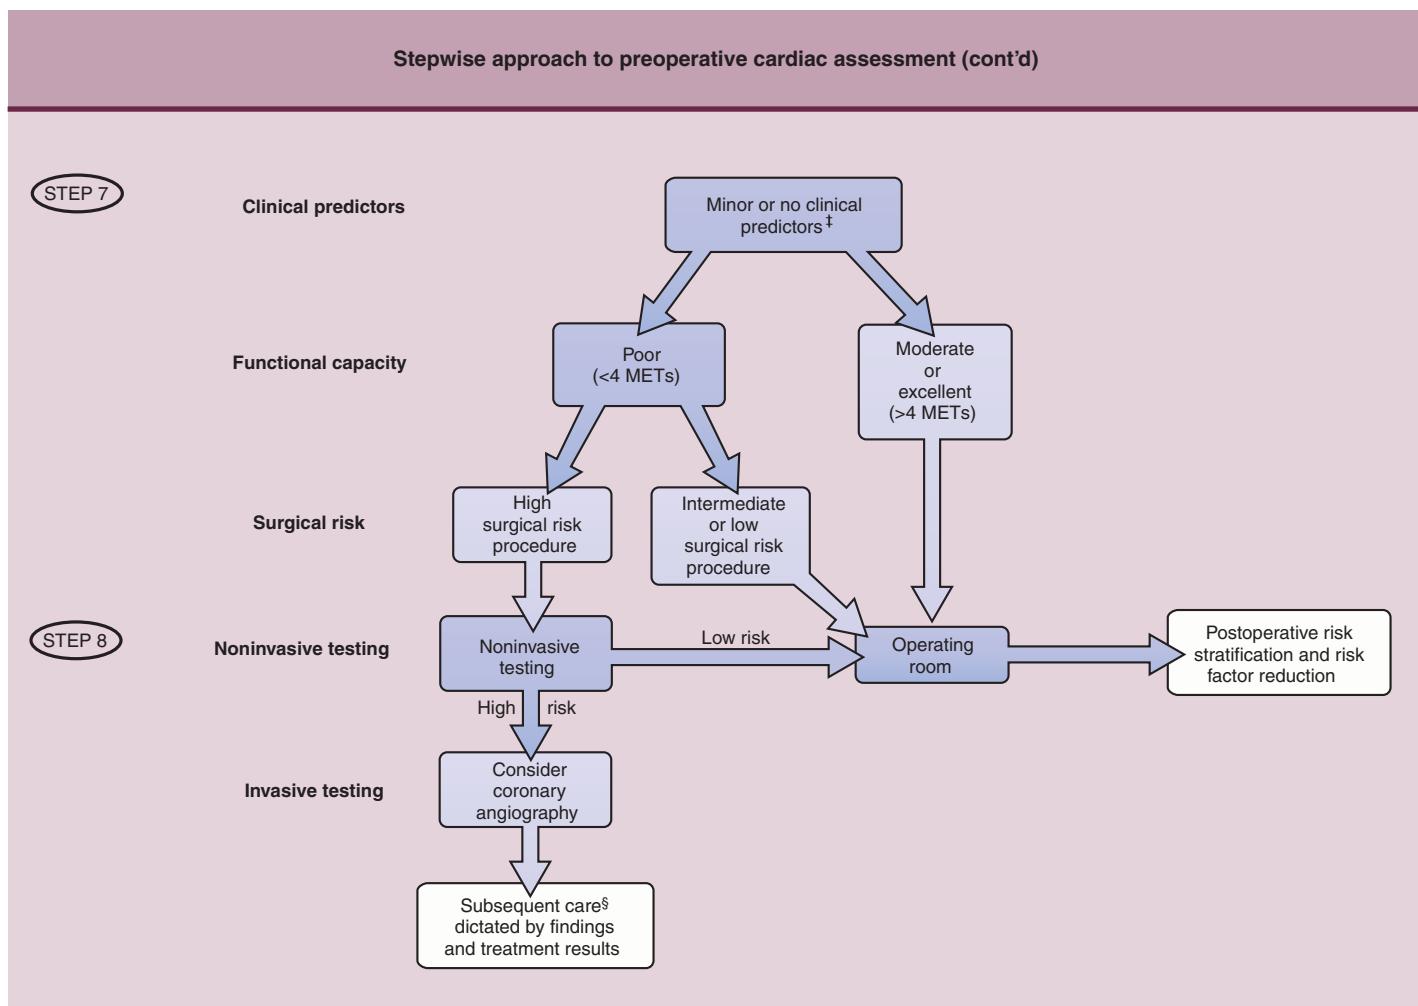

(Continued)

is the use of narcotic analgesia with subsequent respiratory depression. The routine use of deep breathing and coughing techniques with incentive spirometry promotes pulmonary toilet. Patients should ideally be instructed in the use of an incentive spirometer preoperatively to optimize postoperative efforts. In high-risk patients (morbidly obese or with preexisting pulmonary disease), aggressive chest physiotherapy and respiratory therapy should be ordered. Adequate pain control postoperatively is important, since movement-evoked pain may significantly affect pulmonary function after hysterectomy.<sup>78</sup>

Pulmonary edema commonly occurs after gynecologic procedures in older women. Strict assessment of intake and output in the critical 24 to 48 hours after surgery should allow for volume assessment. Decrease in pulse oximetry, continued oxygen requirement, and crackles on physical examination are

clues to the presence of pulmonary edema. A chest radiograph may show bilateral diffuse edema with the presence of Kerley B lines. Treatment is appropriate fluid management and administration of a diuretic agent.

Pneumonia may result from aspiration or nosocomially acquired infection. The risk of aspiration is greatest around the time of intubation and extubation. However, in patients who are morbidly obese or have Dobbhoff feeding tubes, GERD, postoperative emesis, or indwelling nasogastric suctioning tubes, the risk of aspiration pneumonia rises. On the chest radiograph, the most common side of aspiration pneumonia is the right owing to the more vertical orientation of the right mainstem bronchus. The primary insult to the lung is a chemical pneumonitis for which observation and supportive treatment are appropriate. In rare cases, the chemical pneumonitis will progress to full

**Figure 17-1, cont'd. Stepwise approach to preoperative cardiac assessment.** CHF, congestive heart failure; ECG, electrocardiogram; MET, metabolic equivalent; MI, myocardial infarction. \*Major clinical predictors: unstable coronary syndromes; decompensated CHF; significant arrhythmias; severe vascular disease. <sup>†</sup>Intermediate clinical predictors: mild angina pectoris; prior MI; compensated or prior CHF; diabetes mellitus; renal insufficiency. <sup>‡</sup>Minor clinical predictors: advanced age; abnormal ECG; rhythm other than sinus; low functional capacity; history of stroke; uncontrolled systemic hypertension. <sup>§</sup>Subsequent care may include cancellation or delay of surgery, coronary revascularization followed by noncardiac surgery, or intensified care. (From American College of Cardiology/American Heart Association: Guideline update for perioperative cardiovascular evaluation for noncardiac surgery. Executive summary. Circulation 2002;105:1257–1267.)

adult respiratory distress syndrome (ARDS), which will require mechanical ventilation and transfer to an intensive care unit. When a secondary infection of aspiration pneumonitis is suspected, broad-spectrum antibiotic coverage should be initiated. Organisms acquired in nosocomial pneumonia infections are aerobic gram-negative species and *Staphylococcus aureus*. These are common in intensive care units, and prolonged intubation increases the risk of colonization and subsequent pneumonia.

Pulmonary embolus is one of the most feared complications of gynecologic surgery. Recognition and treatment of pulmonary emboli are covered in the preceding thromboembolism sections.

## Section 3 Gynecologic Infectious Disease

# Chapter 18

# Vulvovaginal Infections

Sebastian Faro, MD, PhD

### KEY POINTS

- Infection of the vulva is common; the two categories are skin flora and sexually transmitted disease.
- Erythematous lesions do not always indicate infection.
- Lesions that persist should be studied histologically.

### INTRODUCTION

The vulva and vagina constitute two distinct ecologic niches. The vulva is covered by a thick and fairly resistant dermis and is subjected to a variety of environmental substances like soaps, creams, and ointments, as well as trauma, such as scratching or the placing into the vagina of a variety of instruments either for the introduction of medications or for pleasure. The vulva is inhabited by a microbial flora that, for the most part, maintains a commensal relationship with the host. Infections of the vulva and vulvar organs occur following breaks in the dermis, which allow resistant bacteria to gain entrance to the deeper tissue and cause infection. Infection can also occur following introduction of exogenous bacteria into the deeper tissues or glands of the vulva. An intact dermis and resident microflora limit the use of topical agents that can alter the normal flora and eliminate trauma that results in breaks in the skin, which can prevent vulvar infections.

Vaginal infections and alterations in the resident or endogenous microflora occur at alarming rates. Our understanding of factors and conditions that result in the development of vaginitis, vaginosis, or significant alterations in the vaginal environment are poorly understood. The basis of most alterations of the endogenous microflora, excluding the introduction of bacteria into the vaginal ecosystem, is recognition that the vaginal microflora is a complex biosphere and consists of a variety of gram-negative and gram-positive bacteria including aerobic, facultative, and obligate anaerobic bacteria. A healthy vaginal ecosystem is achieved through a variety of biologic activities that maintain *Lactobacillus* as the dominant bacterium and suppress the numerous nonpathogenic and pathogenic bacteria.

Infection occurring anywhere in the body is caused primarily by the host's endogenous bacteria or pathogens that constitute part of the normal microflora. Normally, the pathogens that reside on the skin do not cause infection unless the dermis is broken (microscopic or macroscopic disruption) and bacteria gain entrance to the deeper tissues. The deeper tissues, in contrast to

the dry dermis, provide nutrients that allow the bacteria to grow. Infection occurs when bacteria invade a sterile site, adhere to cells and invade host cells, or enter the bloodstream. Subsequently the bacteria reproduce and spread to adjacent cells or distant organs. Thus, the development of infection is an orderly process that can be divided into the following steps:

1. Establishment of an initial inoculum that overwhelms the local host defenses
2. Invasion and adherence to host cells
3. Reproduction of bacteria
4. Migration to adjacent tissues or entrance into the blood stream or distant organs
5. Ability to overcome host defenses

### SOFT TISSUE INFECTIONS

Soft tissue infections of the vulva and vagina are frequently minor but under certain circumstances, such as in the diabetic patient, trauma to the vulva, and minor infections that go unnoticed, they can become associated with major morbidity and mortality. Usually, infections of the vulva are secondary to trauma of the skin, for example, scratching or nicking of the skin during depilation (especially shaving). Infection spreads from the dermis to the deeper tissues and can involve the fascia and muscle.

#### Pyoderma

The most common bacteria to cause pyoderma are coagulase-positive staphylococci or hemolytic streptococci. *Staphylococcus epidermidis*, *Staphylococcus hominis*, and *Staphylococcus haemolyticus* are commonly found in areas where there are apocrine glands (e.g., axillae, vulva, inguinal and perianal areas).<sup>1,2</sup> Although these bacteria frequently cause vulvar pyoderma, folliculitis, furuncles, and carbuncles because of the vulva's close proximity to the vagina and rectum, other bacteria endogenous to these two areas should be considered possible causes of infection. Pyoderma is a pyogenic infection of the skin, the hair follicle and its associated glands, or the deeper dermis.

*Pyoderma* is a nonspecific term used to denote a localized purulent skin infection caused by *Staphylococcus aureus* or group A streptococci (*Streptococcus pyogenes*). Infection caused by either of these bacteria is indistinguishable on clinical presentation. However, infection caused by *S. aureus* is characterized by its rapid progression to deeper tissues, resulting in cellulitis.<sup>3</sup> Identification of the bacterium can be only established by obtaining a specimen for Gram staining, culture, and identification.

## Gynecologic Infectious Disease

Antibiotic sensitivities should be obtained on the bacterial isolate. Because of the possibility that bacteria from the vagina and rectum can also cause infection of the vulvar skin, two specimens should be obtained for culture and placed in an anaerobic and aerobic transport system. Gram's stain can differentiate between *Staphylococcus* and *Streptococcus*, but it cannot identify the species. Cases of impetigo have been reported where both *S. aureus* and *S. pyogenes* skin and soft tissue have been reported as coinfecting bacteria.<sup>4,5</sup> If the Gram stain reveals a mixture of gram-positive and gram-negative bacteria, the infection should be considered polymicrobial, and the presence of obligate anaerobic bacteria should be considered when treatment is administered.

**Erysipelas**

Erysipelas is an infection involving the skin but not the subcutaneous tissue found in patients with cellulitis. In addition to *S. aureus* and *S. pyogenes*, *Streptococcus agalactiae* solely or in combination with *S. aureus* can cause skin infections of the vulva. Erysipelas and cellulitis usually arise secondary to trauma of the tissue (e.g., abrasions secondary to scratching). The initial lesion is the development of an erythematous area associated with pain. There also may be central necrosis as the disease process progresses. Patients with erysipelas or cellulitis can develop systemic disease (i.e., bacteremia and sepsis); therefore, administration of antibiotic therapy should not be delayed.

**Folliculitis**

Folliculitis is an infection that originates in a hair follicle from bacteria that reside permanently or transiently on skin appendages (Fig. 18-1). The bacterium most commonly associated with folliculitis is *S. aureus*. Other bacteria from the vagina and rectum can cause folliculitis. In patients with recurrent infection, specimens should be obtained from the lesion and cultured for aerobic, facultative, and obligate anaerobic bacteria. Folliculitis typically presents as a central pustule in a hair follicle surrounded by a narrow erythematous base. If folliculitis is widely distributed over the patient's body, the possibility of

"hot-tub folliculitis" or "swimmer's itch" is considered. "Hot-tub folliculitis" is associated with bathing in poorly chlorinated water at 98.6°F to 104°F, and is caused by *Pseudomonas aeruginosa*.<sup>6</sup> This is a rare infection contracted from recreational or therapeutic use of improperly chlorinated hot tubs, whirlpools, and swimming pools. Clinically the disease presents with painful, papulopustular skin lesions, low-grade fever, and malaise. The infection usually is self-limiting, but it has been associated with serious disseminated disease (e.g., bacteremia and septic shock).

Folliculitis can advance to a subcutaneous abscess that is referred to as a furuncle or "boil." This is usually self-limiting, drains spontaneously, and resolves without requiring antibiotic or surgical intervention (Figs. 18-2 and 18-3). However, if a group of furuncles coalesce, a large, painful, swollen, erythematous, indurated mass with a large central pustule develops. The central pustule is typically a solid core of coagulated pus. Resolution of a carbuncle is accomplished by the administration of antibiotic therapy, especially if the patient is febrile, and surgical incision to remove the central core and drain any pus that may be behind the central core. The abscess cavity should be thoroughly irrigated with either an antibiotic solution (bacitracin 50,000 units plus kanamycin 1 g in 1 L of normal saline). All necrotic tissue should be débrided, and the abscess cavity should be packed with iodoform gauze. The packing should be removed in 24 to 48 hours and the defect allowed to close spontaneously. Antibiotic therapy should be continued until the lesion has healed.

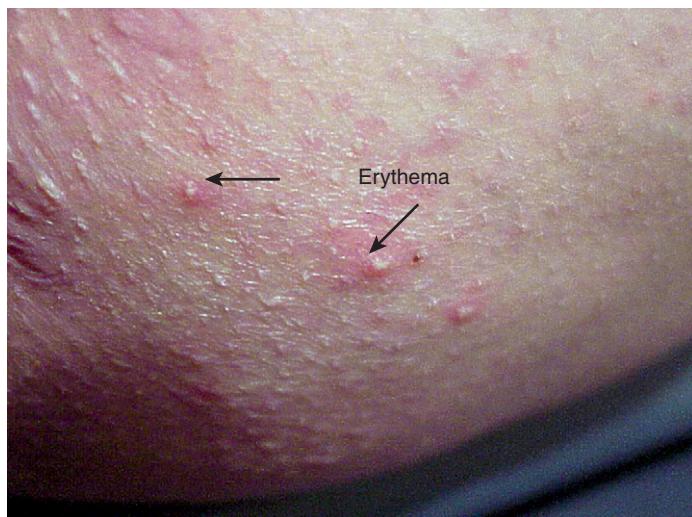

**Hidradenitis Suppurativa**

Hidradenitis suppurativa (also known as Verneuil's disease, acne inversa, and pyoderma fistulans) is a chronic inflammatory disease involving the axillae, inguinal area, vulva, and anogenital area. It can also occur in the breast, under the breast, and in sacral areas. Women are affected more frequently than men, by approximately three to one.<sup>7</sup> The etiology is unknown; however, it is a complex disease that has genetic, hormonal, inflammatory, and infection components.<sup>8,9</sup> The disease process appears to be initiated by occlusion of a hair follicle, resulting in blockage of apocrine gland contents. Bacteria trapped below the occlusion infect the apocrine gland, which results in an intense inflammatory response and the development of an abscess. Bacterial involvement is a secondary feature of hidradenitis, and antibiotic therapy appears to be effective only in early and mild disease. Once the disease has become well established and is chronic, antimicrobial therapy is ineffective.

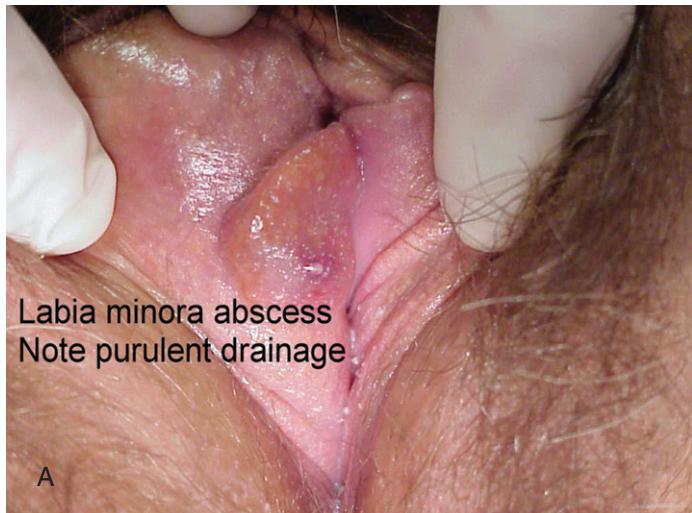

The infection component of hidradenitis suppurativa appears to be polymicrobial, involving at least two bacteria, with *S. aureus* playing a major role<sup>10-12</sup> (Table 18-1).

**Treatment**

Various treatment modalities have been described. However, the mainstay of treatment is surgical excision of the entire lesion and the tracts that develop as the disease progresses. When administered early in the disease process, antibiotic therapy appears to be beneficial if one or two lesions are present. Prior to institution of antibiotic therapy, a specimen should be obtained from the lesion via aspiration or swab. Specimens should be obtained for the isolation of facultative and obligate anaerobic

**Figure 18-1** **Folliculitis.** Note pustules surrounded by erythematous base.

**Figure 18-3** Bilateral labia majora abscesses. Note purulent aspirate.

bacteria. Although the infection may be caused by a single bacterium (e.g., *S. aureus*), it is also likely that the infectious component is polymicrobial. Therefore, empirical administration of antibiotics should provide broad antibacterial coverage, for example, metronidazole plus a quinolone or clindamycin plus a quinolone; a cephalosporin may be substituted for a quinolone. However, if metronidazole is used with a quinolone, such as levofloxacin, the latter would be preferred to a first-generation cephalosporin in an attempt to provide better coverage against *S. aureus*. A specimen for culture should be obtained because if community-acquired *S. aureus* is present, it is likely to be methicillin resistant (MRSA) and may be resistant to the quinolones. Therefore, the sensitivity pattern of the isolate is important to direct the appropriate administration of antibiotic therapy. However, when the disease progresses to the stage where multiple lesions are present and chronically recurring, antibiotic therapy neither arrests the disease nor results in resolution of the disease process. Antibiotic therapy should be instituted prior to performing surgery on these patients in order to provide adequate levels of antibiotic in the tissue surrounding the involved areas.

Oral isotretinoin (Accutane) demonstrated a positive effect in 50% of patients tested.<sup>13</sup> Acitretin administered in a dose of 25 mg twice a day also seems to be effective, but studies are

## Gynecologic Infectious Disease

limited.<sup>14,15</sup> Administration of isotretinoin is recommended for patients several weeks prior to surgery and should be continued for several weeks after surgery.<sup>16</sup>

Infliximab and etanercept are immunosuppressive agents that block tumor necrosis factor alpha (TNF- $\alpha$ ) and have been used to treat inflammatory diseases such as Crohn's disease, psoriasis, and rheumatoid arthritis.<sup>17</sup> Infliximab is a monoclonal antibody with an affinity for TNF- $\alpha$ . It is hypothesized that TNF- $\alpha$  induces proinflammatory cytokines that may play a role in a number of inflammatory conditions, such as hidradenitis suppurativa. Infliximab was administered for the treatment of hidradenitis in a small number of patients, who responded favorably.<sup>18</sup> It is plausible that immunosuppressive agents such as infliximab and etanercept may be useful in the treatment of hidradenitis.

The surgical approach for hidradenitis has included laser ablation, curettage, skinning techniques followed by skin grafts, simple drainage, simple excision with primary closure, simple excision with secondary closure, radical excision with primary closure, radical excision with secondary closure, and radical excision of the lesions and skin grafts. The surgical approach appears to have the best effect on the natural history of severe hidradenitis suppurativa.<sup>19</sup> In a study of 82 patients treated with radical surgical excision, the recurrence rates 3 to 72 months following surgery were as follows: axillary 3%, perianal 0%, inguinoperineal 37%, and submammary 50%.<sup>20</sup> In a study of 106 patients with chronic hidradenitis suppurativa treated with wide surgical excision, 2.5% of the patients experienced a recurrence.<sup>21</sup> In this study, 17.8% of the patients experienced minor complications (e.g., superficial suture dehiscence, post-operative bleeding, and hematoma formation), and 3.7% of the patients developed a wound infection.<sup>21</sup> Prior to institution of any therapy, the patient should be informed that hidradenitis suppurativa is a chronic condition and recurrences are likely to occur. All excised specimens should be submitted for histologic analysis because of the possibility of squamous cell carcinoma and verrucous carcinoma arising in areas of hidradenitis suppurativa, especially anogenital hidradenitis suppurativa.<sup>22,23</sup>

### BARTHOLIN'S GLAND ABSCESS

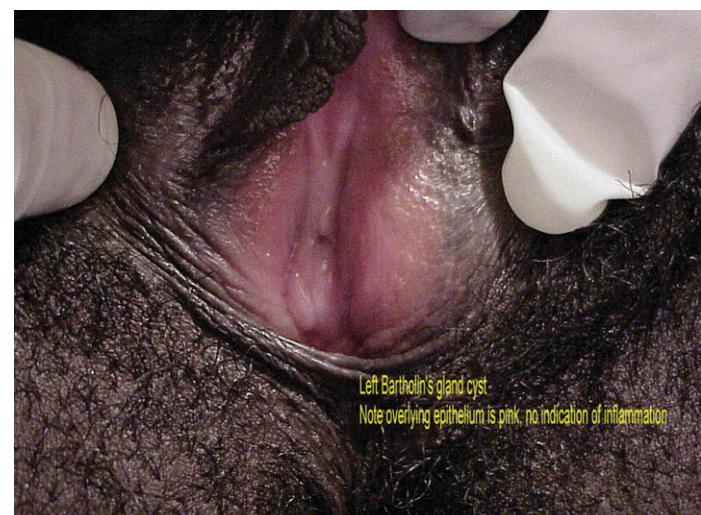

A Bartholin abscess can be differentiated from a Bartholin cyst by the clinical characteristics listed in Table 18-2 and illustrated in Figures 18-4 and 18-5. For a patient with a Bartholin cyst, specimens should be obtained from the endocervix to identify the presence of *Chlamydia trachomatis* and *Neisseria gonorrhoeae*.

For a Bartholin abscess, the surface of both the skin and the vagina should be cleansed with betadine prior to performing marsupialization of the abscess, an incision, drainage, or placement of a Word catheter. A needle should then be inserted at the center of the gland along the vermillion border. A portion of the aspirated pus should be placed into each of the following: one vial containing appropriate transport medium for the isolation of obligate anaerobic bacteria, one vial for the isolation of facultative anaerobic bacteria, and one vial for the detection of *C. trachomatis*; the remaining pus should be sent for Gram staining.

If a Word catheter is to be used, a stab incision with a No. 15 scalpel blade is made. The purulent contents of the abscess

**Table 18-2**  
Differentiation Between Bartholin Abscess and Bartholin Cyst

Bartholin Abscess	Bartholin Cyst
Gland is enlarged	Gland is enlarged
Erythema is present in skin overlying and surrounding the gland	No erythema
Skin overlying the gland typically feels warm to the touch	No increase in temperature
Fever is present, especially if there is tachycardia	No fever
An advancing cellulitis can be present	No cellulitis
WBC count is elevated	No elevation in WBC count
Bacteria and WBCs are present in fluid (pus) contained within Bartholin's gland	No bacteria or WBCs present in fluid (serous fluid contained within the cyst)

**Figure 18-4** **Bartholin cyst.** The tissue overlying the gland is pink.

should be completely drained and the gland irrigated with sterile saline until the effluent is clear. The Word catheter is placed into the gland through the stab incision and the balloon is distended with saline. The balloon should not be distended with air because it will not remain distended and the catheter will fall out. The catheter should be left in place until it falls out spontaneously, which usually occurs after 3 to 6 weeks. The patient should also be placed on an antibiotic regimen that provides activity against *C. trachomatis*, *N. gonorrhoeae*, and gram-positive and gram-negative facultative and obligate anaerobic bacteria, for example, metronidazole 500 mg every 8 hours plus levofloxacin 500 mg every 24 hours orally for 7 to 10 days. The patient should be reevaluated within 3 weeks and again at 6 weeks. The patient should be directed to monitor her temperature, and if she develops an oral temperature above 100.4°F, shaking, chills, nausea, or flu-like symptoms, she should call her physician and be evaluated.

### VULVOVAGINAL CANDIDIASIS

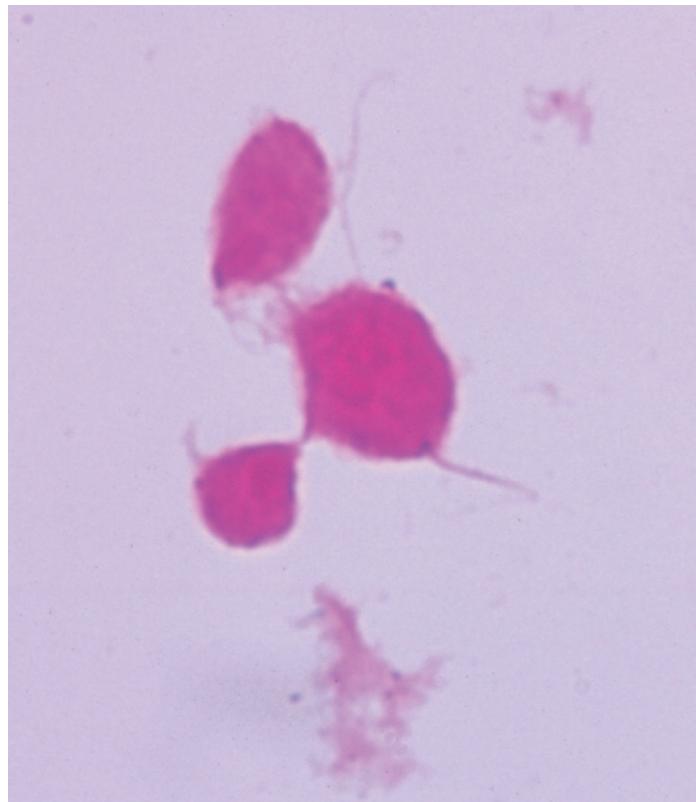

Vulvovaginal candidiasis is probably the most common condition of altered vaginal microflora that occurs in the reproductive-age

**Figure 18-5 Bartholin abscess.** Note erythema of the tissue overlying Bartholin's gland.

group. Approximately 75% of women in the reproductive-age group will experience at least one episode, with up to 50% of these women experiencing a subsequent episode and 5% evolving to recurrent and chronic vulvovaginal candidiasis.<sup>24–28</sup> *Candida* can be isolated from the lower genital tract in approximately 15% to 20% of asymptomatic women with a healthy vaginal ecosystem and microflora.<sup>29–31</sup> Typically the colony counts are extremely low and rarely detected on wet preparation microscopic examination of the vaginal discharge, but the organism is detected on culture of the vaginal discharge. Thus, women with vaginal *Candida* can be grouped into the following categories: (1) asymptomatic individuals with a healthy vaginal ecosystem and *Candida* as part of the endogenous vaginal microflora (i.e., symptomatic carriers); (2) individuals who have infrequent episodes of symptomatic vaginal candidiasis; (3) individuals with recurrent episodes of vaginal candidiasis, less than four episodes per year; (4) individuals with chronic recurrent vulvovaginal candidiasis, more than four episodes per year; (5) individuals with chronic persistent vulvovaginal candidiasis; and (6) individuals with chronic persistent vulvovaginal candidiasis, usually caused by *Candida glabrata*.

Yeasts occupy an interesting position in the schema of vaginitis. Approximately 20% of women will be colonized by yeast that can be considered part of their endogenous healthy vaginal microflora. Therefore, when these women are in an asymptomatic state and lactobacilli are the dominant microbe, a healthy vaginal microflora and ecosystem exist; when these women develop symptomatic vulvovaginal candidiasis, what is the endpoint of treatment? Should the endpoint be eradication of the fungus or resolution of the signs and symptoms of vulvovaginal candidiasis? When evaluating a patient for vulvovaginal candidiasis, the physician should perform the standard pelvic

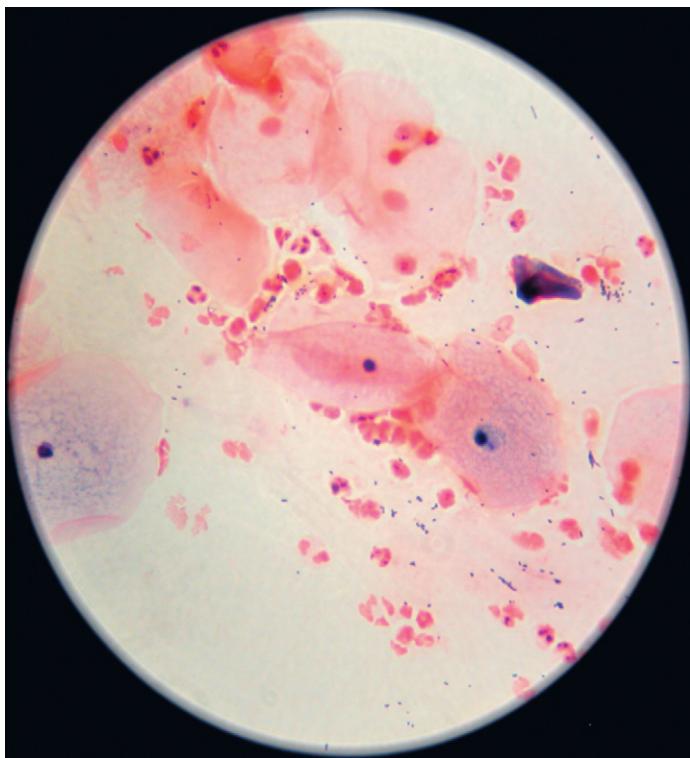

**Figure 18-6 Gram's stain of *Trichomonas vaginalis*.** Note flagella.

examination and determine the presence of typical signs of vulvovaginal candidiasis. In addition, the pH of the vagina should be determined because if yeasts are present and the pH is equal to or greater than 5, additional causes of vaginitis or vaginosis should be sought, for example, trichomoniasis (Figs. 18-6 and 18-7). If white blood cells are present (>5/hpf), specimens should be obtained from the endocervix to determine whether *C. trachomatis* or *N. gonorrhoeae* is present. If the patient's

**Figure 18-7 Microscopic photograph of wet preparation of *Trichomonas vaginalis*.**

**Figure 18-8** Gram's stain of vaginal discharge. Note estrogenized squamous epithelial cells, relative absence of bacteria, and numerous white blood cells. The pH of the vaginal fluid was 5.8. Further evaluation revealed no detectable pathogen or cervical infection.

uterus is tender to palpation, consideration should be given to the possible presence of upper genital tract infection, that is, endometritis or salpingitis (Fig. 18-8). A vaginal specimen should be obtained and cultured for the presence of yeast. The specific species should be identified because this information can be of assistance in determining appropriate antifungal therapy should the initial treatment fail.

#### Diagnosis and Management

The clinical presentation of vulvovaginal candidiasis initially is itching, which can be severe and results in scratching that leaves excoriations on the vulva and introitus. The involved tissue becomes inflamed and can develop a rich erythematous color (Fig. 18-9). The discharge is typically white, unless there is a concomitant infection or abnormality present within the vaginal microflora. The consistency can range from liquid to thick and pasty, and the latter is often referred to as a cottage cheese-like discharge. The patient may also complain of burning and pain following sexual intercourse and urination. Risk factors for vulvovaginal candidiasis include a variety of diseases as well as therapeutic agents and practices<sup>32,33</sup> (Table 18-3).

Establishing a diagnosis of vulvovaginal candidiasis is often difficult even when the patient has all the yeast vaginitis symptoms. Handa and Stice compared potassium hydroxide (KOH) preparations with culturing and found that KOH preparations were positive in 40.5% and fungal cultures were positive in 61.5% of 30 women.<sup>34</sup> Vaginal culture for yeast should be performed when the examiner finds that the signs and

**Figure 18-9** Vulvar candidiasis.

symptoms are suggestive of yeasts but the wet preparation of the discharge, including a KOH preparation, is negative.<sup>31</sup>

The physician should obtain two specimens of the vaginal discharge with a cotton or Dacron-tipped swab, one for culture and one for microscopic examination. The specimens for microscopic examination should be placed in a tube containing 2 to 3 mL of normal saline. Once immersed in saline, the swab should be agitated briskly for several seconds. Then the swab is removed and lightly touched to a glass slide to release one to two drops of the diluted discharge onto the surface of the glass slide. The diluted vaginal discharge is covered with a glass cover-slip and examined microscopically under 40 $\times$  magnification (Fig. 18-10). A second slide is prepared, and the diluted discharge is mixed with 10% KOH. The KOH will dissolve the squamous epithelial cells and white blood cells but not the hyphae or yeast cells. The yeast cell wall is made up of chitin, which is resistant to strong alkali. Culture is necessary to identify the species of yeasts (Table 18-4), since nonalbicans species tend to be resistant to the azole antifungal agents.

**Table 18-3**  
Risk Factors for Development of Vulvovaginal Candidiasis

Pregnancy
Poorly controlled diabetes mellitus
Cushing's disease
Addison's disease
Hypothyroidism
Hyperthyroidism
Cancer
HIV/AIDS
Vaginal trauma
Oral contraceptive use
Antibiotic use
Immunosuppressive therapy
Frequent sexual intercourse
Wearing of tight clothing
IUD use
Ingestion of large amounts of sugar-containing foods

**Figure 18-10 Wet preparation of yeasts, squamous epithelial cells, and bacteria.** This is a hyphal form of *Candida albicans*.

Individuals who experience either their first yeast infection or who have an infrequent recurrent yeast infection can be treated with various antifungal agents (Table 18-5). Patients who have recurrent vulvovaginal candidiasis—four or more episodes within a 12-month period—should probably be placed on suppressive therapy once the acute episode has been resolved. It is in these patients where identification of the yeasts becomes important because the nonalbicans species tend to be resistant to over-the-counter preparations. The nonalbicans species probably account for up to 20% of recurrent cases of vulvovaginal candidiasis, with *C. glabrata* responsible for 95% of the cases. Approaches to the treatment of acute recurrent vulvovaginal candidiasis are listed in Table 18-6.

## NECROTIZING INFECTION

Necrotizing fasciitis is a relatively infrequent infection that affects the subcutaneous tissue and fascia, can result in systemic

**Table 18-5**

## Gynecologic Infectious Disease

no matter how minor, can progress to a necrotizing infection without warning. Successful management of necrotizing fasciitis depends on early recognition and knowledge of the bacteria most likely involved in the infectious process.<sup>37,38</sup>

Infections such as folliculitis, furunculosis, and carbuncles of the vulva, and the infected episiotomy have the potential to evolve into necrotizing fasciitis, especially in immunocompromised patients (e.g., diabetics). In fact, any event that causes a break in the skin and allows bacteria to enter the subcutaneous fatty tissue has the potential to develop into necrotizing fasciitis. Minor infections that have the potential to develop into necrotizing fasciitis are usually those in which the area has been traumatized—by squeezing, pricking with a pin, or scratching. The patient at greatest risk for developing necrotizing fasciitis of the vulva and perineum is the diabetic, especially the insulin-independent diabetic. Individuals who do not have an impaired immune system and maintain good tissue perfusion resulting in high oxygen concentrations in the tissue are less likely to develop necrotizing fasciitis following tissue trauma.

Necrotizing fasciitis is an infection that typically begins in the subcutaneous tissue and progresses to the fascia, which results in destruction of the fatty subcutaneous tissue as well as the fascia. The skin may be spared; however, if the process remains unchecked, necrosis of the skin occurs. The hallmark of necrotizing fasciitis is the initial development of severe pain at the site of infection. Typically the patient states that the pain is severe, even when gentle pressure is applied to the area.

The bacteriology of necrotizing fasciitis of the vulva commonly involves *S. aureus*, *S. pyogenes* (group A *Streptococcus*), *Escherichia coli*, *Peptostreptococcus*, *Prevotella*, and *Bacteroides* as well as many other bacteria.<sup>38</sup> These bacteria are derived from the patient's skin, vagina, and rectum. Involvement is not unexpected, since the vulva and perineum are constantly exposed to these bacteria. In the study reported by Brook and Frazier,<sup>38</sup> the clinical signs and symptoms of necrotizing fasciitis were reviewed over a 17-year period; although they were collected from a variety of cases, the findings are applicable to necrotizing fasciitis of the vulva and perineum (Table 18-7).

**Table 18-7**  
**Clinical Findings Associated with Necrotizing Fasciitis**

Rights were not granted to include this table in electronic media.  
Please refer to the printed publication.

Brook I, Frazier EH: Clinical and microbiological features of necrotizing fasciitis. *J Clin Microbiol* 1995;33:2382–2387.

**Diagnosis and Management**

If a patient is suspected of having necrotizing fasciitis of the vulva and perineum or of any site, it is imperative that the diagnosis be established promptly and therapy initiated immediately. If the diagnosis is in question, a computed tomography (CT) scan can often facilitate in making the diagnosis. Broad-spectrum antibiotic therapy should be administered intravenously immediately, for example, clindamycin 900 mg every 8 hours, ampicillin 2 g every 6 hours, and gentamicin 5 mg/kg of body weight every 24 hours. Gentamicin should be calculated on ideal body weight for patients over 91 kg (200 lb) and should be adjusted for individuals with renal impairment. The patient should be taken to surgery immediately following establishment of the diagnosis, because if imaging studies cannot be performed immediately, surgical exploration of the infected site should not be delayed. The infected area should be thoroughly explored and all necrotic tissue removed. The excision of necrotic tissue should involve all necrotic tissue as well as adjacent tissue and continue until healthy tissue that bleeds briskly is encountered. The débridement should involve all necrotic subcutaneous tissue, fascia, muscle, and skin. Failure to remove all necrotic tissue will necessitate a return to the operating room. Hyperbaric oxygen therapy following débridement has been beneficial in some cases.

**SUMMARY**

Infections of the vulva and perineum should not be taken lightly, and the diagnosis should be established early and appropriate antibiotic therapy instituted. The bacteria most likely to be involved are *S. aureus* methicillin-sensitive (MSSA) as well as methicillin-resistant (MRSA), coagulase-negative staphylococci, *S. agalactiae* (GBS), *S. pyogenes* (GAS), other streptococci, facultative gram-negative anaerobic bacteria (e.g., *E. coli*), and obligate anaerobic bacteria originating from the vagina and rectum. The MRSA community-acquired strains have been changing their resistance patterns; some are sensitive to clindamycin, quinolones, minocycline, trimethoprim/sulfamethoxazole, and rifampin, whereas others are resistant to clindamycin and still others to the quinolones. A culture specimen from the infected site (e.g., an aspirate, tissue, or swab), should always be obtained. This is necessary in the event that the initial, empirically chosen antibiotic regime is not effective. Finally, in the event of an abscess, the area should be incised, loculations broken, and the area completely drained and thoroughly irrigated. In the presence of necrotizing fasciitis, the immediate administration of broad-spectrum antibiotics is required with thorough surgical débridement of all necrotic tissue.

## KEY POINTS

- Sexually transmitted diseases (STDs) are associated with significant social, health and economic burdens.
- Increased resistance of *Neisseria gonorrhoeae* to quinolones antibiotics has limited options for treatment of gonorrhea.
- *Chlamydia trachomatis* is the most common treatable bacterial STD in the United States.
- After a decade of decline, in 2001 rates of primary and secondary syphilis began to rise.
- More than 25% of females in the United States have been infected with genital herpes simplex virus 2.
- *Trichomonas vaginalis* infects approximately 5 million people annually in the United States.
- 500,000 to 1 million new cases of human papillomavirus (HPV)-induced genital warts occur annually in the United States.

Despite many advances in the diagnosis and treatment of STDs, the epidemic of STDs continues unabated.<sup>1–3</sup> Moreover, STDs are associated with significant social, health, and economic burdens both in the United States and worldwide.<sup>1,2,4</sup>

In the developing countries of the world, STDs (excluding HIV/AIDS) are the second leading cause of lost healthy life among women aged 15 to 44 years. The World Health Organization (WHO) estimated in 1995 that 333 million new cases of the four curable STDs occurred in the 15- to 49-year-old age group worldwide annually: gonorrhea 62.6 million, syphilis 12.2 million, chlamydia 89.1 million, and trichomoniasis 167.2 million.<sup>5</sup>

The Institute of Medicine (IOM) in their report, "The Hidden Epidemic: Confronting Sexually Transmitted Diseases," estimated that as of 1993, 12 million new cases of STDs occur annually in the United States.<sup>1</sup> As a result, the United States had the highest rates of curable STDs among countries in the developed world.<sup>1</sup> In fact, the Centers for Disease Control and Prevention (CDC) noted in 1995 that five of the ten most frequently reported infections in the United States were STDs (Table 19-1).<sup>6</sup> In its report, the IOM noted that the economic impact of this "hidden epidemic" was substantial, with an estimated total cost for a selected group of major STDs and related syndromes (excluding HIV) of \$10 billion in 1994.<sup>1</sup> This estimate did not include bacterial vaginosis and trichomoniasis and thus is an underestimate. The estimated annual cost of sexually transmitted HIV infection was nearly \$7 billion, leading to a total annual cost of STDs in the United States of \$17 billion.<sup>1</sup> In 1998, the American Social Health Association (ASHA)

estimated that 15 million new STD cases occur in the United States each year (see Table 19-1).<sup>2</sup> More recently, Weinstock et al estimated that approximately 18.9 million new STD cases occurred in the United States in 2000.<sup>3</sup>

Of particular concern is the incidence and prevalence of STDs among adolescents and young adults (15- to 24-year-olds). Berman and Hein reported that sexually active adolescents have the highest rates of STDs of any age group.<sup>7</sup> An estimated 3 million adolescents acquire an STD annually in the United States.<sup>8</sup> In 2000, of the approximately 18.9 million new cases of STD, 9.1 million (48%) occurred among persons aged 15 to 24.<sup>3</sup> The estimated economic burden of the nine million new cases of STDs that occurred among 15- to 24-year-olds in 2000 was \$6.5 billion.<sup>4</sup>

Clinicians should be aware of several important recent trends in STDs. First is expansion of the scope of STDs from the classic five venereal diseases of gonorrhea, syphilis, chancroid, lymphogranuloma venereum, and granuloma inguinale to include over 30 microorganisms. The spectrum of sexually transmitted infections (STIs) has expanded to include diseases such as vaginitis, mucopurulent cervicitis, pelvic inflammatory disease, infertility, perinatal infections, hepatitis, enteric infections, arthritis syndromes, nongonococcal urethritis, epididymitis, genital tract oncogenesis, and severe immunosuppression (e.g., AIDS).

Secondly, there has been a changing emphasis in the field of STDs. As noted by Cates, there has been a progression in focus from the traditional STDs, such as syphilis and gonorrhea, to the STIs caused by *Chlamydia trachomatis*, herpes simplex virus (HSV), HPV, and most recently to HIV infection and AIDS.<sup>9,10</sup>

Thirdly, the traditional STDs—syphilis, gonorrhea and chlamydia—were caused by bacteria. Consequently, they were relatively easily cured with antimicrobial therapy. The newer STDs tend to be of viral etiology and thus associated with incurable or fatal conditions. Examples include chronic recurrent HSV, HPV-associated genital tract cancer, and HIV and AIDS.

Fourthly, there exists an epidemiologic synergy among STDs. STDs and STIs are historically, behaviorally, and biologically related. Initially, the ulcerative STDs (e.g., syphilis, HSV, chancroid) were shown to be associated with an increased risk of acquiring and transmitting HIV. More recently, STDs associated with cervicitis and vaginal discharge (e.g., gonorrhea, chlamydia, trichomoniasis, and bacterial vaginosis) have also been implicated in increasing the risk for transmission and acquisition of HIV. Further, the immunosuppression seen with HIV infection may worsen the clinical findings of other STDs and cause them to be more difficult to treat.

Lastly, with the exception of HIV/AIDS, the burden of STDs is greater among women than men, and women are more likely

to develop serious long-term consequences of STDs and STIs. Among these are (1) infertility and ectopic pregnancy secondary to damaged fallopian tubes with *Neisseria gonorrhoeae* and *C. trachomatis*; (2) complications of pregnancy, including spontaneous abortion, stillbirth, chorioamnionitis, preterm birth, and low birth weight; (3) congenital or vertically transmitted neonatal infections; and (4) an increased risk for genital cancer with HPV.

This chapter focuses on specific STDs with emphasis on the most common and those having a substantial impact on the health of women.

## GONORRHEA

### Epidemiology, Risk Factors, and Pathogenesis

Gonorrhea, which is caused by the gram-negative diplococcus *N. gonorrhoeae*, is the second most common reported communicable disease (after chlamydia) in the United States, with over 350,000 cases reported in 2002.<sup>11</sup> Because of an assumed 50% under-reporting, it is estimated that approximately 700,000 cases of *N. gonorrhoeae* actually occurred in 2002 in the United States. Following a 74% decrease in reported cases of gonorrhea from 1975 through 1997, an 8.9% increase occurred in 1998. Since then the number of reported cases and the rate of gonorrhea have essentially plateaued.<sup>11</sup> In 2002, the reported gonorrhea rate among women (125.3 cases per 100,000) was similar to that among men (124.2 cases per 100,000). For women, the highest rates of gonorrhea have been reported in non-Hispanic black women aged 15 to 19 years (3307.7 cases per 100,000).<sup>1</sup> The CDC reported that in 2000, 60% of reported gonorrhea cases were in the age group 15 to 24 years.<sup>12</sup>

Humans are the only natural host for *N. gonorrhoeae*. Because of its predilection for columnar or pseudostratified epithelium, mucous membranes that are lined by columnar, cuboidal, or noncornified squamous epithelial cells are most susceptible to infection with *N. gonorrhoeae* in adults. Thus gonococcal infection is most commonly found in the urogenital tract.

Over the past 30 years there has been a phenomenal expansion in our understanding of the pathogenic mechanisms of the gonococcus.<sup>13</sup> Initially, Kellogg et al demonstrated differences in the virulence of *N. gonorrhoeae*, associated with specific colony

types.<sup>14</sup> Of the Kellogg colony types, only types 1 and 2 (now called P+), which contain pili, are capable of producing infection, while types 3 and 4, which do not contain pili (now called P colonies), fail to cause infection.<sup>14</sup> The pili appear to facilitate attachment of gonococci to epithelial surfaces.<sup>14</sup> Other gonococcal surface structures in addition to pili are associated with pathogenesis. These surface structures and functions are determined by proteins present in the outer membrane of the gonococcus, including porin protein (Por), opacity-associated proteins (Opa), and reduction modifiable protein (Rmp).

Additional gonococcal virulence factors include (1) lipopolysaccharides,<sup>15</sup> (2) IgA,<sup>13</sup> and (3) iron-repressible proteins that are involved in uptake of iron—an essential requirement for growth of gonococci.<sup>5</sup>

Like other infections, the initial step in gonococcal infection is adherence of *N. gonorrhoeae* to mucosal cells lining the genitourinary tract. This process of adherence is mediated by pili and other surface proteins.<sup>16</sup> This step is followed by the process of pinocytosis by which the organism is transported into epithelial cells and then into submucosal tissues.<sup>17</sup> Attachment of *N. gonorrhoeae* also results in the release of the endotoxin, gonococcal lipopolysaccharide, which damages the ciliated and nonciliated cells of the fallopian tube epithelium.<sup>15</sup>

Race and age are important determinants and risk factors for gonorrhea.<sup>11</sup> Rates of gonorrhea among non-Hispanic blacks (570 cases per 100,000) are higher than for any other racial/ethnic group in the United States.<sup>11</sup> Hook and Handsfield<sup>18</sup> reported that 77% of reported cases of gonorrhea in the United States in 1995 were among persons aged 15 to 29 years with the highest rates occurring in the 15- to 19-year-old age group. If only sexually active females are considered, the incidence of gonorrhea is twice as high in adolescents than in women aged 20 to 24 years.<sup>18</sup> Additional risk factors for gonorrhea include low socioeconomic status, early onset of sexual activity, unmarried marital status, a past history of gonorrhea, illicit drug use, and prostitution.<sup>4</sup>

Transmission of gonorrhea is almost entirely by sexual contact. The female is at greater risk of infection than the male. While it is estimated that a male having a single sexual encounter with a gonorrhea-infected female will become infected 20% to 25% of the time, the risk of transmission from male to female is estimated at 50% to 90%.<sup>19</sup> A short incubation time of 3 to 5 days occurs.

Among nonpregnant women, *N. gonorrhoeae* is an important cause of urethritis, cervicitis, and pelvic inflammatory disease (PID).<sup>19</sup> Pharyngeal gonorrhea and disseminated gonorrhea occur in men and women. Infection with *N. gonorrhoeae* in pregnancy is also a major concern. Gonococcal ophthalmia neonatorum has long been recognized as a major consequence of maternal infection. More recently, an association between maternal gonococcal infection and disseminated gonococcal infection, amniotic infection syndrome, and perinatal complications such as premature rupture of membranes (PROM), chorioamnionitis, prematurity, intrauterine growth retardation, neonatal sepsis, and postpartum endometritis has been recognized.

### Clinical Features

*N. gonorrhoeae* infects both males and females. In adults, the gonococcus attaches to nonsquamous epithelium-lined mucosal

membranes, and thus the primary involvement site is the genitourinary tract. In males, the infection is usually acute symptomatic urethritis. Female infection is often asymptomatic, and the primary site of involvement is the endocervical canal and the transition zone of the cervix. However, women with endocervical gonorrhea may be symptomatic and most commonly have a vaginal discharge, dysuria, and abnormal uterine bleeding.<sup>18</sup> Urethral colonization occurs in the majority of women with endocervical gonorrhea, and infection of the paraurethral (Skene's) glands, Bartholin's glands, and anorectum also occur.

Uncomplicated anogenital gonorrhea in women may involve the endocervix, urethra, Skene's glands, Bartholin's glands, or anus. The most commonly infected site is the endocervix. Gonococcal infection of the vagina is rare except in prepubertal and postmenopausal patients. Urethral colonization is present in 70% to 90% of women infected with *N. gonorrhoeae*.<sup>20</sup>

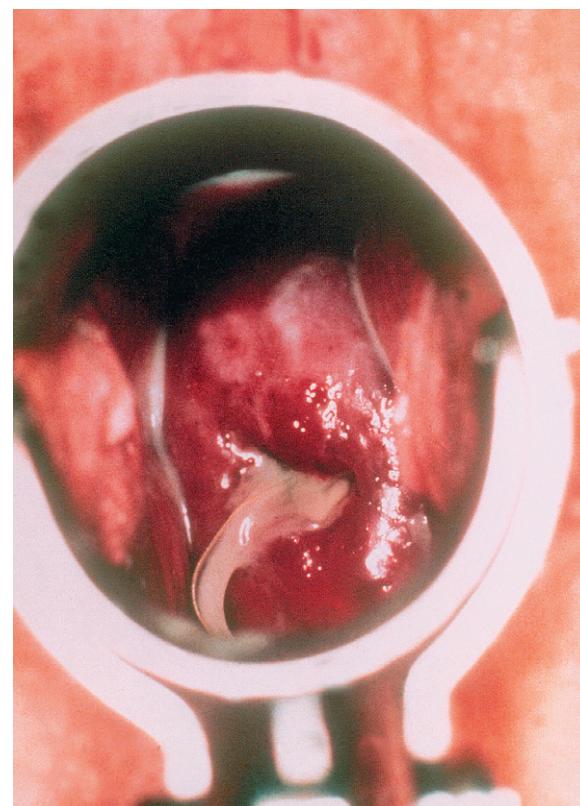

It is now recognized that although the majority of women harboring *N. gonorrhoeae* are asymptomatic, a large number of women with anogenital gonorrhea are symptomatic. Common symptoms include vaginal discharge, dysuria, intermenstrual bleeding, menorrhagia, and pelvic discomfort. The incubation period for urogenital gonorrhea in women is unclear, but those who develop symptomatic gonococcal infection do so within 10 days. In 15% to 20% of women with uncomplicated anogenital gonorrhea, upper genital tract infection (PID) occurs.<sup>21</sup> Gonococcal-associated PID tends to occur at the end of or just after menstruation.

The cervix infected with *N. gonorrhoeae* can appear healthy or reveal an inflamed cervical canal with ectopy and a mucopurulent exudate (Fig. 19-1). The area of ectopy is edematous, erythematous, and friable. In general, these signs of gonococcal cervicitis are indistinguishable from other causes of cervicitis, and thus an absolute diagnosis of gonococcal cervicitis requires confirmatory laboratory tests. Gonococcal infection of the urethra, Skene's glands, or Bartholin's glands may be associated with mucopurulent exudate that can be expressed from these structures. If routine screening for *N. gonorrhoeae* is not employed during pelvic examinations, the presence of lower genital tract complaints or signs such as abnormal bleeding, discharge, dysuria, mucopurulent endocervicitis, or pelvic discomfort should suggest that cultures be obtained to determine whether the gonococcus is present.

Non-lower-tract gonococcal disease may result from direct or contiguous spread and by bloodstream dissemination. Direct or contiguous spread occurs for PID, anorectal infection, perihepatitis (Fitz-Hugh-Curtis syndrome), conjunctivitis, and pharyngeal gonococcal infection.

Acute PID is a local complication and the most common complication of gonorrhea in women, occurring in an estimated 10% to 20% of untreated cases.<sup>21</sup> Bartholin's gland abscess is the next most frequent complication of gonococcal infection in women.

Disseminated gonococcal infection (DGI), the most common systemic complication of gonorrhea, occurs when gonococcal bacteremia produces extragenital manifestations of gonococcal infection. The prevalence of DGI among total gonorrhea cases ranges from 0.1% to 0.3%, with females predominating over males by about 4:1.<sup>22</sup> The majority of women with DGI develop symptoms either during pregnancy, especially in the third trimester, or within 7 days from the onset of menstruation.

**Figure 19-1 Gonococcal mucopurulent endocervicitis.** (Reprinted with permission from Sweet RL, Gibbs RS: Atlas of Infectious Diseases of the Female Genital Tract. Philadelphia, Lippincott Williams & Wilkins, 2004.)

Patients are considered to have proven DGI if they have positive cultures from blood, joint fluid, skin lesions, or otherwise sterile sources.<sup>2</sup> This group makes up less than 50% of DGI cases.<sup>23</sup> DGI is defined when *N. gonorrhoeae* can be cultured from the primary site in the lower genital tract or pharynx or in a sexual partner. Patients with a clinical syndrome consistent with DGI and an appropriate clinical response to treatment but in whom all culture sites are negative are considered to have possible DGI.<sup>18</sup>

Disseminated gonococcal infection manifests two stages: an early bacteremia stage and a late stage. The bacteremia stage is characterized by chills, fever, typical skin lesions, and asymmetric joint involvement. Blood cultures are positive for *N. gonorrhoeae* in half of cultures during the bacteremia stage. The bacteremia stage is associated with a dermatitis that is characterized by a variety of skin lesions due to gonococcal emboli and occurs in 50% to 75% of cases.<sup>24</sup> These lesions appear initially as small vesicles that become pustules and develop a hemorrhagic base. The center becomes necrotic. These lesions occur on any body region but are most frequently present on the volar aspects of the upper extremities, the hands, and the digits. These skin lesions resolve spontaneously without residual scarring.

Joint symptoms are frequently present during the early stage, with arthritis developing in 30% to 40% of cases.<sup>18,24</sup> Asymmetric joint involvement is the usual pattern, most often affecting the knee, elbow, wrist, ankle, and metacarpophalangeal joints. The

## Gynecologic Infectious Disease

arthritis is migratory (i.e., one joint heals as another becomes affected). In two thirds of patients, tenosynovitis is present.<sup>24</sup> The most frequent sites are the dorsal tendons of the hands, wrists, and ankles.

The late stage of disseminated gonococcal infection is characterized by frank arthritis with permanent joint damage, endocarditis, meningitis, pericarditis, osteomyelitis, and perihepatitis.<sup>18,24</sup> With arthritis, the knees, ankles, and wrist joints are the sites most commonly involved.

While the problem of gonococcal ophthalmia neonatorum has been addressed for over 100 years, the effects of gonorrhreal infection on both mother and fetus were not fully appreciated until 30 years ago. Studies have demonstrated an association between untreated maternal endocervical gonorrhea and perinatal complications, including an increased incidence of PROM, preterm delivery, chorioamnionitis, neonatal sepsis, and maternal postpartum sepsis.<sup>21-24</sup>

### Diagnosis

The laboratory diagnosis of infection with *N. gonorrhoeae* requires identification of the organism at infected sites. Methods available include Gram's stain, cultures, immunochemical detection, and molecular diagnostic techniques.

In men with urethral discharge and dysuria, the Gram stain of the urethral exudate is considered diagnostic for *N. gonorrhoeae* when gram-negative diplococci are seen within or closely associated with polymorphonuclear leukocytes. However, the majority of women with gonorrhea (pregnant and nonpregnant) are asymptomatic. Thus, the diagnosis depends on sampling of potential infected sites. The major site of primary infection in women is the endocervix. Unfortunately, microscopic examination of a gram-stained specimen from the endocervix in asymptomatic women produces a diagnosis of gonorrhea in only 60% of women compared with 95% of men.<sup>18</sup>

In women the diagnosis of *N. gonorrhoeae* infection requires isolation of the organism by culture or use of nucleic acid amplification tests (NAATs). Ideally, all sexually active women should be screened at every opportunity (i.e., annual routine pelvic examination, any visit for a gynecologic complaint). Obviously, this would be a major logistic and economic burden, especially in patient populations with low rates (<1%) of gonorrhea. At a minimum, certain at-risk patient groups should be routinely screened. These include partners of men with gonorrhea or urethritis, women with symptoms and signs referred to the lower genital tract, patients with known other STDs, patients with multiple sexual partners, and patients with PID.

Clinical isolation is best performed using selective media for *N. gonorrhoeae*, such as Thayer-Martin medium containing the antibiotics that inhibit the growth of contaminating organisms present in the same body sites as the gonococcus. Proper collection, handling, and processing of culture specimens are crucial to obtaining accurate results. *N. gonorrhoeae* does not tolerate drying and thus requires immediate inoculation on an appropriate medium and placement in an incubator. When culture facilities are not readily available, a holding or transport medium should be used.

The diagnosis of *N. gonorrhoeae* infection is made by identification of the organism with a typical growth on selective media, a positive oxidase reaction, and a gram-negative diplococcal

morphology on gram staining of the isolated colonies. Fermentation reactions may be also performed. They take advantage of the ability of the gonococcus to ferment glucose but not sucrose or maltose.

Reliable nonculture assays for detection of gonorrhea have recently become available and have gained increasing acceptance.<sup>18</sup> Hook and Handsfield suggested that utilization of these new nonculture assays will continue to increase owing to their satisfactory performance and extensive promotion by manufacturers and because specimens used by those assays for gonorrhea can also often be used to test for *C. trachomatis*.<sup>18</sup> The first widely accepted technique was the nonamplified DNA probe test (e.g., Gen-Probe PACE 2). Currently nonamplified DNA probes are the most commonly used nonculture method for diagnosis of gonorrhea in the United States.<sup>13</sup> Nonamplified DNA probes have sensitivity ranging from 89% to 97% and specificity of 99%. Thus, they compare favorably to culture with selective media.

More recently, NAATs have been introduced for detection of *N. gonorrhoeae*. These techniques include ligase chain reaction (LCR), polymerase chain reaction (PCR), and transcription-mediated amplification (TMA). NAATs have excellent sensitivity and specificity.<sup>25</sup>

### Treatment

The choice of antimicrobial agents for the treatment of gonococcal infection is largely dependent on in vitro resistance patterns to *N. gonorrhoeae*. Additional factors that influence the choice of antimicrobial agents include maximizing compliance with single-dose (observed) therapy and the probability that patients infected with *N. gonorrhoeae* are coinfected with other STDs (especially *C. trachomatis*).<sup>18</sup>

While most *N. gonorrhoeae* is sensitive to a large number of antimicrobial agents including penicillins, tetracyclines, macrolides, cephalosporins, erythromycin, aminoglycosides, and quinolones, increasing resistant strains have appeared.<sup>26</sup> These resistant strains include penicillinase-producing *N. gonorrhoeae* (PPNG), as well as high-level chromosomal resistance to penicillin; plasmid-mediated resistance to tetracycline; chromosomally mediated resistance to cephalosporins, tetracycline, spectinomycin, and aminoglycosides; and most recently fluoroquinolone resistance. The prevalence of fluoroquinolone-resistant *N. gonorrhoeae* in Asian countries is high (China 86.9%, Japan 64%, and the Philippines 54.3%).<sup>27</sup> Of concern is the rapid increase in fluoroquinolone-resistant strains in the United States, with 12% in Hawaii, 19% in California, and 14% in Massachusetts in 2003.<sup>28</sup> The recommended treatment regimens for uncomplicated gonorrhea of cervix and urethra are listed in Table 19-2.

Among women with gonorrhea, 10% to 30% are coinfected with chlamydia.<sup>18</sup> Thus, CDC recommends that women treated for gonorrhea should also be presumptively treated for chlamydial infection. Azithromycin 1 g orally in a single dose or doxycycline 100 mg orally twice a day for 7 days are the preferred regimens in nonpregnant women, while in pregnancy an erythromycin regimen or amoxicillin should be used (see chlamydia treatment).

Pregnant or lactating women should not be treated with quinolones.<sup>26</sup> In pregnant women *N. gonorrhoeae* should be

**Table 19-2****CDC-recommended Treatment of Uncomplicated Gonococcal Infections of the Cervix, Urethra, and Rectum in Adults, 2002****Recommended regimen**

Cefixime 400mg orally in a single dose  
or  
Ceftriaxone 125 mg IM in a single dose  
or  
Ciprofloxacin 500 mg orally in a single dose  
or  
Ofloxacin 400 mg orally in a single dose  
Plus  
Azithromycin 1 g orally in a single dose  
or  
Doxycycline 100 mg orally twice a day for 7 days

**Alternative regimens**

1. Spectinomycin 2g IM in a single dose
2. Single dose of cephalosporins such as ceftizoxime 500 mg IM, cefotaxime 500 mg IM, cefotetan 1 g IM, and cefoxitin 2 g IM with probenecid 1 g orally
3. Single dose of other quinolones such as enoxacin 400 mg orally, lomefloxacin 400 mg orally, and norfloxacin 800 mg orally

treated with a recommended or alternative cephalosporin.<sup>26</sup> When cephalosporins can not be tolerated, spectinomycin 2 g should be administered intramuscularly (IM). Either erythromycin or amoxicillin is the recommended treatment for presumptive chlamydial infection in pregnancy.

Test of cure is no longer recommended for individuals with uncomplicated gonorrhea who received any CDC-recommended regimen for uncomplicated gonorrhea.<sup>29</sup> Persons with persistent

symptoms should be retested, and any *N. gonorrhoeae* recovered should be tested for antimicrobial susceptibility. Because patients infected with gonorrhea are at high risk for reinfection, repeat screening 1 to 2 months after treatment is appropriate.

In addition, sexual partners of patients with gonorrhea should be examined, tested, and treated (prior to culture results). Treatment should be with one of the CDC regimens for uncomplicated gonorrhea, preferably with treatment for coexistent chlamydial infection.

Ceftriaxone is the drug of choice for DGI. Patients allergic to penicillins and cephalosporins can be treated with spectinomycin 2 g IM every 12 hours. The current CDC recommendations and alternative drugs are listed in Table 19-3.

## **CHLAMYDIA**

*Chlamydia trachomatis* is the most common bacterial sexually transmitted organism in the United States, with an estimated 4 million new cases occurring each year at an estimated cost of \$2.4 billion.<sup>30</sup> In addition, chlamydial infection is the most commonly reported infectious disease in the United States, and in 2002 834,555 cases of genital chlamydial infection were reported to the CDC.<sup>31</sup> Washington et al estimated that over three fourths of the health care costs associated with chlamydial infection are for women.<sup>32</sup> Of most concern is the recognition that the health consequences of chlamydial infection are greatest for women. This is primarily due to the increased risk of women infected with *C. trachomatis* for PID and its sequelae of tubal factor infertility, ectopic pregnancy, and chronic pelvic pain.<sup>30</sup> Additionally, pregnant women infected with *C. trachomatis* but untreated are at increased risk for adverse pregnancy outcome including preterm delivery, PROM, and low-birth-weight infants.<sup>31</sup> Infants born to mothers with untreated chlamydial infection of the cervix are at increased risk for neonatal conjunctivitis and pneumonia.<sup>32</sup> Moreover, women infected with *C. trachomatis* appear to be at increased risk for acquisition of HIV infection.<sup>33</sup>

During the past 20 years, the spectrum of diseases caused by *C. trachomatis* has expanded dramatically, and an increasing number of infections have been attributed to *C. trachomatis* (Table 19-4).<sup>30</sup>

*C. trachomatis* is a high-prevalence agent associated with a wide variety of complications. Unfortunately, the majority (50% to 70%) of chlamydial infections of the lower genital tract in women are asymptomatic and can progress to the upper genital tract to produce serious complications such as PID, tubal factor infertility, and ectopic pregnancy.<sup>30</sup> Other long-term consequences of chlamydial infection include neonatal conjunctivitis and chlamydial pneumonia of the newborn; and association with fetal wastage, PROM, preterm labor and delivery, and post-partum endometritis also has been suggested.

There are four recognized species within the genus *Chlamydia*: *C. trachomatis*, *C. psittaci*, *C. pneumoniae*, and *C. pecorum*. *C. psittaci* is the causative agent of psittacosis, a common pathogen in avian species and lower mammals. *C. pneumoniae* (TWAR) is a recently identified species that causes acute respiratory tract infection.<sup>34</sup> The clinical syndromes associated with *C. pneumoniae* infection include bronchitis, pneumonia, otitis, pharyngitis, and sinusitis.<sup>34</sup> *C. pneumoniae*

**Table 19-3****CDC-recommended Treatment for Disseminated Gonococcal Infection, 2002****Recommended initial regimen**

Ceftriaxone 1 g IM or IV every 24 hours

**Alternative initial regimens**

Cefotaxime 1 g IV every 8 hours

or

Ceftizoxime 1 g IV every 8 hours

or

For persons allergic to β-lactam drugs

Ciprofloxacin 500 mg IV every 12 hours

or

Ofloxacin 400 mg IV every 12 hours

or

Spectinomycin 2 g IM every 12 hours

All regimens should be continued for 24 to 48 hours after improvement begins, at which time therapy may be switched to one of the following regimens to complete a full week of therapy:

Cefixime 400 mg orally twice a day

or

Ciprofloxacin 500 mg orally twice a day\*

or

Ofloxacin 400 mg orally twice a day\*

\*Ciprofloxacin and ofloxacin are contraindicated in pregnant or lactating women.

Table 19-4 Clinical Spectrum of <i>Chlamydia trachomatis</i> Infection

\*Relationship not firmly established.

may play a role in coronary artery disease.<sup>35</sup> *C. pecorum* is a recently recognized species that causes disease in the reproductive tract of sheep, cattle, and swine.<sup>36</sup>

Although all chlamydiae share a common genus-specific antigen (chlamydial lipopolysaccharide), *C. trachomatis* may be further differentiated on a serologic basis. There are currently 15 recognized serotypes (Table 19-5). The *C. trachomatis* serotypes are responsible for three major groups of infections. Three of these serotypes (L1, L2, L3) represent the agents causing lymphogranuloma venereum. Serotypes A, B, Ba, and C are the agents responsible for endemic blinding trachoma. The remaining serotypes of *C. trachomatis* (D, E, F, G, H, I, J, K) are the oculogenital and sexually transmitted strains that cause inclusion conjunctivitis, newborn pneumonia, urethritis, cervicitis, epididymitis, salpingitis, acute urethral syndrome, and perinatal infections.

The chlamydial organism exists in two forms: (1) the elementary body, which is the infectious particle and capable of entering uninfected cells; and (2) the reticulate body, which multiplies by binary fission within the host cell to produce the inclusions that are identified in properly stained cells.<sup>37</sup> The reticulate bodies condense and reorganize to form new elementary bodies, and at the end of the 48- to 72-hour growth cycles, the cell bursts with release of elementary bodies.

*C. trachomatis* is an obligate intracellular bacterium.<sup>37</sup> It is an extremely well-adapted human parasite that depends on the host cell for nutrients and energy.<sup>37</sup> Although chlamydiae are

capable of limited metabolic activities, they do not possess an enzyme system capable of generating ATP and have been considered energy parasites.

### Epidemiology, Risk Factors, and Pathogenesis

For the oculogenital serotypes, the primary method of transmission is sexual. Schachter has stated that *C. trachomatis* is probably the most common sexually transmitted bacterial pathogen in Western industrialized society.<sup>37</sup> *C. trachomatis* appears to be more difficult to transmit than *N. gonorrhoeae*.<sup>38</sup> Lycke et al studied partners of men with chlamydial or gonococcal urethritis and noted that female partners were infected 45% and 80% of the time, respectively.<sup>38</sup> Male-to-female and female-to-male transmission of chlamydia are equally efficient.<sup>38</sup>

Chlamydiae cause between one third and one half of nongonococcal urethritis in men.<sup>39</sup> Double infections with gonococci are common in both men and women, and between 20% and 40% of men and between 30% and 50% of women with lower genital gonorrhreal infection have concomitant chlamydial infection.<sup>38</sup> Epididymitis is an important complication of chlamydial infection of the male urethra, and *C. trachomatis* is the major cause of epididymitis in men under the age of 35. Rectal and pharyngeal infections also occur in both sexes.<sup>40</sup> Reiter's syndrome is a systemic clinical syndrome associated with chlamydial infection in men.

A number of clinical conditions in the female have been attributed to *C. trachomatis* (see Table 19-4).<sup>40</sup> These include mucopurulent endocervicitis, endometritis, salpingitis, acute urethral syndrome, urethritis, and perinatal infections. The anatomic site within the female genital tract most commonly infected with *C. trachomatis* is the cervix. No specific symptoms are associated with the cervical infections, and so many of the chlamydial infections of the cervix are clinically inapparent. This is unfortunate because mucopurulent cervicitis (the female equivalent of nongonococcal urethritis) caused by *C. trachomatis* predisposes to acute PID in nonpregnant women and to maternal and infant infections during pregnancy. In addition,

Table 19-5  
Taxonomy and Association of Chlamydia with Human Disease

Species	Serotype	Disease
<i>Chlamydia psittaci</i>	Many	Psittacosis
<i>Chlamydia pneumoniae</i>	TWAR	Acute upper and lower respiratory tract infections

	D, E, F, G, H, I, J, K	Inclusion conjunctivitis, nongonococcal urethritis, proctitis, epididymitis, cervicitis, endometritis, salpingitis, pneumonia of newborn
	L1, L2, L3	Lymphogranuloma venereum

\*Relationship not firmly established.

asymptomatic chlamydial cervicitis is a major reservoir for sexual transmission of *C. trachomatis*.

In 1996 chlamydia became a notifiable disease, and by 2002 over 834,000 cases of genital chlamydia infection were reported to the CDC (296.55 cases per 100,000) making chlamydia the most frequently reported infection in the United States.<sup>31</sup> The annual incidence of new chlamydia infections in the United States is estimated to be over 4 million cases.<sup>37</sup> Of the reported U.S. cases, over 75% were in women.<sup>31</sup> These reported rates for women are an overestimate of the female-to-male ratio of chlamydial infection because women are more likely to be screened. Chlamydial infections are present through all strata of society, but the highest rates occur in the young and the poor. As noted by Stamm, in areas where intensive chlamydia control programs have been instituted, dramatic decreases in the prevalence of chlamydia have occurred.<sup>40</sup> Such has been reported in Sweden where the number of cases of chlamydial infection decreased greater than 50% from 1987 to 1994<sup>29</sup> and in selected areas of the United States (e.g., Pacific Northwest and Wisconsin) where similar results have been reported.<sup>39</sup>

While 3% to 5% of sexually active women in the United States carry chlamydia in their cervix, high-risk populations can be readily identified. A number of patient characteristics have been found to be predictors of chlamydial genital infections.<sup>40-42</sup> These include young age (<25 years), socioeconomic status, nonwhite race, number of sexual partners, new partner, douching, and use of nonbarrier methods of contraception.

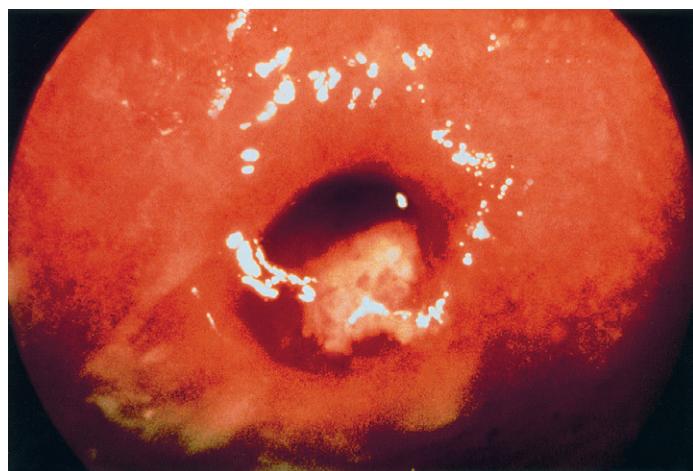

The majority of women with chlamydial disease remain untreated because their infection is either asymptomatic or relatively inapparent. In general, one half to two thirds of chlamydial infections of the cervix are asymptomatic.<sup>40,43</sup> Untreated, the infection can persist for several years and subject those infected to the risks of spread of *C. trachomatis* to the upper genital tract, with subsequent infertility and ectopic pregnancy.<sup>44</sup>

Over 1 million women acquire PID each year in the United States. Both medically and economically PID is the most important genital disease caused by *C. trachomatis*. Studies in the United States suggest that 20% to 50% of these cases are associated with *C. trachomatis*.<sup>45</sup> Thus, 200,000 to 500,000 cases of chlamydia-associated PID occur annually in the United States and are estimated to require 50,000 to 100,000 hospitalizations each year. In addition, these women are exposed to a significantly increased risk for infertility and ectopic pregnancy.

The infant born to a woman with a chlamydial infection of the cervix is at 60% to 70% risk of acquiring the infection via vertical transmission during passage through the birth canal.<sup>45</sup> Approximately 25% to 50% of exposed infants will develop chlamydial conjunctivitis in the first 2 weeks of life, and 10% to 20% of the infants will develop chlamydial pneumonia within 3 to 4 months of birth.

### Clinical Features

The majority (up to 85% to 90%) of chlamydial infections are asymptomatic.<sup>40,45</sup> Although the majority of infected women are asymptomatic, an estimated one third will have signs of infection at the time of examination.<sup>40</sup> In women, the most common findings on examination are the presence of mucopurulent endocervical discharge and hypertrophic cervical ectopy

**Figure 19-2 Chlamydial mucopurulent endocervicitis.** (Reprinted with permission from Sweet RL, Gibbs RS: Atlas of Infectious Diseases of the Female Genital Tract. Philadelphia, Lippincott Williams & Wilkins, 2004.)

(Fig. 19-2). A broad spectrum of clinical presentations has been described for chlamydial infection in women. These include Bartholinitis, endocervicitis, endometritis, PID, perihepatitis, acute urethral syndrome, urethritis, and reactive arthritis (Reiter's syndrome).<sup>40,45</sup>

### Endocervicitis

The anatomic site within the female genital tract most commonly infected with *C. trachomatis* is the cervix. *C. trachomatis* is a major cause of mucopurulent cervicitis (MPC). The infected cervix may range from clinically normal to a severely eroded cervix with a hypertrophic cervical erosion and a mucopurulent endocervical discharge. Hypertrophic cervicitis is the term applied to the presence of cervical ectopy that is edematous, congested, and friable.

A diagnosis of mucopurulent cervicitis is suggested by demonstrating (1) yellow or green mucopus on a swab of endocervical secretions ("positive swab test"); (2) more than 10 PMNs per oil immersion field of a Gram stain of the endocervix; or (3) friability, erythema, or edema within a zone of cervical ectopy.<sup>40</sup>

The acute urethral syndrome, which is defined as acute dysuria and frequent urination in women with pyuria but whose voided urine is sterile or contains less than 10 microorganisms/mL<sup>32</sup> is a common and perplexing problem for the clinician. Based on studies in STD clinics of cultures for *C. trachomatis* from the cervix and urethra, 25% of positive women harbor the organism only in their urethra<sup>46</sup>; an additional 50% harbor the organism in both cervix and urethra. Stamm and coworkers identified a causative role for *C. trachomatis* in up to 25% of women with the acute urethral syndrome.<sup>47</sup> Several findings on history are suggestive of *C. trachomatis* as the causative agent in women with symptoms of acute urethral syndrome.<sup>47</sup> These include a recent change in sexual partner, the use of oral contraceptives, and a longer duration of presenting symptoms—approximately 7 to 10 days—as compared with 4 days for women with acute cystitis or bacteriuria. In addition, women with chlamydia are less likely to give a history of recurrent urinary tract infections,

## Gynecologic Infectious Disease

in contradistinction to women with acute cystitis or bladder bacteriuria.

Multiple investigations have demonstrated that endometritis in nonpregnant women is another manifestation of genital chlamydial infection.<sup>48</sup> Histologic endometritis based on the presence of plasma cells and infiltration of the superficial epithelium by PMN leukocytes has been detected in nearly one half of patients with chlamydial mucopurulent cervicitis.<sup>40</sup> The presence of histologic endometritis has been associated with both cultural and immunohistologic detection of *C. trachomatis*.<sup>48</sup> In addition, histologic endometritis can be detected in nearly all patients with chlamydial salpingitis.<sup>40</sup>

The most serious complication of chlamydial infection in women is acute PID. As reviewed by Cates et al<sup>49</sup> and Sweet,<sup>50</sup> microbiologic and serologic studies have firmly established *C. trachomatis* as an important sexually transmitted organism that leads to acute PID.

Initial evidence that *C. trachomatis* is an important etiologic agent in acute salpingitis came from European investigations (predominantly Scandinavian).<sup>45</sup> Of major importance was the report by Mardh et al of a 30% isolation of *C. trachomatis* from the fallopian tubes of women with acute salpingitis in whom isolation attempts were performed on material aspirated from the involved fallopian tubes visualized by laparoscopy.<sup>51</sup>

In the mid 1980s studies in the United States that utilized appropriate methodology for obtaining chlamydial specimens (i.e., tubal biopsy, tubal aspirate, swab of endosalpinx, endometrial biopsy, with or without protected endometrial aspirate) confirmed that *C. trachomatis* is a major etiologic agent for acute PID in the United States.<sup>52-54</sup> Currently it is estimated that *C. trachomatis* is responsible for 20% to 40% of clinically apparent acute PID in the United States.<sup>30,32,50</sup>

Cates and Wasserheit have estimated that clinically apparent PID (symptomatic or visually confirmed) accounts for less than half of the total cases of PID.<sup>30</sup> The remaining cases are due to unrecognized ("silent" or "atypical") PID. Thus, chronic, subacute, or latent upper genital tract infection is present in a large number of women.<sup>55</sup> Neither the magnitude of nor an accepted definition of these unrecognized infections has been established. Unfortunately, unrecognized PID appears to be as likely as recognized PID to result in progressive scarring of the fallopian tubes, resulting in tubal factor infertility and ectopic pregnancy.<sup>56</sup> Further support for the role of *C. trachomatis* in the etiology and pathogenesis of acute PID arises from a large number of studies demonstrating a statistically significant association for tubal factor infertility and ectopic pregnancy with previous systemic chlamydial infection identified by the presence of antibody against *C. trachomatis*.<sup>45</sup>

Acute perihepatitis (Fitz-Hugh-Curtis syndrome) is a localized fibrinous inflammation affecting the anterior surface of the liver and the adjacent parietal peritoneum. Most commonly, this entity is associated with acute PID. However, the symptoms of PID are often moderate or even absent in this syndrome. The clinical picture is often characterized by an acute onset of severe right upper quadrant abdominal pain resembling that of acute cholecystitis. Several investigations have demonstrated a putative role for *C. trachomatis* in the Fitz-Hugh-Curtis syndrome.<sup>57,58</sup>

Infection with *C. trachomatis* in pregnant women is a major concern. The prevalence of chlamydial infection of the cervix in

pregnant women has been reported to range from 2% to 37%, with the general estimate for the United States being 5%.<sup>45</sup> In general, the higher prevalence rates occur in studies conducted among indigent patients in urban inner city areas and among adolescents.<sup>52</sup> While it is well documented that infants born through an infected birth canal are likely to become infected with *C. trachomatis* and develop inclusion conjunctivitis or pneumonia, the effect of maternal chlamydial infection on pregnancy outcome and perinatal complications such as preterm labor and delivery, PROM, and postpartum endometritis has also been demonstrated.

An association between *C. trachomatis* and postpartum infection was initially described in the ophthalmology literature.<sup>53,54</sup> Subsequently in a prospective investigation, Wager et al from Seattle suggested that pregnant women in whom *C. trachomatis* was recovered at their initial prenatal visit were at significant increased risk for developing late-onset endometritis following a vaginal delivery.<sup>59</sup> Subsequent studies have both confirmed<sup>60</sup> and not confirmed<sup>61</sup> a putative role for *C. trachomatis* in postpartum endometritis.

Several studies have demonstrated that patients with chlamydial cervicitis who undergo pregnancy termination are at high risk for postabortion endometritis.<sup>62</sup> Approximately 10% to 35% of women who have cervical *C. trachomatis* at the time of elective abortion develop postabortal pelvic infection compared with 2% to 10% of chlamydia negatives.

### Diagnosis

Until recently, the "gold standard" for the diagnosis of *C. trachomatis* was cell culture. However, methodologic difficulties, including cold-chain transport of specimens, delay in obtaining results (7 days), expense, need for substantial technical expertise, and relative insensitivity, led to the development of non-culture based testing for *C. trachomatis*.<sup>45</sup> Antigen and nucleic acid detection methods were introduced during the 1980s into clinical practice for diagnosing genital chlamydia infection and rapidly became the most widely available diagnostic tests for detection of *C. trachomatis*. More recently, nucleic acid amplification technology was introduced into clinical practice for detection of *C. trachomatis*.<sup>45</sup>

Because chlamydiae are obligatory intracellular parasites, culture cannot be performed on artificial media but requires a susceptible tissue culture cell line. Culture has the advantage that it preserves organisms for further studies including antimicrobial susceptibility testing and genotyping. Moreover, because it detects only viable chlamydial elementary bodies and is unlikely to be contaminated, culture remains the standard for medicolegal matters such as sexual abuse in adults or children.

Nonculture, non-nucleic acid amplification testing is based on direct visualization of chlamydia by staining with fluorescein-labeled specific antibodies (direct immunofluorescence; DFA), immunohistochemical detection of antigen (enzyme-linked immunoassay [EIA] and rapid tests), and detection of hybridization to a DNA probe.<sup>63</sup> The advantages of these nonculture, non-nucleic acid amplification techniques include (1) laboratories lacking the expertise or facilities to perform culture can make these tests widely available, (2) specimen transport is less rigorous, and (3) the technology is standardized.<sup>63</sup> Multiple investigations have compared these tests favorably to culture.<sup>63</sup>

As a result, most laboratories in North America and Western Europe use antigen detection tests (DFA and EIA) or nucleic acid hybridization tests (DNA probe).<sup>63</sup>

However, these tests have reduced sensitivities and specificities compared with culture and even more so when compared with NAATs.<sup>63</sup> In addition, use of nonculture, non-nucleic acid amplification techniques in populations with a low prevalence of infection is problematic as the proportion of false positives will rise as the prevalence of infection decreases.

In general, direct fluorescent monoclonal antibody staining in the hands of an experienced technician has sensitivity of 80% to 85% and specificity greater than 99% compared with cell culture.<sup>40,63</sup> The EIA method has a sensitivity that is generally in the range of 60% to 80% compared with culture.<sup>63</sup> Its specificity, with use of antibody-blocking reagents is greater than 99%.<sup>63</sup> Rapid, office-based direct EIA kits have been developed for detection of *C. trachomatis*. The results are read visually, usually in about 30 minutes. In general, the rapid tests have proved to be less sensitive and specific than laboratory-performed EIAs or the PACE 2 DNA probe.<sup>63</sup>

DNA probes are commercially available for detection of *C. trachomatis*. This DNA probe uses the technique of nucleic acid hybridization to identify *C. trachomatis* DNA directly from urogenital swab specimens.

An important advantage of the DNA probe is that it can be used in conjunction with a probe for detection of *N. gonorrhoeae* as a single-swab specimen.<sup>63</sup> In addition, DNA probe does not require cold-chain transportation or that specimens remain stable in storage; minimal technical expertise is required, and testing procedures can be automated, leading to decreased costs. Black noted that the DNA probe is probably the most commonly used test for detecting *C. trachomatis* in public health laboratories in the United States.<sup>63</sup> However, DNA probe is less sensitive than NAATs, and CDC recommends that positive results in a low prevalence population be confirmed.<sup>52</sup>

The most important recent advance in the diagnosis of chlamydial infections of the genital tract has been development of tests utilizing NAATs.<sup>40,63</sup> Nucleic acid amplification testing is extremely sensitive (detects as little as a single gene copy) and highly specific.<sup>63</sup> As a result, these tests can be utilized for non-invasive (urine or vaginal swab) specimen procurement to screen asymptomatic men and women for chlamydial infection.<sup>40,63</sup> The two most widely used nucleic acid amplification tests are PCR and LCR, which target nucleotide sequences on the plasmid of *C. trachomatis*, which are present in multiple copies within each elementary body. A third methodology, transcription-mediated amplification (TMA) is now available; this test amplifies chlamydial ribosomal RNA. The lower limit of detection for these tests is in the range of 1 to 10 elementary bodies (Ebs). In comparison, EIA requires 10,000 Ebs, DNA probe 1000 Ebs, and culture 10 to 100 Ebs. Thus NAATs are the most sensitive.

Nucleic acid amplification technologies detect DNA or RNA targets and do not require the presence of viable or intact organisms for a positive test.<sup>63</sup> This has major implications when considering "test of cure." It has been suggested that a culture-negative, nucleic acid-positive state following appropriate treatment lasts up to 3 weeks after which both culture and NAAT will be negative.

**Table 19-6**  
**CDC-recommended Treatment for Chlamydial Infection of the Lower Genital Tract, 2002**

**Recommended regimen**

Azithromycin 1 g orally in a single dose  
or  
Doxycycline 100 mg orally twice a day for 7 days

**Alternative regimens**

Erythromycin base 500 mg orally four times a day for 7 days  
or  
Erythromycin ethylsuccinate 800 mg orally four times a day for 7 days  
or  
Ofloxacin 300 mg orally twice a day for 7 days

**Treatment**

CDC-recommended treatment for chlamydial infection of the lower genital tract in nonpregnant patients is provided in Table 19-6.<sup>64</sup> Either doxycycline 100 mg orally twice a day for 7 days or azithromycin 1 g orally as a single dose are the suggested treatments of choice. The fluoroquinolones, ofloxacin and levofloxacin, and erythromycin base or erythromycin ethylsuccinate are alternative regimens.

An antichlamydial agent, usually doxycycline or clindamycin in the parenteral regimens and doxycycline or ofloxacin in the oral regimens,<sup>64</sup> is part of a combination therapy approach to the treatment of acute PID.

CDC recommendations for the treatment of chlamydial genital tract infection during pregnancy is provided in Table 19-7.<sup>64</sup> Since doxycycline and fluoroquinolones are contraindicated for pregnant women, erythromycin base and amoxicillin are the recommended regimens for treatment of chlamydial infection during pregnancy. Crombleholme et al were the first group to demonstrate the efficacy of amoxicillin in preventing vertical transmission of *C. trachomatis*.<sup>65</sup> In addition amoxicillin was well tolerated. Subsequent randomized, prospective trials comparing amoxicillin and erythromycin for the treatment of chlamydial infection in pregnancy demonstrated treatment success in 85% to 99% of amoxicillin-treated patients compared with 72% to 88% of erythromycin-treated cases. At the time

**Table 19-7**  
**CDC-recommended Treatment of Chlamydial Genital Tract Infection During Pregnancy, 2002**

**Recommended regimen for pregnant women**

Erythromycin base 500 mg orally four times a day for 7 days  
or  
Amoxicillin 500 mg orally three times a day for 7 days

**Alternative regimens for pregnant women**

Erythromycin base 250 mg orally four times a day for 14 days  
or  
Erythromycin ethylsuccinate 400 mg orally four times a day for 14 days  
or  
Azithromycin 1 g orally in a single dose

## Gynecologic Infectious Disease

when the current CDC guidelines for treatment of chlamydial infection were published, the safety and efficacy of azithromycin in pregnant and lactating women had not been established.<sup>48</sup> Thus, azithromycin was suggested as an alternative regimen for pregnant women.<sup>48</sup> Other alternatives include erythromycin ethylsuccinate and the option of reducing the dose of erythromycin base or ethylsuccinate by half but doubling the length of therapy for patients not able to tolerate the larger dose of erythromycin.<sup>48</sup> Erythromycin estolate is contraindicated in pregnancy because it is associated with drug-induced hepatotoxicity.<sup>48</sup>

### SYPHILIS

Syphilis is a chronic systemic infectious process caused by the spirochete *Treponema pallidum*. In the late 1980s syphilis reemerged in epidemic form in the United States with significant increases in the incidences of primary and secondary syphilis and especially of syphilis in pregnancy and of congenital syphilis.<sup>66,67</sup> Starting in 1991 syphilis rates sharply declined in the United States.<sup>68</sup> However, in 2001, the number of reported cases of syphilis began to increase again.<sup>69</sup>

That syphilis in pregnant women caused infection of the fetus, with resultant stillbirths, premature births, congenital abnormalities, and active disease at birth has been known for several centuries. Because of this significant morbidity, great emphasis has been placed on routine screening of all pregnant women for the presence of syphilis.

#### Epidemiology, Risk Factors, and Pathogenesis

Acquisition, with the exception of congenital syphilis, is generally through sexual contact. *T. pallidum* enters the body through breaks in mucosal surfaces or abraded areas of the skin. Subsequently, the chancre (the primary lesion) appears at the site of entry of the spirochetes. The chancre, if untreated, resolves within 3 to 6 weeks and is followed by a secondary stage. Secondary syphilis is a systemic disease with dermatologic manifestations, lymphadenopathy, and spirochetemia and lasts 2 to 6 weeks. This stage is also self-limiting, and with resolution of the secondary stage, the patient enters the latent phase in which there are no clinical manifestations of disease. Individuals with primary, secondary, or early latent (up to 1 year) syphilis have replicating treponemal organisms and are capable of transmitting syphilis to susceptible hosts. Without therapy, approximately one third of patients develop tertiary syphilis, with progressive damage to the central nervous system (CNS), cardiovascular system, musculoskeletal system, or other parenchyma.

The incidence of primary and secondary syphilis (best indicator of incidence trends) peaked in 1947 at 76 cases per 100,000 population.<sup>70</sup> Following the introduction of penicillin into clinical practice, the incidence of primary and secondary syphilis fell dramatically, reaching a nadir of 4 cases per 100,000 by the late 1950s. Beginning in 1959 this trend reversed with a 3-fold increased incidence by 1965. From 1965 through 1982 there was steady but slow increase in the incidence of reported cases of primary and secondary syphilis that peaked in 1982 at 14.6 cases per 100,000 persons. Much of this increase was due to increased rates among homosexual and bisexual men.<sup>71</sup> From

1982 until 1985 there was a 22% decrease in reported cases of primary and secondary syphilis. In large part this decrease occurred among white homosexual and bisexual men<sup>67</sup> probably as a result of changes in sexual behavior as a result of the AIDS epidemic.

Commencing in 1985 the United States experienced the most recent epidemic of syphilis.<sup>68</sup> From 1985 to 1990 the incidence of primary and secondary syphilis rose sharply, reaching a peak in 1990 of 23.5 cases and 17.3 cases per 100,000 in men and women, respectively.<sup>69,70</sup> Much of the increase occurred among African American men and women. This increased spread of syphilis has been linked to increased use of illicit drugs, especially "crack cocaine," and high-risk sexual behavior associated with drug use. In 1991 the rates of primary and secondary syphilis again fell dramatically.

During 2002, a total of 6862 primary and secondary syphilis cases were reported (2.4 cases per 100,000 population), an increase from the 6103 cases reported in 2001.<sup>72</sup> While the rate in men increased by 27%, in women it decreased by 21%.<sup>72</sup> A total of 412 cases of congenital syphilis were reported in 2002 (10.2 per 100,000 live births). This is a sharp decline from the peak of 107.3 per 100,000 in 1991. This decline is related to the reduction in the rate of primary and secondary syphilis among women over that period of time.

#### Clinical Features

The probability of acquiring syphilis from an infectious partner during a sexual encounter is approximately 50%. Following exposure to syphilis, there is an incubation period ranging from 10 to 90 days before the primary lesion, the chancre, appears at the point of entry. The chancre is a painless, ulcerated lesion with a raised border and an indurated base (Fig. 19-3). Most commonly, the "hard" chancre of syphilis appears in the genital area. In men, the lesion is easily apparent, and syphilis is often diagnosed in its primary stage in men. Although chancres on the female external genitalia are easily recognized, more commonly the lesion is on the cervix or in the vagina and not recognized. Thus, the chancre often escapes detection in women, and it is unusual to diagnose the primary stage of syphilis in females. Usually only a single chancre is present, but multiple chancres occur in up to 30% of cases.<sup>73</sup> Painless inguinal lymphadenopathy is frequently present. The primary chancre, even without treatment, heals spontaneously in 3 to 6 weeks.

Following resolution of the primary stage, the patient enters the secondary or spirochetemia (bacteremia) stage. Syphilis always disseminates. Thus, any organ can potentially be infected especially the CNS. While the secondary stage of syphilis is characterized by involvement of all major organ systems by *T. pallidum*, it presents most commonly with skin and mucous membrane lesions. These clinical manifestations of secondary syphilis include a generalized maculopapular rash that begins on the trunk and proximal extremities and spreads to the entire body especially the palms and soles; there are mucous patches, condyloma latum, and generalized lymphadenopathy.

During the secondary stage of syphilis, the CNS is invaded by spirochetes in 40% of cases.<sup>74</sup> Although abnormal levels of protein and cell counts in the cerebrospinal fluid (CSF) are common and headache or meningismus may develop, frank "aseptic" meningitis is uncommon (1% to 2% of cases).<sup>73</sup> Even

**Figure 19-3 Primary chancre of syphilis.** (Reprinted with permission from Sweet RL, Gibbs RS: *Atlas of Infectious Diseases of the Female Genital Tract*. Philadelphia, Lippincott Williams & Wilkins, 2004.)

without treatment these findings of secondary syphilis spontaneously clear within 2 to 6 weeks, and the latent stage of syphilis is entered, in which there is no apparent clinical disease. In the prepenicillin era about 25% of such patients had a recrudescence of secondary syphilis. These relapses usually occurred within 1 year, and thus the term early latency applies to this time period (<1 year). The mucocutaneous lesions associated with such relapses are highly contagious. The late latent stage (>1 year) is not infectious by sexual transmission, but the spirochete may still be transplacentally transmitted to the fetus.

If treatment is not provided, one third of patients progress and develop tertiary syphilis with involvement of the cardiovascular, central nervous, or musculoskeletal system, with or without involvement of various organ systems by gummas (late benign tertiary syphilis).<sup>75</sup> When tertiary syphilis occurs, one half of patients develop late benign syphilis (gummas), one fourth cardiovascular disease, and one fourth neurologic disease. The cardiovascular manifestations of tertiary syphilis include aortic aneurysm and aortic insufficiency. In the CNS, tertiary disease produces general paresis, tabes dorsalis, optic atrophy, and meningovascular syphilis; the Argyll-Robertson pupil (which does not react to light, but accommodates) is virtually pathognomonic. The pathogenesis of tertiary syphilis is based on the tropism of *T. pallidum* for arterioles, resulting in obliterative endarteritis with subsequent tissue destruction.<sup>73</sup>

The clinical spectrum in congenital syphilis includes stillbirths, neonatal death, clinical apparent congenital syphilis during the early months of life (early congenital syphilis), and development of the classic stigmata of late congenital syphilis.<sup>76</sup> While the most severe effects on pregnancy outcome occur with primary or secondary syphilis, at present pregnant women with syphilis are usually asymptomatic in the latent stage and have had the disease for more than 1 year. Consequently, most infants (approximately two thirds) with early congenital syphilis are asymptomatic at birth and do not develop evidence of active disease for 3 to 8 weeks. Chancres do not occur unless the disease is acquired at the time of passage through the birth canal. The characteristic manifestations of early congenital syphilis (onset <2 years of age) include a maculopapular rash that may progress to desquamation or vesiculae and bullae formation, snuffles (a flu-like syndrome associated with a nasal discharge), mucous patches in the oral pharyngeal cavity, hepatosplenomegaly, jaundice, lymphadenopathy, Parrot's pseudoparalysis due to osteochondritis, chorioretinitis, and iritis.<sup>76</sup>

Untreated or incompletely treated early congenital syphilis will progress to the classic manifestations of late congenital syphilis. These include Hutchinson's teeth, mulberry molars, interstitial keratitis, eighth nerve deafness, saddle nose, rhagades, saber shins, and neurologic manifestations (mental retardation, hydrocephalus, general paresis, optic nerve atrophy, and Clutton's joints). These stigmata associated with late congenital syphilis are the result of scarring induced by early lesions or reactions to persistent inflammation.<sup>76</sup>

### Diagnosis

The most specific and sensitive method for diagnosing syphilis is demonstration of *T. pallidum* in fresh specimens obtained from the lesions of infected individuals. Dark-field examination and direct fluorescent antibody tests are the definitive methods for diagnosing early syphilis. However, this methodology is applicable only to the lesions of primary or secondary syphilis. A specimen for dark-field examination or fluorescent antibody test should be obtained from any lesion suspected of being a chancre or manifestation of secondary syphilis.

The majority of men and nearly all women diagnosed with syphilis are in the latent stage. Thus, the diagnosis is most often based on serologic testing, which is a two-step process initially using nonspecific tests for reagin-type antibodies followed by specific antitreponemal antibody tests.<sup>77</sup> Nonspecific antibody tests for syphilis available today include the VDRL and the rapid plasma reagent test (RPR). These are used as screening tests. The titers of nontreponemal tests usually correlate with active disease and so results of the VDRL or RPR should be quantitated.<sup>77</sup> Treponema-specific tests are employed for confirming the diagnosis of syphilis in patients that have reactive VDRL or RPR tests. These tests include the *T. pallidum* immobilization (TPI) test, the fluorescent treponemal antibody absorbed (FTA-ABS) test, and the microhemagglutination assay for antibody to *T. pallidum* (MHA-TP). Because MHA-TP is less expensive and easier to perform, it has largely replaced the FTA-ABS test for confirmation of positive screening tests.

CDC recommends that all pregnant women should be screened serologically for syphilis early in pregnancy (i.e., first prenatal visit)<sup>77</sup> For populations that do not have optimal

**Table 19-8****Criteria for Performance of Cerebrospinal Fluid Examination in Patients with Latent Syphilis to Exclude Neurosyphilis**

- Neurologic or ophthalmic signs or symptoms
- Evidence of active tertiary syphilis (e.g., aortitis, gumma, and iritis)
- Treatment failure
- HIV infection with late latent syphilis or syphilis of unknown duration

prenatal care, CDC recommends that RPR-card test screening (a rapid screening test for syphilis) be performed when pregnancy is diagnosed and treatment given if the card is positive.<sup>77</sup> In populations with a high prevalence of syphilis or for patients at high risk, serologic testing should be performed twice during the third trimester—at 28 weeks' gestation and at delivery.<sup>77</sup>

Controversy has arisen over whether all patients (including pregnant women) who are asymptomatic but have a positive serologic diagnosis of syphilis should have a lumbar puncture for the detection of asymptomatic neurosyphilis. The lumbar puncture ensures proper treatment of neurosyphilis (see treatment section). Evaluation of syphilis patients with neurologic abnormalities should include CSF examination.<sup>77</sup> Although there is a high frequency of CSF abnormalities (elevated cell count, elevated protein concentration, reactive VDRL) in early syphilis, treatment results are good and so CSF examination is not necessary in asymptomatic early syphilis.<sup>21</sup> CDC recommends that all patients with latent syphilis be evaluated clinically for evidence of tertiary disease (e.g., aortitis, neurosyphilis, gummas, or iritis). Patients who demonstrate any of the criteria listed in Table 19-8 should have a prompt CSF examination.<sup>77</sup> With syphilis of more than 1 year's duration, CSF examination should be considered. CSF demonstrating pleocytosis, elevated protein concentrations, and a reactive VDRL is diagnostic of active neurosyphilis.

CDC emphasizes that no single test can be used to diagnose neurosyphilis.<sup>77</sup> The diagnosis can be made using various combinations of reactive serologic tests, abnormal CSF cell count, elevated protein, or a reactive CSF VDRL. The RPR test should not be performed on CSF. When reactive in a nonbloody tap, CSF VDRL is diagnostic of neurosyphilis. However, it may be nonreactive in the presence of neurosyphilis.

**Treatment**

All patients with a history of sexual contact with a person with documented syphilis or either a positive dark-field examination or serologic evidence of syphilis with a specific treponemal test should be treated. In addition, those for whom the diagnosis cannot be ruled out with certainty or in those with previous treatment who have evidence of reinfection such as dark-field positive lesions or a 4-fold rise in titer of a quantitative non-treponemal test should receive appropriate treatment.

Parenteral penicillin G is the preferred drug for the treatment of all stages of syphilis.<sup>77</sup> The type of penicillin preparation used (i.e., benzathine, aqueous procaine, or aqueous crystalline), dosage, and length of treatment are dependent on the stage of syphilis and the clinical manifestations present. Parenteral penicillin G is the only therapy with documented efficacy for

treating neurosyphilis or syphilis in pregnancy. Thus, CDC recommends that patients with neurosyphilis and pregnant women with syphilis who report being allergic to penicillin should be treated with penicillin after desensitization.<sup>77</sup>

Table 19-9 contains CDC-recommended treatment regimens for the various stages of syphilis in nonpregnant, pregnant, and HIV-infected patients. Forty years of CDC experience

**Table 19-9****CDC-recommended Treatment of Syphilis in Adults, 1998****Primary and secondary syphilis**

## Recommended regimen

Benzathine penicillin G, 2.4 million units IM in a single dose

## Penicillin allergy (nonpregnant)

Doxycycline 100 mg orally twice a day for 2 weeks

or

Tetracycline 500 mg orally four times a day for 2 weeks

**Latent Syphilis**

## Early latent syphilis (&lt;1 year)—recommended regimens

Benzathine penicillin G, 2.4 million units IM in a single dose

## Late latent syphilis (&gt;1 year)—recommended regimens

Benzathine penicillin G, 7.2 million units total, administered as 3 doses of 2.4 million units IM each, at 1-week intervals

## Penicillin allergy (nonpregnant)

Doxycycline 100 mg orally twice a day

or

Tetracycline 500 mg orally 4 times a day

Both drugs administered for 2 weeks if duration of infection known to have been <1 year; otherwise administered for 4 weeks

**Tertiary syphilis (gumma and cardiovascular)**

## Recommended regimen

Benzathine penicillin G, 7.2 million units total, administered as 3 doses of 2.4 million units IM, at 1-week intervals

## Penicillin allergy

Same as for late syphilis

**Neurosyphilis**

## Recommended regimen

Aqueous crystalline penicillin G 18–24 million units per day, administered as 3–4 million units IV every 4 hours, for 10–14 days

## Alternative regimen (if compliance assured)

Procaine penicillin 2.4 million units IM daily, plus probenecid 500 mg orally four times a day, both for 10–14 days

**Syphilis during pregnancy**

## Recommended regimens

Penicillin regimen appropriate for the pregnant woman's stage of syphilis

Some experts recommend additional therapy (e.g., a second dose of benzathine penicillin 2.4 million units IM) 1 week after the initial dose, particularly for women in the third trimester and for those who have secondary syphilis during pregnancy

## Penicillin allergy

A pregnant woman with a history of penicillin allergy should be treated with penicillin after desensitization

**Syphilis among HIV-infected patients**

## Primary and secondary syphilis

Recommended benzathine penicillin 2.4 million units IM

Some experts recommend additional treatments such as multiple doses of benzathine penicillin G as in late syphilis

Penicillin allergic patients should be desensitized and treated with penicillin

Latent syphilis (normal CSF examination)

Benzathine penicillin G 7.2 million units as 3 weekly doses of 2.4 million units each

demonstrate that parenteral penicillin G is effective in achieving local cure (healing of lesions and prevention of sexual transmission) and in preventing tertiary syphilis when used for the treatment of primary and secondary syphilis.<sup>77</sup> Thus, for patients (nonpregnant and pregnant) who are not allergic to penicillin, the recommended regimen for primary and secondary syphilis is benzathine penicillin G 2.4 million units IM in a single dose. CDC suggests that all patients with syphilis be tested for HIV infection.<sup>77</sup> Patients with syphilis who have symptoms or signs suggesting neurologic or ophthalmic disease should have CSF analysis and slit-lamp examination to rule out neurosyphilis and syphilitic eye disease, respectively.<sup>21</sup> Lumbar puncture is recommended for patients when clinical signs or symptoms of neurologic disease are present or patients fail to respond to treatment.<sup>77</sup>

In nonpregnant penicillin-allergic patients with primary or secondary syphilis, treatment with doxycycline 100 mg twice a day for 2 weeks or tetracycline 500 mg four times a day for 2 weeks is suggested.

An additional alternative in nonpregnant patients allergic to penicillin, for whom compliance and follow-up can be assured, is erythromycin 500 mg orally four times a day for 2 weeks.<sup>77</sup> However, erythromycin is less effective than other recommendations for treatment of primary or secondary syphilis.<sup>77</sup> Pregnant patients who are allergic to penicillin should be desensitized and treated with penicillin.

Assessing response to treatment is based on serologic titers as well as clinical findings. With primary or secondary syphilis patients should be reexamined clinically and serologically at 6 months and 12 months after treatment.<sup>77</sup> HIV-infected patients should be examined more frequently at 3-month intervals. Quantitative nontreponemal titers (VDRL or RPR) should decline 4-fold by 6 months after treatment.<sup>77</sup> Failure to do so identifies patients at risk for treatment failure and those who should be screened for HIV infection. At a minimum, such patients require additional clinical and serologic follow-up. When follow-up cannot be assured, re-treatment is recommended. Those patients whose signs or symptoms either persist or recur or who have a 4-fold rise in titer of nontreponemal testing are either considered to be reinfected or the treatment has failed.<sup>77</sup> For re-treatment it is best to provide three weekly injections of benzathine penicillin G 2.4 million units IM, unless CSF examination demonstrates the presence of neurosyphilis, which requires treatment as discussed following.

For non-penicillin-allergic patients with early latent syphilis and with normal CSF examination (if performed), the recommended regimen is benzathine penicillin G 2.4 million units IM in a single dose. With late latent syphilis (duration >1 year or unknown), the recommendation is benzathine penicillin G 7.2 million units total, administered as three doses of 2.4 million units each IM, at 1-week intervals. In nonpregnant patients with latent syphilis who are allergic to penicillin, nonpenicillin therapy should be used only after CSF examination rules out neurosyphilis. Either doxycycline 100 mg orally twice a day or tetracycline 500 mg orally four times a day are recommended in such individuals. For early latent syphilis, the duration of therapy is 2 weeks, and with a duration greater than 1 year it is 4 weeks.<sup>77</sup> Pregnant patients allergic to penicillin should be desensitized and treated with penicillin.

Follow-up in patients with latent syphilis requires quantitative nontreponemal serologic tests to be repeated at 6 months, 12 months, and 24 months after treatment.<sup>77</sup> If titers increase 4-fold or if a titer initially greater than 1:32 fails to decline 4-fold within 12 to 24 months, or if the patient develops signs or symptoms of syphilis, the patient should be evaluated for neurosyphilis and re-treated appropriately depending on the findings of CSF examination.

Patients with late (tertiary) syphilis findings of gumma or cardiovascular disease (not neurosyphilis) should be treated with benzathine penicillin G 7.2 million units total, administered as 3 doses of 2.4 million units IM, at 1-week intervals. Penicillin-allergic nonpregnant patients are treated according to the regimens recommended for late latent syphilis (see Table 19-9). Pregnant penicillin-allergic patients should be desensitized and treated with penicillin (see later discussion).<sup>77</sup> All patients with symptomatic late syphilis should undergo CSF examination before therapy in order to exclude neurosyphilis.<sup>77</sup>

Patients with neurosyphilis or syphilitic eye disease who are not allergic to penicillin should be treated with 18 to 24 million units of aqueous crystalline penicillin G daily, administered as 3 to 4 million units IV every 4 hours for 10 to 14 days. For patients for whom compliance can be assured, 2.4 million units of procaine penicillin IM daily, plus probenecid 500 mg orally 4 times a day for 10 to 14 days, is an alternative.<sup>77</sup>

## CHANCROID

Chancroid, commonly referred to as "soft" chancre, is an acute ulcerative disease often associated with inguinal adenopathy (bubo). The causative agent of chancroid is *Haemophilus ducreyi*. This bacterium is a small, nonmotile, gram-negative rod that has a characteristic "chaining" appearance on Gram's stain that results in its "school of fish" appearance.

### Epidemiology, Risk Factors, and Pathogenesis

Chancroid is a common disease and major public health problem in many countries in the developing world. In many of these countries, chancroid is endemic and WHO estimates an annual incidence of 7 million cases.<sup>78</sup> Although rare in the United States, outbreaks of chancroid have been reported in urban areas.<sup>79</sup> In 2002 only 67 cases of chancroid were reported to CDC. Although chancroid has become an infrequent STD in the United States, in endemic areas it should be considered in the differential diagnosis of high-risk patients with a painful genital ulcer.

Sex workers are thought to be the reservoir of disease in the epidemics that have occurred in North America.<sup>80</sup> Major risk factors for chancroid include use of crack cocaine and exchange of sex for money or drugs.<sup>81</sup> The disease occurs most commonly in men, especially young, sexually active males who have a history of recent contact with sex workers.<sup>80</sup> Chancroid is more prevalent among lower socioeconomic groups. Uncircumcised males appear to be more susceptible to *H. ducreyi*.<sup>80</sup> Males are more frequently symptomatic. Asymptomatic women with lesions of chancroid are rarely seen.

The importance of chancroid is further demonstrated by the recognition that chancroid is a major cofactor in the heterosexual transmission of HIV and has been strongly associated with increased infection rates for HIV, especially in Africa.<sup>82</sup>

### Clinical Features

The lesions of chancroid are generally limited to genital sites. In men, they are most commonly found in the internal surface of the prepuce and the frenulum, and in women on the labia, clitoris, and fourchette.

The incubation period of chancroid is 3 to 10 days, with most from 4 to 7 days. At the site of entry, a small papule develops surrounded by a zone of erythema. Within 2 to 3 days the lesion becomes pustular or vesiculopustular and ulcerates. The classic ulcer of chancroid is superficial and shallow with a ragged edge. The chancre is surrounded by an inflammatory red halo. The base of the ulcer is covered with a necrotic exudate. The chancre of chancroid is painful and tender. In addition, it is not indurated (i.e., "soft"). Whereas only a single ulcer is present in 50% of male patients, multiple ulcers are the rule in women; Plummer et al report that women have a mean of 4.5 discrete ulcers.<sup>83</sup>

In approximately half of cases, a bubo develops. The bubo appears 7 to 10 days after the initial lesion and is characterized by acute, painful, tender, inflammatory inguinal adenopathy. The bubo is unilateral in about two thirds of cases and is unilocular. If untreated, the bubo will rupture, forming a large ulcer in the inguinal area. Bubo formation is less common in women.<sup>83</sup>

In men the usual clinical complaints relate to the ulcerative lesion or tender inguinal adenopathy. Women tend to have less specific symptoms such as dysuria, rectal bleeding, dyspareunia, or vaginal discharge.<sup>83</sup> The combination of a painful ulcer and tender inguinal adenopathy is suggestive of chancroid but only occurs in one third of patients. The presence of a painful ulcer in combination with suppurative inguinal adenopathy is almost pathognomonic for chancroid.

### Diagnosis

The diagnosis of chancroid is based on gram-stained smears, culture, and clinical characteristics of lesions. Gram's stain of the exudate from the lesion or an aspirate of the bubo may reveal the presence of gram-negative rods that tend to form chains ("school of fish"). However, the sensitivity of gram staining is only 50%.<sup>84</sup> A definitive laboratory diagnosis of chancroid depends on isolation of *H. ducreyi* from the lesion or bubo. However, the organism is fastidious, and isolation of *H. ducreyi* is not routinely performed in most general clinical microbiology laboratories. Gonococcal agar base or Mueller-Hinton agar base supplemented with 0.2% activated charcoal, 1% bovine hemoglobin, 1% CVA enrichment, and 3 mg/mL vancomycin is the preferred medium for primary isolation of *H. ducreyi*.<sup>12</sup> Even with use of specific media the sensitivity of culture is at best 80%.<sup>82</sup> PCR assays compare favorably with culture, having a sensitivity of greater than 95%.<sup>85</sup> However, no U.S. Food and Drug Administration (FDA)-approved PCR test is available. The CDC recommends that a probable diagnosis of chancroid may be made if the following criteria exist: (1) the individual has one or more painful genital ulcers, (2) there is no evidence of syphilis by dark-field examination of lesion or by serology performed at least 7 days after onset of ulcers, and (3) either the clinical presentation of the genital ulcer or regional lymphadenopathy is typical for chancroid and a test for HSV is negative.<sup>86</sup>

**Table 19-10  
CDC-recommended Treatment of Chancroid, 2002**

#### Recommended regimen

- Azithromycin 1 g orally in a single dose
- or
- Ceftriaxone 250 mg IM in a single dose
- or
- Ciprofloxacin\* 500 mg orally twice a day for 3 days
- or
- Erythromycin base 500 mg orally four times a day for 7 days

\*Contraindicated for pregnant and lactating women.

### Treatment

Current CDC recommendations for the treatment of chancroid are presented in Table 19-10. No instance of antimicrobial resistance by *H. ducreyi* to azithromycin, ceftriaxone, or erythromycin has been reported. The fluoroquinolones are also effective treatment for chancroid. CDC suggests that all patients diagnosed with chancroid be tested for HIV infection.

Follow-up examination should occur 3 to 7 days after initiation of therapy.<sup>82</sup> With successful treatment, symptomatic improvement of the ulcer is present within 3 days and objective improvement within 7 days after therapy. Clinical resolution of fluctuant buboes is slower than that of ulcers and may require needle aspiration.<sup>82</sup>

In pregnancy, ciprofloxacin is contraindicated and the safety of azithromycin has not been established. Thus, ceftriaxone or erythromycin is the preferred regimen for pregnant and lactating women. No adverse effects of chancroid on pregnancy outcome or on the fetus have been demonstrated.<sup>82</sup>

### LYMPHOGRANULOMA VENEREUM

Lymphogranuloma venereum (LGV) is a sexually transmitted disease caused by *C. trachomatis* serotypes L1, L2, and L3. The disease is manifested by both generalized systemic symptoms and a wide spectrum of anogenital lesions, lymphadenopathy, and gross devastation of perineal tissue.<sup>87</sup> LGV is uncommon in the United States. It usually presents as inguinal adenopathy, since the painless genital ulcer stage of the disease often goes unnoticed.

### Epidemiology, Risk Factors, and Pathogenesis

Although LGV is worldwide in distribution, it most commonly occurs in tropical areas. LGV is endemic in East and West Africa, India, parts of southeastern Asia, South America, and the Caribbean.<sup>87</sup> In North America, Europe, Australia, and most of Asia and South America it is a sporadic disease.<sup>87</sup>

While LGV is no longer a reportable disease, an estimated 350 cases per year occur in the United States. The majority of acute LGV cases occur in men, with a male-to-female ratio of 5:1 or greater. As is true for other STDs, LGV is more common in urban settings, among people with numerous sexual partners, and among lower socioeconomic classes.<sup>87</sup> While transplacental congenital infection has not been reported, acquisition during passage through an infected birth canal can occur.<sup>87</sup>

### Clinical Features

LGV is primarily an infection of lymphatic tissue in which inflammation spreads from infected lymph nodes into adjacent tissue.<sup>88</sup> The infected lymph nodes enlarge, necrose, and form abscesses that coalesce and rupture, leading to fistula formation and sinus tracts.<sup>88</sup> Healing is the result of fibrosis, with resultant obstruction of lymphatic vessels, chronic edema, and enlargement of affected anatomic locations. It is believed that most of the tissue damage associated with LGV is caused by a cell-mediated "hypersensitivity" to chlamydial antigens.<sup>88</sup>

The clinical presentation of LGV has primary, secondary, and tertiary stages. Following an incubation time that ranges from 3 to 21 days, the primary lesion in men usually occurs on the coronal sulcus, while in females, the most common site is the posterior vaginal wall, followed by the fourchette, cervix, and vulva. This primary lesion is vesicular or papular and painless; it may ulcerate but heals within a few days without scarring. The primary lesion generally is not appreciated or recognized by patients.

The secondary stage of LGV develops 1 to 4 weeks following the primary lesion and is characterized by acute lymphadenitis with bubo formation (inguinal syndrome) with or without acute hemorrhagic proctitis (anogenitorectal syndrome). This invasive stage of LGV is often preceded by the onset of systemic symptoms such as fever, malaise, headache, and myalgia.<sup>88</sup> Inguinal adenopathy is the most frequent clinical manifestation of LGV. The adenopathy is unilateral in two thirds of cases and begins as firm, discrete, multiple nodes that are slightly tender. Over the next week or two, a more extensive adenitis commences as the nodes become matted together and adherent to the subcutaneous tissue and overlying skin. The skin often is discolored, and the lesion becomes painful. The horizontal group of superficial inguinal nodes is most commonly involved, but the femoral nodes may also be affected. If both groups become involved, the inguinal ligament creates a groove between the node groups, producing the "grove sign," which is considered pathognomonic for LGV. The matted mass proceeds to suppurate, and multiple draining sinuses arise from the necrotic lymph nodes. Approximately one third of inguinal buboes in LGV become fluctuant and rupture. In the anogenitorectal syndrome, proctocolitis and hyperplasia of intestinal and perirectal lymphatic tissue occur. This form of secondary LGV is found predominantly in women and homosexual men. Symptoms include anal pruritus, mucous rectal discharge, fever, rectal pain, and tenesmus.<sup>88</sup>

The tertiary stage involves the external genitalia and anorectal areas. It is characterized by progressive tissue destruction and extensive scarring. Especially in women, this phase of disease may be the initial clinical manifestation for which the patient seeks care. This stage may present as hypertrophic ulceration and elephantiasis. Hypertrophic lesions are more common among women, but elephantiasis occurs in both men and women. Sinuses, fistula tracts, and ultimately strictures may occur in the vulva, perineum, and rectum.

### Diagnosis

Diagnosis of LGV solely on clinical grounds is, at best, difficult. The diagnosis can be made by isolation or identification of the chlamydial organism or with the use of serology. Schachter and

coworkers reported that aspiration and culture of pus from fluctuant nodes was positive in approximately 50% of cases.<sup>89</sup>

The Frei intradermal test was for many years the backbone of diagnostic efforts for LGV. A positive Frei is not evidence of active infection but only indicates previous LGV infection. Moreover, the Frei antigen is common to all *Chlamydia*, and thus the specificity of a positive Frei test is poor for LGV, limiting its clinical usefulness.

The most commonly used diagnostic test for LGV at present is the complement fixation test for *Chlamydia* group antibodies. This test is very sensitive, and titers greater than 1:64 are considered diagnostic. However, CF titers are present with mucosal infections due to other chlamydial subgroups, although usually at lower titers.<sup>89</sup> The microimmunofluorescence test of Wang and Grayston can be used for typing isolates of *Chlamydia* and thus can identify the chlamydia biovars responsible for LGV. However, this test is available only in a limited number of laboratories.

### Treatment

As recommended by CDC, doxycycline 100 mg orally twice a day for 21 days is the therapy of choice for LGV.<sup>90</sup> An alternative regimen is erythromycin 500 mg orally four times a day for 21 days. Although the activity of azithromycin against *C. trachomatis* suggests it would be effective in multiple doses over 2 to 3 weeks, no clinical studies have been reported.<sup>90</sup> In pregnant or lactating women the erythromycin regimen should be used. Sexual contacts of a person with LGV within 30 days prior to onset of symptoms should be examined, tested for urethral or cervical chlamydial infection, and treated. Fluctuant inguinal nodes should be aspirated to prevent sinus tract formation. Incision and drainage or surgical extirpation of nodes is contraindicated, as such intervention will delay healing and may further obstruct lymphatic drainage. Late sequelae such as strictures or fistulas may require surgical intervention.

## **DONOVANOSIS (GRANULOMA INGUINALE)**

Donovanosis (granuloma inguinale) is a chronic, progressively destructive ulcerative infection of the genital area caused by the bacterium *Calymmatobacterium granulomatis*. Previously the disease was called granuloma inguinale. The presence of Donovan bodies characterizes this infection.

### Epidemiology, Risk Factors, and Pathogenesis

Donovanosis is most common in Papua New Guinea, Southern Africa, northeast Brazil, French Guyana, and Australia among aboriginal tribes.<sup>90</sup> It is rare in temperate climates. Although no longer a reportable disease, an estimated fewer than 100 cases occur annually in the United States.<sup>91</sup>

The variable incubation time and initial subtle clinical findings have confused the epidemiology of donovanosis.<sup>92</sup> It is generally believed that donovanosis is an STD. However, its exact mode of transmission is still not clearly understood, and young children and very old adults also develop the infection in the absence of sexual activity.

The sexually transmitted hypothesis is supported by a variety of evidence<sup>92</sup> including the following: (1) most lesions occur on the genitalia, (2) the disease occurs most frequently in the

## Gynecologic Infectious Disease

sexually active age group, (3) there is almost always a history of sexual exposure before the appearance of the ulcer, (4) other STDs are present among donovanosis patients, and (5) donovanosis has been proved to exist in more than 50% of the sexual partners of patients with the disease.

### Clinical Features

Donovanosis is a low-grade chronic infection of low infectiousness, and repeated close physical contact seems to be necessary for transmission.<sup>92</sup> The incubation period varies from a few days to a few months. The disease has an insidious onset, and the earliest lesion presents as a painless papule or nodule that often is unnoticed by patients. Most cases (90%) involve the genitals. In women the most common sites are the labia and fourchette. The epithelium overlying the lesion subsequently ulcerates, producing an enlarging granulomatous, beefy red, velvety ulcer. If untreated, the lesions may spread to involve the inguinal regions, producing a "pseudobubo," which is a subcutaneous granulomatous process rather than adenopathy. Unless secondarily infected, the lesions of granuloma inguinale are painless.

### Diagnosis

The diagnosis of donovanosis is usually made on clinical grounds because of the characteristic granulomatous process. *C. granulomatis* is difficult to culture, and so the diagnosis is made by histologic identification of *C. granulomatis*. Donovan bodies in macrophages on the smear or biopsy specimen must be demonstrated for a certain diagnosis.

### Treatment

CDC proposes either trimethoprim-sulfamethoxazole one double strength tablet orally twice a day or doxycycline 100 mg orally twice a day given over a minimum 3-week period of time as the recommended agents for the treatment of donovanosis.<sup>93</sup> Alternative agents include ciprofloxacin 750 mg orally twice a day or erythromycin base 500 mg orally four times a day for a minimum 3-week course. Addition of gentamicin 1 mg/kg IV every 8 hours should be considered if lesions fail to respond in the first few days of therapy.<sup>93</sup> Therapy should be continued until the lesions are completely healed.

Sexual partners should be examined and treated if they had sexual contact in the 60 days preceding the onset of symptoms and have clinical signs and symptoms of the disease. In pregnancy and during lactation the erythromycin regimen is recommended and the addition of parenteral gentamicin should be given strong consideration.<sup>93</sup>

## HERPES SIMPLEX VIRUS (GENITAL HERPES)

Herpes simplex virus (HSV), a member of the Herpesviridae family, is a double-stranded DNA virus. Two major serotypes, HSV-1 and HSV-2, are recognized. Genital herpes is an STD caused by either HSV-1 (also associated with oral/facial lesions) or HSV-2. These viruses cause infection following entry through mucous membranes or skin, resulting in typical vesicular lesions. HSV is neurotropic with sensory nerve involvement and latency within dorsal root ganglia.<sup>91</sup> Following primary infection, HSV replicates at the site of entry and subsequently ascends via the

axon to the dorsal root ganglion, where it persists in a latent form throughout life. Active replication and recurrent infection may or may not ensue.

### Epidemiology, Risk Factors, and Pathogenesis

There has been a dramatic increase in the prevalence of HSV infections in the United States with the CDC demonstrating a 9-fold increase in physician visits for genital herpes from 1966 to 1997.<sup>94</sup> An estimated 500,000 to 1 million new cases of genital HSV infections occur annually in the United States. While approximately 5 million adults in the United States have a history of genital herpes infection, large serologic studies for HSV-2 assessing type-specific HSV-2 antibodies to glycoprotein G have demonstrated an overall seroprevalence for HSV-2 infection of 21.9% with 25.6% of females seropositive.<sup>95</sup> Thus, an estimated 45 million Americans have been infected with HSV-2 genital herpes.

Based on clinical history, serologic testing, and HSV typing, three types of genital herpes infection have been recognized (Table 19-11). Primary infection is an initial infection with either HSV-1 or HSV-2 in the absence of evidence for prior exposure (i.e., lack of antibodies to either). Nonprimary first clinical episode is an initial episode (either clinical or subclinical) with HSV-1 and HSV-2 in an individual with serologic evidence of prior exposure to the other serotype. Recurrent genital herpes is reactivation of latent virus.

As noted previously, recent seroprevalence studies with type specific anti-HSV-2 antibody (glycoprotein G) demonstrate that the overwhelming majority of HSV-2 seropositive adults report no history of clinically diagnosed genital herpes.<sup>94</sup> In addition, even the majority of "severe" first clinical episodes are not true primary infections but rather recurrent infections of nonprimary first episodes. Of significant importance is the recognition that patients with past clinical or subclinical genital herpes may asymptotically shed HSV from the genital tract on approximately 1% of days.

More recent prospective studies on the natural history of genital herpes infection report that nearly 40% of newly acquired HSV-2 infections were associated with clinically symptomatic disease.<sup>96</sup> This large study of 2393 sexually active HSV-2 seronegative patients demonstrated rates of new HSV-1 and HSV-2 infection of 1.6 and 5.2 cases per 100 person-years, respectively. Women were significantly more likely to have symptomatic infection. Survey studies of adult women have identified isolation of HSV from the genital tract of 0.02% to 4% of women, with the higher rates occurring in high-risk patients attending STD clinics. Among pregnant women, isolation of HSV has been reported in 0.01% to 4% of asymptomatic

**Table 19-11**  
**Types of Genital Herpes Simplex Infection**

- Primary infection: initial infection with either HSV-1 or HSV-2, without evidence of prior exposure to either (i.e., antibodies)
- Nonprimary first episode: initial clinical episode with HSV-1 or HSV-2 in patient with prior exposure to the other viral serotype
- Recurrent infection: reactivation of latent virus

women; patients without symptoms account for one third to two thirds of positive cultures.<sup>97</sup>

It appears that there is not an increase in frequency or severity of genital herpes infections during pregnancy. A 3-fold increase in spontaneous abortion has been reported with maternal HSV infection in early pregnancy. While Brown et al reported no overall differences in mean birth weight, gestational age at birth, risk of intrauterine growth restriction (IUGR), stillbirth, or neonatal death with acquisition of HSV infection during pregnancy, primary genital herpes in the third trimester was associated with preterm birth, IUGR, and substantial risk for neonatal herpes infection.<sup>98</sup>

Clearly, the major impact of genital herpes infection in pregnancy is neonatal herpes infection. An estimated 700 to 1000 cases of neonatal herpes occur each year in the United States, an incidence of 1 in 3500 to 1 in 5000 births. In utero transplacental acquisition of herpes producing congenital herpes rarely occurs. However, when it does, it is associated with devastating outcomes—death in 31% and neurologic sequelae in nearly all survivors.<sup>99</sup> The overwhelming majority (>85%) of neonatal herpes is acquired intrapartum from an infected maternal genital tract.<sup>99</sup>

Risk factors associated with the transmission of HSV from mother to neonate include HSV type (HSV-2 > HSV-1), mother's clinical stage of infection, anatomic site of viral shedding, use of fetal scalp electrode, and presence and specificity of transplacental passively transferred HSV antibodies from mother to infant. Infants born to mothers with recently acquired first episodes of HSV infection were 10-fold more likely to acquire neonatal herpes as were those born to mothers with recurrent infection. With first-episode infection, whether primary or nonprimary, the rate of neonatal infection is similar, 40% and 31%, respectively. Passive transfer of maternal antibodies to HSV-2 (but not HSV-1) are protective, as demonstrated by Prober et al who reported that following exposure to HSV at vaginal delivery, 0 of 34 infants in whom antibody was present developed neonatal herpes infection (95% confidence interval, 0% to 8%).<sup>100</sup> Cervical shedding of HSV is associated with an increased risk of perinatal transmission.

In pregnancy, primary infection may range from asymptomatic to severe, produce transplacental or neonatal infection, and result in up to 40% or higher risk for neonatal herpes (depending on presence or absence of maternal antibody). With nonprimary first episode transmission, maternal symptoms range from asymptomatic to severe, mainly neonatal infection occurs, and the risk for neonatal infection is up to 40%. For recurrent infection, maternal symptoms range from asymptomatic to severe, only neonatal infection occurs, and the estimated risk for neonatal infection is from less than 1% to 4%.

### Diagnosis

Until recently viral culture was the best diagnostic test for confirmation of HSV infection. HSV grows rapidly (most cultures are positive at 48 to 72 hours) and is easily transported. A false-negative rate of 5% to 30% is associated with a single herpes culture. Cultures are more likely to be positive with first episodes of HSV infection and in patients with vesicles or pustules compared with ulcerative and crusted lesions. Use of specific monoclonal antibodies in immunofluorescence or immunoassay

tests have enhanced and accelerated detection of HSV in culture with resultant good sensitivity and specificity.<sup>101</sup>

Similarly to other infections, the laboratory diagnosis of HSV infections has been revolutionized by introduction of NAATs such as PCR. PCR has excellent sensitivity and specificity compared with viral culture for detection of HSV.

The introduction of type-specific serology has further facilitated diagnosis. Each HSV type has identifiable proteins in a characteristic protein coat. Glycoprotein G-1 is associated with HSV type 1 and glycoprotein G-2 with HSV type 2. Within several weeks of infection, type-specific antibodies to the viral proteins develop and persist.<sup>102</sup> Detection of HSV-2 antibodies, using glycoprotein G technology, is virtually diagnostic of genital herpes infection. Type-specific serologic assays are commercially available and can be used for patients without active lesions or who have lesions which are culture negative. Current FDA-approved type-specific assays include HerpeSelect-1 ELISA IgG and HerpeSelect-2 ELISA IgG and HerpeSelect 1/2 Immunoblot IgG. When submitting specimens, confirm that glycoprotein G-based serologic testing is available. Screening for HSV-1 and -2 infection in the general population is not indicated.<sup>103</sup> However, screening may be useful in counseling couples when one partner has genital HSV and the other does not know or is uncertain, especially for planning pregnancy or in pregnancy.

### Treatment

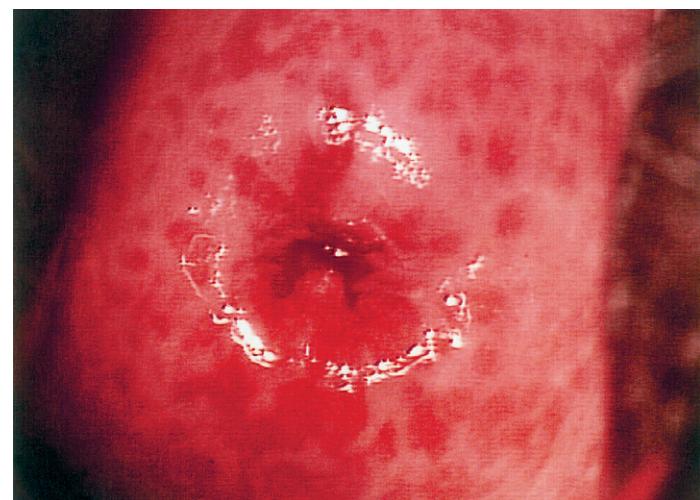

While there is no cure for HSV infection, antiviral medications are available that reduce the duration and frequency of outbreaks, reduce asymptomatic HSV shedding, and reduce transmission.<sup>104</sup> Acyclovir, the first effective antiviral agent for genital herpes, became available in the early 1980s. Acyclovir interferes selectively with viral thymidine kinase and inhibits viral DNA synthesis. Because of its selectivity for HSV-infected cells, acyclovir has a high margin of safety. Subsequently, two additional antiviral agents, valacyclovir and famciclovir, have become available for the treatment and suppression of HSV infection. These agents also inhibit actively replicating virus by interfering with viral DNA synthesis.

Current CDC-recommended treatment guidelines for HSV infections are listed in Table 19-12. If lesions of first-episode herpes infection are not fully healed, treatment with antiviral agents can be extended beyond 10 days. Intravenous acyclovir should be reserved for severe primary outbreaks or disseminated herpes infections. In these instances, the recommended treatment is acyclovir 5 to 10 mg/kg every 8 hours IV for 2 to 7 days or until clinical improvement followed by oral antiviral therapy to complete at least a total of 10 days of therapy.<sup>104</sup>

Following the first clinical episode of genital herpes, patients may choose two alternative approaches. They may take episodic therapy upon signs of recurrent outbreak, or they may select to receive continuous suppressive therapy. Episodic treatment has been shown to decrease the proportion of patients with outbreaks, reduce duration of symptoms, and shorten the duration of viral shedding.<sup>102</sup> On the other hand, suppressive therapy reduces the frequency of genital herpes recurrences by 70% to 80% among patients with frequent recurrences, with many patients reporting no symptomatic outbreaks.<sup>102</sup>

Interest has focused on the use of acyclovir prophylaxis during late pregnancy to prevent HSV recurrence at delivery.<sup>105</sup>

<b>Table 19-12 CDC-recommended Regimens for Genital Herpes, 2002</b>	
<b>Recommended regimens: first clinical episode</b>	
Acyclovir 400 mg orally three times a day for 7–10 days	
Acyclovir 200 mg orally five times a day for 7–10 days	
Famciclovir 250 mg orally three times a day for 7–10 days	
Valacyclovir 1 g orally twice a day for 7–10 days	
<b>Recommended regimens: episodic recurrences</b>	
Acyclovir 400 mg orally three times a day for 5 days	
Acyclovir 200 mg orally five times a day for 5 days	
Acyclovir 800 mg orally twice a day for 5 days	
Famciclovir 125 mg orally twice a day for 5 days	
Valacyclovir 500 mg orally twice a day for 3–5 days	
Valacyclovir 1 g orally once a day for 5 days	
<b>Recommended regimens: suppression of recurrent episodes</b>	
Acyclovir 400 mg orally twice a day	
Famciclovir 250 mg orally twice a day	
Valacyclovir 500 mg orally once a day*	
Valacyclovir 1 g orally once a day	
*Valacyclovir 500 mg once a day might be less effective than other dosing regimens in patients who have frequent ( $\geq 10$ episodes per year) recurrences.	

**Figure 19-4 Strawberry cervix associated with trichomoniasis.**

(Reprinted with permission from Sweet RL, Gibbs RS: *Atlas of Infectious Diseases of the Female Genital Tract*. Philadelphia, Lippincott Williams & Wilkins, 2004.)

Acyclovir is well tolerated in pregnancy with minimal fetal drug accumulation. The Acyclovir in Pregnancy Registry assessed data from over 1200 pregnant women exposed to acyclovir and found no increases in drug-related fetal abnormalities attributed to acyclovir use.<sup>105</sup> However, long-term developmental outcomes were not evaluated. Although some authorities believe that insufficient data exist to recommend prophylaxis in pregnancy,<sup>104</sup> the American College of Obstetricians and Gynecologists suggests that use of acyclovir to suppress recurrent HSV infection in late pregnancy is acceptable.<sup>106</sup> Sheffield and colleagues performed a meta-analysis of acyclovir prophylaxis to prevent HSV recurrence at delivery.<sup>107</sup> Acyclovir prophylaxis commencing at 36 weeks' gestation was effective in reducing clinical HSV recurrence for the following: at the time of delivery (OR 0.25; 95% CI 0.15–0.40), cesarean deliveries for clinical recurrence of genital herpes (OR 0.30; 95% CI 0.13–0.67), total HSV detection at delivery (OR 0.11; 95% CI 0.04–0.31), and asymptomatic HSV shedding at delivery (OR 0.09; 95% CI 0.02–0.39).

## TRICHOMONIASIS

*Trichomonas vaginalis*, a flagellated protozoan, is the etiologic agent of trichomoniasis (Fig. 19-4). The urogenital tract is the primary site of infection, which presents with a wide spectrum of symptoms.<sup>106</sup> Trichomoniasis has been suggested as a putative agent for adverse pregnancy outcomes, including PROM, low-birth-weight infants, preterm delivery, and spontaneous abortion.<sup>107</sup> In addition, *T. vaginalis* has been identified as a predisposing factor in transmission and acquisition of HIV.<sup>108</sup>

## Epidemiology, Risk Factors, and Pathogenesis

At one time *T. vaginalis* was responsible for approximately 25% of cases of clinically evident vaginitis.<sup>109</sup> During the past decade the prevalence appears to have decreased. The prevalence of *T. vaginalis* is estimated at 3% to 5%, ranging from 2% to 3% in middle-class women to over 50% in women attending STD clinics.<sup>109,110</sup>

Contradictory results have been reported regarding an association between *T. vaginalis* and adverse pregnancy outcomes. Hardy et al reported that in an adolescent pregnant population with a prevalence of 34%, *T. vaginalis* was associated with low birth weight and preterm birth.<sup>111</sup> Despite a similar high prevalence of trichomoniasis, Mason and Brown found no association with adverse pregnancy outcome.<sup>112</sup> Similarly, Minkoff et al found no significant association between *T. vaginalis* and preterm labor.<sup>7</sup> On the other hand, the Vaginal Infection and Prematurity Study demonstrated that the presence of *T. vaginalis* in the vagina at mid pregnancy was significantly associated with preterm low birth weight (OR 1.6; 95% CI 1.3–1.9).<sup>97</sup> However, a recent treatment trial sponsored by NIH demonstrated that metronidazole treatment of asymptomatic women with trichomoniasis (based on culture) resulted in an increased risk of preterm birth compared with placebo.<sup>113</sup>

## Clinical Features

Patients with symptomatic trichomoniasis present with a copious vaginal discharge that most commonly is yellow-green and malodorous. Vulvar irritation is also frequently noted. The pH of the discharge is above 4.5. While the discharge is classically described as frothy or bubbly yellow-green, observational studies have demonstrated that frothiness was detected in only

12% to 34% of cases.<sup>110</sup> In addition, punctate mucosal hemorrhages of the cervix (strawberry cervix), may occur. These hemorrhages are noted by the naked eye in less than 10% of trichomoniasis cases; this finding is more commonly identified with colposcopy.<sup>110</sup> These data emphasize the inaccuracy of diagnosing vaginal infections on the basis of "characteristic" discharges or clinical signs and symptoms.

### Diagnosis

Most commonly, the diagnosis of trichomoniasis is made by light microscopic examination of a saline wet mount demonstrating motile organisms. In addition, a heavy polymorphonuclear infiltrate is present.<sup>110</sup> Unfortunately, the sensitivity of the wet mount is only 60% to 70%. Trichomoniasis also can be diagnosed on a Papanicolaou (Pap) smear, but sensitivity is low (52% to 67%), as is specificity.<sup>110</sup>

At present, culture is the best available method for confirming the presence of *T. vaginalis*.<sup>110</sup> Although culture for *T. vaginalis* is not difficult, it requires use of special media, such as Diamond or Kupferberg. The medium is incubated after inoculation, and a drop of the medium is examined daily by light microscopy for 5 to 7 days to look for motile trichomonads.

An FDA-approved DNA probe-based test for *T. vaginalis*, Affirm VP III, has sensitivity of 90% to 100% compared with culture methods.<sup>114</sup> Use of PCR testing for *T. vaginalis* was assessed in several recent studies that demonstrated higher sensitivity with PCR than with wet-mount microscopy, Diamond culture, modified Kupferberg culture, or Pap smear. The PCR test also was highly specific for *T. vaginalis*. Most importantly, PCR has excellent sensitivity and specificity for both symptomatic and asymptomatic women. An additional advantage of PCR testing is that patients can self-collect specimens from the distal vagina, precluding the need for a vaginal speculum examination.<sup>115</sup>

### Treatment

Until recently, the only treatment available in the United States for trichomoniasis was metronidazole. Tinidazole, a related 5-nitroimidazole derivative, has recently received FDA approval. An additional 5-nitroimidazole derivative, ornidazole, is available in other countries.

CDC guidelines for treatment of trichomoniasis are listed in Table 19-13.<sup>25</sup> Cure rates are equivalent (86% to 97%) for the single 2-g dose, and the 7-day regimens and side effects (mainly nausea) are similar.<sup>110,116</sup> The physician should prescribe metronidazole for the sexual partners of women with trichomoniasis.<sup>116</sup> Metronidazole can be used safely in pregnancy.<sup>116</sup>

While uncommon, relative resistance of *T. vaginalis* to metronidazole has been documented.<sup>117</sup> CDC recommendation

**Table 19-13**  
**CDC-recommended Treatment for Trichomoniasis, 2002**

#### Recommended regimen

Metronidazole 2 g orally in a single dose

#### Alternative regimen

Metronidazole 500 mg twice a day for 7 days

for treatment failures is re-treatment with metronidazole 500 mg twice daily for 7 days. If repeated failure occurs, a single 2-g dose once daily for 3 to 5 days is suggested. If patients still have persistent trichomoniasis, CDC recommends excluding reinfection, evaluating in vitro susceptibility of the isolate, and managing in consultation with an expert.<sup>26</sup> Such consultation is available through CDC.

The suggested tinidazole treatment regimen for trichomoniasis is a single 2-g oral dose. Tinidazole has been reported to be effective in cases of metronidazole-resistant trichomoniasis (cure rate of 90%) when used in a dosage of 1 g orally twice a day plus 500 mg twice a day vaginally for 14 days.

### SCABIES

Scabies is a highly contagious infection caused by the itch mite *Sarcoptes scabiei*. The adult female excavates a burrow in the skin, where fertilization takes place. Following fertilization, the female emerges and excavates a new burrow, which she extends by 0.5 to 5 mm a day as she begins laying 2 to 3 eggs per day. The eggs hatch in 3 to 4 days, and the larvae emerge from the burrow and dig into adjacent skin where three moltings occur before adulthood is achieved.

### Epidemiology, Risk Factors, and Pathogenesis

Scabies is common throughout the world and appears in epidemics at 10- to 30-year intervals.<sup>118</sup> It is more common in men than in women and in whites than in blacks. Scabies is now considered an STD, and close and prolonged contact with an infected person is required for transmission. Unlike other STDs scabies is also spread by nonsexual contact; close person-to-person contact (e.g., crowded living conditions or sharing a bed) can be responsible.

### Clinical Features

Scabies presents with a pruritic, pleomorphic rash. It has an insidious onset and a characteristic pattern of involvement that includes wrist, finger webs, elbows, axillae, genitals, and buttocks. Patients report a gradual onset of pruritus and rash over 3 to 4 weeks after the initial infestation.<sup>118</sup> With repeat infestations, the onset of symptoms is relatively prompt, within hours. Much of the symptomatology of scabies is the result of the host immune response to *S. scabiei*.<sup>118</sup>

Pruritus is the predominant symptom and may be intense. Typically, the itching is worse at night. The physical findings include presence of the burrows, a papular erythematous rash, and persistent pruritic nodules.<sup>26</sup> The burrows are 5 to 10 mm long, and the organism may be seen as a tiny brown and white speck at the inner end of the burrow.

### Diagnosis

The burrow of scabies is pathognomonic. It is a short, wavy, dirty-appearing line that often crosses skin lines and is most commonly located on finger webs, volar wrists, and elbows.<sup>118</sup> Use of a magnifying glass is sufficient, and the burrows can be more easily seen after ink staining.<sup>118</sup> Most sites also contain small, erythematous, excoriated papules. Confirmation of the diagnosis is made by identifying the mite, eggs, or fecal pellets on microscopic examination. Fresh lesions should be used for obtaining mites. Skin scrapings are preferred for microscopic identification of scabies.<sup>118</sup>

Scabies is called the great imitator because patients can have a variety of lesions. Thus, many dermatologic conditions must be considered in the differential diagnosis.<sup>118</sup> These include eczema, acute urticaria, impetigo, erythrasma, insect bites, neurodermatitis, and dermatitis herpetiformis. However, the history of insidious onset and the presence of nocturnal pruritus and of pleomorphic lesions and their characteristic distribution should strongly suggest scabies. Presence of itching in family members also indicates a high likelihood of scabies.

### Treatment

Successful treatment of scabies necessitates correct application of an effective scabicide to the patient, sexual contacts, and family members. The current CDC-recommended regimen for the treatment of scabies is permethrin cream 5% applied to all areas of the body from the neck down and washed off after 8 to 14 hours.<sup>119</sup> Alternative regimens include Lindane 1%, 1 ounce of lotion or 30 g of cream applied thinly to all areas of the body from the neck down and washed off thoroughly after 8 hours.<sup>118</sup> More recently, ivermectin 200 µg/kg orally, repeated in 2 weeks, has been suggested as an alternative therapy for scabies.<sup>120</sup>

Pregnant and lactating women should not be treated with lindane. Permethrin is recommended for the treatment of scabies in pregnant or lactating women.<sup>119</sup>

At the conclusion of therapy, the patient's underwear, nightclothes, sheets, and pillowcases should be decontaminated by machine washing or machine drying using the hot cycle or removed from body contact for more than 72 hours.<sup>118</sup>

Sexual partners and close household contacts should be treated as described previously. If no clinical improvement is noted, a single treatment after 1 week is appropriate. Clothing and bed linen used within the previous 2 days should be washed and dried by machine (hot cycle) or dry-cleaned.

### PEDICULOSIS PUBIS

*Phthirus pubis*, the crab louse, is the etiologic agent for pediculosis pubis. An estimated 3 million cases of pediculosis are treated each year in the United States. Infestation by the crab (or pubic) louse should be considered in any patient complaining of groin irritation or pruritus.

#### Epidemiology, Risk Factors, and Pathogenesis

Acquisition of *P. pubis* is nearly always through sexual contact. However, it may be spread through fomites. Pediculosis pubis is more contagious than any other STD, with a 95% chance of contracting the disease with a single sexual encounter. Pediculosis pubis is most commonly encountered during adolescence and young adulthood; from ages 15 to 19, it is more common in females, while after 20, males are more commonly infected.<sup>121</sup>

Twenty-four hours after mating, the female begins to lay eggs at a rate of approximately four per day. The eggs are attached to a hair near its root. After an incubation time of 7 days, a nymph is hatched and proceeds through three molts over a period of 8 to 9 days. Once the louse reaches sexual maturity, its life expectancy is 3 to 4 weeks.<sup>121</sup>

#### Clinical Features

The incubation time of pediculosis is 30 days. Patients come in with irritation or pruritus secondary to bites. The intense itching

is believed to be due to allergic sensitization. On occasion, patients may see the crab louse moving over the skin. Distribution involves the pubic, perineal, and perianal regions. With bites by a large number of lice over a short period of time, systemic manifestations such as mild fever, malaise, or irritability may occur.

#### Diagnosis

Visualization of lice, larvae, and nits with use of a magnifying glass is diagnostic for pediculosis pubis. Microscopic examination reveals the typical crab-like morphology.

#### Treatment

The recommended treatment regimens for pediculosis pubis include permethrin 1% cream-rinse applied to affected area and washed off after 10 minutes, pyrethrin with piperonyl butoxide applied to affected area and washed off after 10 minutes, and lindane 1% shampoo applied for 4 minutes to the affected area and then thoroughly washed off. Lindane is not recommended for pregnant or lactating women. Following either treatment, combing the infested areas with a fine-toothed comb facilitates removal of remaining lice and nits.

Re-treatment is indicated after 7 days if lice are found or eggs are observed at the hair-skin junction. Clothing or bed linen that may have been contaminated within the last 2 days should be washed and dried on the hot cycle or dry-cleaned. All sexual partners, family members, and close contacts must be treated at the same time, even if asymptomatic.

### MOLLUSCUM CONTAGIOSUM

Molluscum contagiosum is a viral skin infection of children and young adults. The molluscum contagiosum virus is a poxvirus. Characteristic small, firm, umbilicated papules occur on the extremities or trunk and, in sexually transmitted cases, in the genital area. Examination of infected cells reveals the pathognomonic molluscum bodies, which are ovoid accumulations of maturing virions.<sup>122</sup>

#### Epidemiology, Risk Factors, and Pathogenesis

Molluscum contagiosum is transmitted by skin-to-skin contact, fomites, and autoinoculation. The incubation period averages from 2 to 3 months and ranges from one week to 6 months. There are two major forms of molluscum contagiosum.<sup>26</sup> The childhood disease affects the face, trunk, and limbs and is transmitted by skin contact and fomites. Disease affecting young adults is sexually transmitted and occurs in the genital area. It is usually acquired by skin contact during sexual intercourse. Prior to the onset of the AIDS epidemic, molluscum contagiosum cases had quadrupled in the United Kingdom from the early 1970s to 1980s and increased 11-fold in the United States according to surveys of private physicians between 1966 and 1983.<sup>123,124</sup>

#### Clinical Features

Molluscum contagiosum affects normal skin rather than mucous membranes. The characteristic dome-shaped papules with central umbilication develop slowly and remain stable for long periods of time. Lesions are multiple but generally number less than 20.

Lesions are usually flesh-colored but may have a gray-white, yellow, or pink color.

The disease is usually asymptomatic, but occasionally pruritus is present. The usual life of a lesion is less than 2 months, but they can last for several years. Most commonly, the crop of molluscum contagiosum lesions tends to be self-limited and of 6- to 9-month duration.<sup>123</sup>

### Diagnosis

Examination reveals the characteristic smooth, light-colored papules with an umbilicated center. They are usually multiple and have the distribution noted previously for either childhood disease or sexually transmitted forms. Microscopic examination can confirm the diagnosis, if it is in doubt. The lesion can either be squeezed to express the white caseous material from its core or removed by curettage. The specimen is stained with Gram's, Wright's, or Giemsa stain. The cells will reveal the pathognomonic large intracytoplasmic molluscum bodies.<sup>122</sup>

### Treatment

Molluscum contagiosum is a benign and self-limited disease. While lesions often resolve spontaneously, treatment may shorten their duration and result in decreased autoinoculation or transmission. Several alternative therapies are available.<sup>123</sup> A small superficial incision in the top of the lesion may be made and the contents removed with a comedo extractor. Curettage of the lesion, followed by cautery, is effective. For multiple lesions, freezing with liquid nitrogen has been successful. Sexual partners should be examined and treated as well.

## CONDYLOMA ACUMINATUM (GENITAL WARTS)

Condylomata acuminata, or genital warts, are caused by human papillomavirus (HPV). HPVs are composed of double-stranded DNA and characterized by the ability to infect and transform epithelial cells.<sup>125</sup> Over 100 types of HPV have been described, of which 35 primarily infect the genital tract (Fig. 19-5).

The common genital HPV types are either high-risk or low-risk types based on their oncogenic potential. HPV types in the low oncogenic risk group include 6, 11, 42, 43, and 44. They are associated with genital warts, condyloma, and some cases of low-grade squamous intraepithelial lesions (LGSIL) but rarely invasive cancers. The high oncogenic risk group includes HPV types 16, 18, 31, 33, 35, and 39. These are commonly detected in women with high-grade squamous epithelial lesions (HSIL) and invasive cancers. Genital warts are the focus of this review.

### Epidemiology, Risk Factors, and Pathogenesis

An estimated 24 million Americans are infected with HPV, and between 500,000 and 1 million new cases of HPV-induced genital warts occur each year in the United States.<sup>126</sup> The prevalence of subclinical HPV infection, based on studies using PCR, is substantial, with recent studies demonstrating that at least 50% of sexually active women have been infected with one or more types of HPV. Clinically evident genital warts (*condyloma acuminatum*) continue to occur in epidemic proportions.<sup>127</sup> Gall suggests that there has been a 10-fold increase in HPV-related cases in STD clinics as well as private physician offices.<sup>128</sup> Thus, genital warts appear to be the most common viral STD. In 1995 genital warts accounted for more

**Figure 19-5** Genital warts (*condyloma acuminatum*) on the external genitalia and perineal area. (Reprinted with permission from Sweet RL, Gibbs RS: *Atlas of Infectious Diseases of the Female Genital Tract*. Philadelphia, Lippincott Williams & Wilkins, 2004.)

than 240,000 initial physician office visits.<sup>126</sup> The Institute of Medicine estimates that the economic burden of HPV in the United States exceeded \$3.8 billion in total costs in 1997 (excluding costs of HPV-related cervical cancer).<sup>6</sup> More recently, Insinga et al estimated the costs associated with genital warts in a private health plan; on average episodes of genital warts involved 3.1 physician visits and incurred costs of \$436.<sup>129</sup>

Genital HPV infections are primarily transmitted through sexual contact, and the sexual transmission of HPV associated with genital warts (*condyloma acuminatum*) is well established.<sup>125</sup> The lesions occur in the urogenital and anorectal areas. The highest prevalence is in young, sexually active adolescents. An estimated 1% of sexually active men and women between 18 and 49 years of age have external genital warts.<sup>130</sup> The infectivity rate is about 65% among sexual contacts. The average incubation period is 2 to 3 months. Women and men are affected with equal frequency.

Risk factors associated with HPV infection include increased number of sexual partners,<sup>26</sup> cigarette smoking,<sup>26</sup> and long-term use of oral contraceptives.<sup>26</sup> Winer et al followed a cohort of female university students and demonstrated that in addition to smoking and oral contraceptive use, report of a new male sexual partner, especially one known for less than 8 months before sex occurred, was predictive of incident infection.<sup>131</sup>

A higher frequency of genital warts is associated with immunosuppressive states. An increase has been reported in female renal transplant recipients,<sup>132</sup> and the frequency and severity of genital warts is increased during pregnancy.<sup>133</sup>

## Gynecologic Infectious Disease

HPV infection in HIV-infected women has been the focus of recent interest. Of most concern has been the finding that neoplastic lesions of the cervix associated with genital HPV infection progress at an increased rate in HIV-infected women.<sup>134</sup>

The HPV viral genome is organized into three major regions. There are two protein-encoding regions (early and late gene regions) and a noncoding upstream regulatory region (URR).<sup>135</sup> The URR controls transcription of the early and late regions and thus regulates production of viral protein and infectious particles (open reading frames; ORFs), which are transcriptional units that encode for proteins and are designated E1, E2, E4, E5, E6, and E7.<sup>135</sup> Early region gene expression controls replication, transcription, and cellular transformation of viral DNA. In addition it plays a role in unregulated cellular proliferation. The gene products encoded by E1 and E2 ORFs are critical for viral replication. While E6 and E7 ORFs encode proteins critical for viral replication, they also encode proteins critical for host cell immortalization and transformation. The late gene region contains two ORFs (L1 and L2, which encode structural proteins critical to production of viral capsid).<sup>135</sup>

Acute HPV infection of the genital tract probably occurs when microtrauma allows virus to enter the skin or mucosa of the genital tract.<sup>131</sup> Virus enters cells at the basal layer of the epithelium and matures as it passes through the parabasal, spinous, and granular layers of epithelium.<sup>131</sup> It is at the granular level that viral DNA replication, late region protein synthesis, and viral particle assembly occur. Following acute HPV infection, three clinical sequelae potentially can occur.<sup>135</sup> First, latent viral infection occurs when the HPV genome is stabilized as a non-integrated episome and remains in host cells without causing clinical or morphologic changes in the squamous epithelium of the genital tract. Thus, with latent infection patients display no clinical evidence of infection but still harbor HPV. Second, active infection may occur, manifested by proliferation of squamous epithelial cells into benign tumors (i.e., genital warts, condyloma acuminatum). This takes place when HPV undergoes vegetative replication. Third, high-risk oncogenic types of HPV that are associated with high-grade lesions can become integrated into the host genome. Viral integration results in loss of control of proliferation by several critical oncoproteins or tumor suppressors.

In genital warts the viral DNA is an episome and not integrated into the host DNA. Major changes take place as lesions become dysplastic or invasive.<sup>136</sup> Viral DNA is integrated into the host genome and thus can be transferred to progeny cells. Deletion of late viral genes that encode the structural viral proteins occurs. Among the early viral genes those that play a role in abnormal growth of cells (E6, E7) continue to be expressed, whereas there is a loss of those early viral genes (E1, E2) that have a negative effect on the expression of growth-promoting genes. As a result, dysplastic and malignant lesions tend not to produce virus particles.

### Clinical Features

The American Medical Association Expert Panel on External Genital Warts developed a consensus statement regarding diagnosis, treatment, and evaluation of patients with external genital warts, as summarized by Beutner et al.<sup>137</sup> External genital warts are defined as visible warts occurring in the urogenital and/or

anorectal regions. The morphologic appearance of external genital warts is similar whether they involve the penis, urethra, perineum, anus, rectum, vulva, or vagina. Lesions on the cervix may be flat and endophytic. External genital warts are frequently multifocal presenting with one or more lesions at a single anatomic site (e.g., vulva). Alternatively, they may be multicentric presenting with lesions on different anatomic sites.<sup>137</sup>

The AMA consensus group delineated four morphologic types of external genital warts: (1) condylomata acuminata that are cauliflower-shaped; (2) papular warts that are dome-shaped (usually skin-colored) 1- to 4-mm papules; (3) keratotic genital warts that have a thick horny layer and may resemble a common wart or seborrheic keratosis; and (4) flat-topped papules that appear macular to slightly raised.<sup>137</sup> These morphologic types are usually associated with one of the two major types of skin found in the genital area.<sup>5</sup> Condylomata acuminata occur generally on moist, partially keratinized and non-hair-bearing skin. Keratotic and smooth papular external genital warts occur on fully keratinized skin (hair-bearing or non-hair-bearing). Flat-topped papular warts occur on either type of skin surface.

Genital warts in women are generally located on the external genitalia and perineal regions. Exophytic genital warts (condylomata acuminata) usually present initially on the fourchette and adjacent labia and then may spread rapidly to involve other parts of the vulva. The vagina may be affected, rarely extensively. In addition, the cervix may be involved but with "flat condylomata" rather than the typical exophytic lesions. Cervical lesions are flat and endophytic condylomata that can usually be recognized only with the aid of a colposcope.

Patients with genital warts complain of lesions on their genitalia and rarely report other symptoms. Occasionally patients have itching, burning, pain, or bleeding.

### Diagnosis

Koutsky and Kiviat emphasize the importance of diagnosing two clinical manifestations of genital HPV infection: (1) genital warts that can be visualized with the naked eye, and (2) squamous intraepithelial lesions (SILs) of the cervix that can be detected by routine cytologic screening.<sup>125</sup>

Most condylomata are so characteristic in appearance that the diagnosis is primarily made on visual examination alone. External genital warts usually can be easily visualized with gross inspection, and such clinical is accurate and consistent with histologic diagnosis.<sup>137</sup> Some experts suggest that use of bright light and a hand lens, magnifying loop, or colposcope may be helpful in identifying external genital warts. In women lesions that must be differentiated from genital condylomata include epithelial papillae, small sebaceous glands, and perianal fibro-epithelial polyps. The most important infection that must be differentiated from genital warts is the condyloma latum of secondary syphilis. If lesions appear atypical or the diagnosis is uncertain, biopsy should be performed. Additional indications for biopsy include (1) progression of disease during treatment; (2) prompt or frequent recurrence; and (3) warts that are pigmented, indurated, ulcerated, or fixed to underlying tissue.<sup>137</sup> Histologically, condylomata acuminata are characterized by papillate epidermal hyperplasia, parakeratosis, koilocytes, occasional atypical mitotic figures, and increased numbers of dilated and tortuous capillaries.

## Treatment

The therapeutic approach for HPV infection of the genital tract is dependent on the anatomic location of disease (external genitalia/perianal, cervical, vaginal, or urethral), the clinical presentation of disease (clinical vs. subclinical), and the extent of disease. The primary goal of treatment of external genital warts (*condyloma acuminatum*) is to eliminate warts that cause physical or psychological symptoms or distress.<sup>137</sup> Elimination of genital warts may or may not decrease infectivity because internal sites (vagina or cervix) and clinically normal skin may act as reservoirs for infection.<sup>137</sup>

CDC issued recommendations for the treatment of HPV infection in 2002.<sup>138</sup> In most patients treatment will include wart-free periods of varying length. CDC notes that no evidence indicates that currently available treatment modalities eradicate or affect the natural history of HPV infection.<sup>138</sup> Visible genital warts that are not treated may resolve spontaneously, remain unchanged, or increase in size or number.

For external genital/perianal warts (*condyloma acuminatum*) the recommended therapeutic measures are listed in Table 19-14. None of the currently available treatments is superior to other treatments, and no single treatment is ideal for all patients or all warts.<sup>138</sup> Available treatments for visible genital warts are divided into two categories: (1) patient-applied therapies (e.g., podofilox and imiquimod) and (2) provider-administered treatments (e.g., cryotherapy, podophyllin resin, trichloroacetic acid [TCA], bichloroacetic acid [BCA], interferon, and surgery). Factors influencing choice of treatment include wart size, wart number, anatomic site, wart morphology, patient preference, cost of treatment, convenience, side effects, and provider experience.<sup>138</sup> Many patients require a course of therapy rather than a single treatment, and thus it is important that providers have a treatment plan or protocol for the management of genital

warts.<sup>138</sup> CDC recommends that the treatment modality be changed if the patient has not improved substantially after three provider-administered treatments or if warts have not completely cleared following six treatments.<sup>138</sup>

The use of podophyllin, podofilox, and imiquimod is contraindicated in pregnancy. During pregnancy the best approach to treatment is removal of lesions by excision, electrocautery, or cryosurgery. TCA application has been used in pregnancy without adverse effects.<sup>139</sup> Laser therapy is another alternative for pregnant women with extensive disease.

For the treatment of vaginal exophytic warts, the recommendations include (1) cryotherapy with liquid nitrogen, (2) TCA or BCA 80% to 90%, or (3) podophyllin 10% to 25% in compound tincture of benzoin.<sup>138</sup> Because of concern about potential systemic absorption it is best not to use podophyllin in the vagina. Podophyllin is contraindicated in pregnancy. Podofilox is not approved for vaginal use, since the patient can not visualize the lesions for application. For urethral meatus warts either cryotherapy with liquid nitrogen or podophyllin is recommended.<sup>138</sup> With anal warts cryotherapy with liquid nitrogen, TCA or BCA 80% to 90%, or surgical excision is recommended.<sup>138</sup>

<b>Recommended regimens</b>	
Patient-applied	
1.	Podofilox 0.5% solution or gel: Apply podofilox-solution with a cotton swab, or podofilox gel with a finger, to visible genital warts twice a day for 3 days, followed by 4 days of no therapy. Repeat cycle as necessary for a total of four cycles. or
2.	Imiquimod 5% cream: Apply with finger at bedtime, 3 times a week for up to 16 weeks
Provider-administered	
1.	Cryotherapy with liquid nitrogen or cryoprobe. Repeat every 1 to 2 weeks. or
2.	Podophyllin resin 10%-25% in compound tincture or benzoin. Repeat weekly if necessary. or
3.	TCA or BCA 80%-90%. Repeat weekly if necessary. or
4.	Surgical removal by tangential scissors excision, tangential shave excision, curettage, or electrosurgery
<b>Alternative regimens</b>	
1.	Intralesional interferon or
2.	Laser surgery

## KEY POINTS

- Clinical signs of pelvic inflammatory disease (PID) are vaginal leukorrhea, irregular uterine bleeding, breakthrough bleeding while taking oral contraceptives, vague lower abdominal pain, possible elevated body temperature.
- *Chlamydia trachomatis* tends to cause minimal symptoms (asymptomatic PID), can go undetected or result in infertility or ectopic pregnancy.
- Gonococcal or polymicrobial PID can cause significant destruction of fallopian tubes and development of pyosalpinx or tubo-ovarian abscess.
- All sexually active women should be screened for sexually transmitted infections (STIs) if they are not in a monogamous relationship, do not live with their sexual partner, have endocervical mucopus, their endocervical epithelium is hypertrophied, their cervix bleeds easily when gently touched, or a sexual partner is known to have an STI.
- A patient found to have chlamydia or gonorrhea should be treated for both STIs.
- A patient found to have trichomoniasis should be tested for other STIs.

PID has been and continues to be a devastating disease that primarily affects women in the reproductive age group. However, the disease can occur in any group if conditions permit bacteria to gain entrance to the lower or upper genitalia. The genital tract is a complex system of organs beginning with the vulva, leading to the vagina, and progressing to the cervix, uterus, fallopian tubes, and pelvic cavity. The genital tract can be viewed as a conduit leading from microbe-contaminated areas—the vulva, vagina, and cervix—to sterile areas—the uterus, fallopian tubes, pelvic cavity, and abdominal cavity.

The creation of broad-spectrum antibiotics and prevention programs caused a significant decrease in both the progression of sexually transmitted bacteria that infect the lower genital tract and the progression to PID. Educational and prevention programs have made an impact on the transmission of sexually transmitted diseases (STDs), which can lead to PID. The development of broad-spectrum antibiotics along with shorter treatment regimens has led to better compliance. Better compliance resulted in quicker eradication of the infecting bacteria, including both STDs and vaginal microflora, and reduced the progression of infection leading to PID.

## EPIDEMIOLOGY

In the United States there are an estimated 9 million cases of STDs among individuals between the ages of 15 and 24 years.<sup>1</sup> The estimated total costs of these STDs in the United States are between \$9.3 and \$15.5 billion.<sup>2,3</sup>

PID is actually a spectrum of infections that begins with cervicitis and can progress to endometritis, salpingitis, and tubo-ovarian abscess. The two sexually transmitted bacteria responsible for the majority of PID cases are *Chlamydia trachomatis* and *Neisseria gonorrhoeae*. Women at the greatest risk for acquiring an STD and PID are between 15 and 25 years of age.<sup>4,5</sup> All sexually active women are at risk for acquiring one or more STDs as well as PID if they place themselves at risk (Table 20-1). The Centers for Disease Control and Prevention (CDC) reported 80,000 cases of acute PID and approximately 40,000 cases of chronic PID in hospitals in 2002.<sup>6</sup> CDC estimated that there were 200,000 initial patient visits to physicians' offices for PID in 2002.<sup>6</sup> CDC also reported that from 1980 until 2000 the incidence of PID was declining, but there appeared to be an increase in the number of acute PID cases in 2001: in 1980 there were approximately 108,000 cases, in 2000 there were approximately 60,000 cases, in 2001 there were 70,000 cases, and in 2002 about 80,000 cases of PID.

Throughout the 1980s and early 1990s cases of PID steadily increased, and the incidence parallels the increase in the number of *C. trachomatis* and *N. gonorrhoeae* cases. However, when a decrease in the number of *N. gonorrhoeae* cases was seen there was a concurrent decrease in the number of PID cases. This decrease has been associated with a plateau in the number of PID cases. However, it is difficult to determine whether this plateau is real or a result of the restrictions placed on hospital admissions by the insurance industry, thus resulting in fewer individuals receiving treatment. In addition, patients are frequently given antibiotics for a variety of suspected infections, antibiotics that are also used to treat cervical chlamydial infection. However, chlamydial infection is frequently asymptomatic and, if left untreated, can progress to asymptomatic upper genital tract infection. Thus, the patient does not realize she has the infection until she attempts to become pregnant and finds out that she is infertile or has an ectopic pregnancy.

PID is a primary sequela in 10% to 40% of acute, untreated, and undiagnosed cervical chlamydial infection.<sup>5,7</sup> It is estimated that PID develops in 3% to 6% of acute cases of treated chlamydial cervicitis because progression of the infection occurred before treatment was initiated.<sup>8</sup> The cost for PID, including the sequelae of chronic pelvic pain, ectopic pregnancy, and treatment for infertility, is estimated to be \$1060 to

**Table 20-1**  
**Risk Factors for Pelvic Inflammatory Disease Acquisition**

1. Multiple sexual partners
2. Failure to use barrier contraception
3. Illicit drug use
4. Sexual partner with an STD
5. History of STD

\$3626.<sup>9,10</sup> However, ectopic pregnancy and infertility are unpredictable, on a per case basis, following an episode of PID because the initial episode can be asymptomatic. Ectopic pregnancy can result from damage to the lining of the fallopian tubes. In fact, 95% of ectopic pregnancies occur in the fallopian tubes, with 2.5% found in the cornua of the uterus and the remainder in the ovary, cervix, and abdominal cavity.<sup>11</sup> Ectopic pregnancy continues to be a significant cause of morbidity and mortality, responsible for 10% to 15% of all maternal deaths.<sup>12</sup> The incidence of ectopic pregnancy is 19.7 cases per 1000 pregnancies in the United States, and it is the leading cause of maternal mortality in the first trimester.<sup>13</sup> PID is the most common precursor to ectopic pregnancy. The bacteria that can damage the fallopian tubes, and readily do so, are *C. trachomatis* and *N. gonorrhoeae*. These bacteria typically cause asymptomatic infection that can result in significant damage to the ciliated and nonciliated epithelial cells lining the fallopian tubes. Non-functioning ciliated cells result, and the inflammatory response can cause adhesions within the fallopian tube (Fig. 20-1). This can all take place without the patient experiencing any significant pain. Frequently the patient may have cramping, which resembles the cramping associated with menstruation, or irregular or

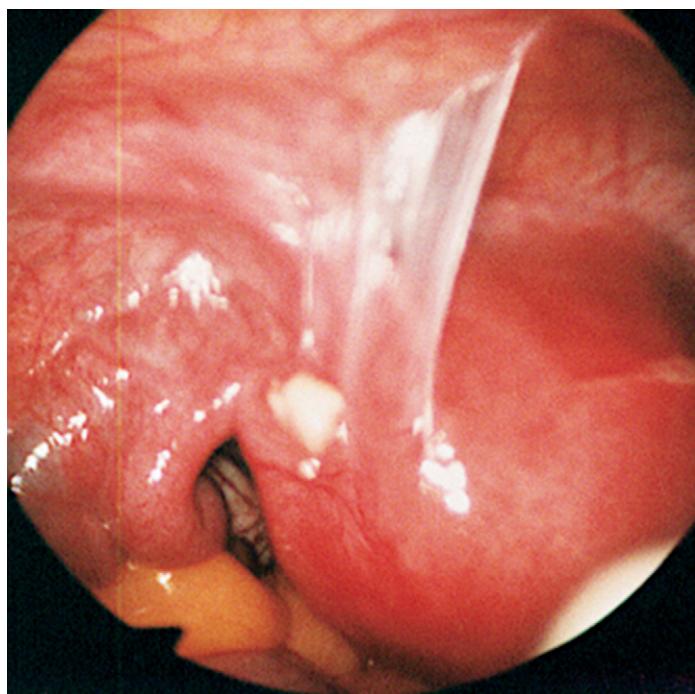

breakthrough bleeding. Unfortunately, the endogenous aerobic, facultative, and obligate anaerobes also can cause significant fallopian tube damage, but unlike *C. trachomatis* and *N. gonorrhoeae*, the former bacteria typically cause symptomatic infection. To prevent the sequelae of PID, the examining physician must be alert not only to the pertinent facts in the patient's history that place her at risk for PID but also to the subtle clinical signs of pelvic infection (cervicitis, endometritis, and salpingitis).

## MICROBIOLOGY

The two most common sexually transmitted bacteria that cause PID are *C. trachomatis* and *N. gonorrhoeae*, separately or together. In fact, 40% of cases of cervicitis are caused by concomitant infection with both of these bacteria.<sup>14</sup> Infection with either or both can be asymptomatic; therefore, these infections are typically diagnosed by the history or the pelvic examination reveals a clinical clue of infection.

Infection of the upper genital tract can occur either from the endogenous vaginal microflora secondary to infection by *C. trachomatis* and/or *N. gonorrhoeae* or via contamination from inflammatory bowel disease, for example, diverticulitis. There has been much speculation about an association between bacterial vaginosis and PID. Some investigators draw such an association because in patients who develop tubo-ovarian abscesses, obligate anaerobic bacteria are often recovered. However, other investigators report no such bacteria in patients with acute gonococcal PID.<sup>15</sup> That the bacteriology is qualitative and not quantitative is a common error made in many studies. The mere presence of a bacterium isolated from the lower genital tract does not mean that it is significant. Another problem is that isolating bacteria from the endometrium cannot be regarded as definitive proof that the organism is a causative agent in endometritis when instead it may be a contaminant from the lower genital tract. Other erroneous conclusions regarding the failure to recover anaerobes are that the specimens were improperly collected, were not placed in an appropriate transport medium, or were not processed appropriately by the laboratory. Not all abscesses contain obligate anaerobic bacteria. The involvement of obligate anaerobic bacteria in tubo-ovarian abscesses can originate in one of four ways: (1) bacteria ascend from the lower genital tract (a plausible hypothesis); (2) the bowel becomes inflamed because infectious exudate from the fallopian tubes covers the rectosigmoid colon and the bacteria migrate across an inflamed intact bowel; (3) a patient with diverticulitis can have an inflamed diverticulum fuse with the fallopian tube or ovary and, through pressure necrosis, a fistula forms, providing a conduit for bacteria to migrate from the large bowel to the adnexa; or (4) bacteria from the lower genital tract can be forcibly pushed into the upper genital tract during procedures, for example, hysterosalpingography, artificial insemination, chromoperturbation, hysteroscopy, and fetal reduction performed transvaginally. In fact, any procedure invading the upper genital tract via the transvaginal/cervical route can induce an upper genital tract infection if the vaginal flora is significantly altered, for example, if there is a preponderance of gram-negative bacteria.

The development of a tubo-ovarian abscess must be preceded by a break in the ovarian cortex. This usually occurs when there

**Figure 20-1** Filmy adhesions between the uterus and anterior abdominal wall.

is spontaneous rupture of the ovarian cortex, for example, with ovulation or rupture of an ovarian cyst. If infected fluid is exiting the fallopian tube at the time of ovulation, an avenue for entrance of bacteria through the ruptured cortex of the ovary exists. Once bacteria enter the ovary, they can reproduce and penetrate deeper ovarian tissue, resulting in an infected ovary.

Another potential mechanism is an inflamed and infected fallopian tube densely adherent to the ovary. The pressure builds within the pyosalpinx, and via pressure necrosis the ovarian cortex is breached, which allows infected material to enter the ovary. These proposed mechanisms allow bacteria to gain entrance to sterile tissue and then grow, causing additional tissue destruction.

The progression from symptomatic or asymptomatic acute salpingitis to pyosalpinx to either hydrosalpinx or tubo-ovarian abscess depends on the bacteria involved. If the infection involves only *C. trachomatis*, *N. gonorrhoeae*, or both, the infection may not progress to abscess formation. If facultative and/or anaerobic bacteria become involved in the infection, then abscess development is more likely to occur. Infection of the cervix with either of these sexually transmitted bacteria is typically asymptomatic and if the subtle clinical presentation goes unnoticed, progression can continue. Therefore, the physician should proceed with the examination and obtain endocervical specimens for the detection of *C. trachomatis* and *N. gonorrhoeae*. Since there is no way to determine the duration of infection, the physician should consider that the infection has been in the cervix long enough to allow for ascending infection. Treatment should include coverage for upper genital tract infection.

## CLINICAL SIGNS AND SYMPTOMS

The initial infection begins with cervicitis and is usually asymptomatic but the patient may experience either postcoital bleeding or acute onset dyspareunia. Examination, in the presence of cervical infection, reveals numerous white blood cells (WBCs) in the vaginal discharge.<sup>16,17</sup> The infected cervix can appear inflamed, that is, the endocervical columnar epithelium becomes hypertrophied, markedly erythematous, and everted. It can be fragile and bleed easily when gently touched with a cotton-tipped applicator or when a specimen for a Papanicolaou (Pap) smear is obtained. The patient is frequently without symptoms and does not realize she is infected (has cervicitis). Untreated cervicitis can result in progression of infection to the uterus, which is known as endometritis.

Pelvic examination of a patient with cervicitis, endometritis, and salpingitis frequently reveals a purulent vaginal discharge. The discharge contains a large number of WBCs, and the morphology of the endogenous bacterial microflora can range from one dominated by large bacillary forms (consistent with lactobacilli) to one containing a variety of bacterial morphotypes. The cervix will be tender to palpation and motion. A cotton- or Dacron-tipped swab is inserted into the endocervical canal and examined for the presence of mucopus<sup>18-20</sup> (Fig. 20-2). Evaluation of a patient suspected of having cervicitis includes obtaining specimens from the endocervix for the isolation of *C. trachomatis* and *N. gonorrhoeae*.

The patient with endometritis may fail to realize that symptoms such as mild lower abdominal pain or cramping can

**Figure 20-2 Endocervical mucopus.**

be associated with irregular uterine bleeding or spotting. The patient taking oral contraceptive pills who has developed endometritis also can develop breakthrough bleeding. Thus, the symptoms of endometritis can be mistaken for an irregularity in estrogen and progesterone production or the presence of a submucous fibroid or endometrial polyp. The presence of endometrial cancer, however, is unlikely, since PID usually occurs in women of young reproductive age and they are unlikely to develop endometrial cancer. Patients with more advanced endometritis can have fever, purulent vaginal discharge, lower abdominal pain, or intensified cramping.

Pelvic examination can reveal the presence of an associated cervicitis, and uterine tenderness on palpation and motion. This examination should include an endometrial biopsy. The biopsy specimen should be divided as follows: (1) a portion submitted for histologic analysis; (2) a portion placed in transport medium for the processing, isolation, and identification of aerobic and facultative bacteria; (3) a portion placed in a proper transport medium for the isolation and identification of *C. trachomatis* and *N. gonorrhoeae*; and (4) a portion placed in transport medium for the processing, isolation, and identification of obligate anaerobic bacteria.

Patients with salpingitis can be completely asymptomatic, have vague symptoms, or be symptomatic. The patient can also have an elevated temperature, but less than 101°F. In a patient with salpingitis, the bimanual pelvic examination reveals the presence of pain and tenderness on palpation and motion of the adnexa.

The following laboratory tests should be obtained from the patient's venous blood work: a complete blood count, to determine whether the WBC count is elevated and whether the neutrophils are elevated; blood urea nitrogen (BUN); creatinine; and electrolytes. A C-reactive protein level or sedimentation rate should also be obtained. If a pelvic mass is suspected, a pelvic ultrasound examination should be obtained. If a mass is present, the ultrasound examination can differentiate between agglutination of the bowel (which typically appears as an amorphous mass) and the adnexa and the presence of an abscess (a uniloculated or multiloculated cystic mass). If an abscess is

## Gynecologic Infectious Disease

present, the characteristics of the abscess can be discerned, whether it is uniloculated or multiloculated, and whether the external walls are thin or thick. These characteristics may play a role in the success or failure of antibiotic therapy in the treatment of tubo-ovarian abscesses. However, there is no scientific basis for the role of the characteristics of an abscess, that is, whether the abscess is uniloculated or multiloculated or thick- or thin-walled, and whether these characteristics play a role in antibiotic treatment. Ultrasonographic examination can be helpful in determining whether there is free fluid in the pelvis. If a patient comes in with PID, free fluid in the pelvis, elevated temperature, and abdominal/pelvic rebound tenderness, a ruptured or leaking tubo-ovarian abscess should be suspected. This is a surgical emergency. A delay in administering antibiotic therapy and surgical intervention results in significant morbidity and mortality.

The patient with intact tubo-ovarian abscesses is at low risk for bacteremia and sepsis. The marked inflammation of the pelvis and abdominal peritoneum results in dilation of blood vessels, allowing for the transmigration of bacteria and resulting in bacteremia. The presence of free purulent fluid containing large numbers of bacteria, including abscessogenic combinations in the peritoneal cavity, results in the potential for abscesses to develop through the abdominal and pelvic cavities. There is also a release of endotoxins, resulting in the up-regulating of the cytokine system, which if left unchecked will lead to the release of tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) and then to septic shock.

Laparoscopy has become an extremely useful tool for diagnosing pelvic disease, and it is particularly useful for both diagnosing and treating PID. However, interpreting the appearance of the fallopian tubes may be difficult at times. A study by Molander and colleagues found that the accuracy of laparoscopic diagnosis of PID was 78%, the sensitivity was 27%, and the specificity was 92%.<sup>21</sup> These investigators found that the laparoscopic diagnosis of PID was inferior to histologically proved PID. However, laparoscopy can be used to determine the degree of infection by noting the presence or absence of edema and erythema of the uterus, tubal erythema and edema, tubal adhesions, status of tubal fimbriae, and type of fluid present in the cul-de-sac (serous, serosanguineous, bloody, or purulent). Laparoscopy without the aid of previous imaging studies may not reveal whether there is an intraloop bowel abscess or a tubo-ovarian abscess, and how complex the tubo-ovarian abscess is. In addition, the physician can determine by the presence of perihepatic adhesions whether the infection has progressed out of the pelvis. This is often referred to as the Fitz-Hugh-Curtis syndrome.<sup>22–24</sup> However, the presence of perihepatic adhesions is not pathognomonic of past PID. Perihepatic adhesion can result from any inflammatory process that involves the surface of the liver and the anterior abdominal wall overlying the liver.<sup>25,26</sup>

## MANAGEMENT

The first consideration is to determine whether the patient can be treated as an outpatient or whether hospitalization is necessary (Table 20-2). Patients with signs and symptoms of mild disease can be treated as outpatients. However, the patient must be compliant to taking the prescribed antibiotics and

**Table 20-2**  
**Characteristics of Pelvic Inflammatory Disease to Determine Whether Patient Should Be Treated as Outpatient or Inpatient**

Outpatient Treatment	Inpatient Treatment
1. Absence of nausea and vomiting	1. Temperature $\geq$ 101°F
2. Oral temperature < 101°F	2. Markedly elevated WBC count
3. Absence of a pelvic mass	3. Patient has nausea or vomiting
4. Compliant patient	4. Presence of peritonitis
5. No evidence of pelvic or abdominal peritonitis	5. Presence of pelvic mass

appear for follow-up evaluation at the specified times. The patient should also refrain from sexual intercourse and douching. The patient should be reevaluated in 72 hours. The goal of treatment is to (1) eradicate the offending bacteria, (2) prevent damage to the fallopian tubes that can result in infertility or ectopic pregnancy, and (3) prevent the formation of tubo-ovarian abscesses. Since acute early PID is most commonly, but not exclusively, caused by *C. trachomatis* and/or *N. gonorrhoeae* the antibiotic therapy should provide excellent coverage against both. In addition, since it is not possible to determine the time sequence between acquisition of the infecting bacteria, the progression from lower to upper genital tract, and possible damage to upper genital tract organs, additional antibiotic coverage for gram-negative and gram-positive facultative and obligate anaerobic bacteria should be provided.

Patients treated as outpatients should receive antibiotics that provide good activity against *C. trachomatis*; *N. gonorrhoeae*; and aerobic, facultative, and obligate anaerobic bacteria (Table 20-3). The patient must be compliant and not have nausea.

Treatment of acute uncomplicated PID in patients for whom there are uncertainties regarding compliance should be in the hospital. Intravenous antibiotic therapy should be considered in patients when there are concerns about the extent of the disease.<sup>27</sup> If the patient has an elevated temperature, has continued lower abdominal pain, or has a pelvic mass, she should be admitted to the hospital and reevaluated to determine whether she truly has PID. Imaging studies should be considered to determine whether a mass is present in the pelvis. The use of ultrasound to reveal the presence of a mass can have significant bearing on the management of the PID patient. The characteristics of a suspected tubo-ovarian abscess also can have significant implications with regard to medical management. A uniloculated abscess with a thin wall is more likely to respond to antibiotic therapy in contrast to the thick-walled, multiloculated abscess (Figs. 20-3 to 20-6). The latter is likely to have a decreased blood supply; therefore, antibiotics are less likely to achieve the concentrations needed to kill the offending bacteria. In addition, fluid present in the pelvis can indicate a leaking or ruptured tubo-ovarian abscess. If there was evidence of pelvic peritonitis and ileus, then the diagnosis of a leaking or ruptured abscess can be made. In this instance, antibiotic therapy alone is not indicated, and appropriate management is depicted in Table 20-4.

Intravenous antibiotics should be continued until the patient is afebrile for 72 hours, the WBC count returns to normal, peristalsis returns to the bowel, and the patient is tolerating

Table 20-3 Antibiotic Choices for Treatment of PID	
Outpatient Treatment	Inpatient Treatment
1. Cefoxitin 2 g IM + probenecid 1 g orally <i>plus</i> doxycycline 100 mg orally twice daily for 10–14 days or tetracycline 500 mg orally four times daily for 10–14 days*	1. Cefoxitin 2 g IV every 6 hours, or cefotetan IV 2 g every 12 hours <i>plus</i> doxycycline 100 mg orally or IV every 12 hours <sup>†</sup> <i>or</i>
2. Metronidazole 500 mg three times daily <i>plus</i> levofloxacin 500 mg once daily for 10–14 days <sup>‡</sup>	2. Clindamycin 900 mg IV every 8 hours <i>plus</i> gentamicin loading dose IV or IM (2 mg/kg body weight), followed by maintenance dose (1.5 mg/kg) every 8 hours <sup>§</sup>
3. Ofloxacin 400 mg orally every 12 hours for 10 days <sup>‡</sup>	3. Ampicillin/sulbactam 3 g IV every 6 hours until signs and symptoms have resolved, followed by doxycycline 100 mg orally twice daily for 10 days <sup>¶</sup>

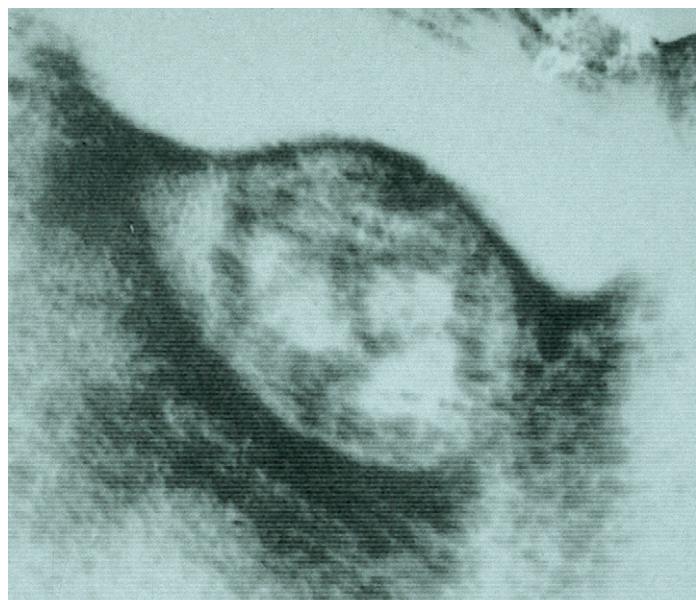

Figure 20-5 Ultrasonogram demonstrating multiloculated tubo-ovarian abscess.

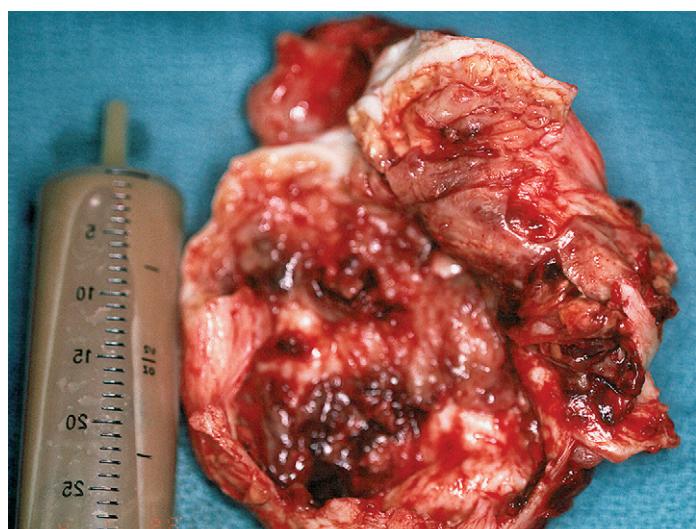

Figure 20-6 Gross specimen of multiloculated tubo-ovarian abscess.

**Table 20-4**  
**Management of Patient with Leaking or Ruptured Tubo-ovarian Abscess**

1. Laboratory tests: CBC with differential, serum electrolytes, blood urea nitrogen, blood glucose, liver enzymes and functions
2. Imaging studies of the pelvis to reveal detail of the pelvic organs: Ultrasonography and computed tomography (CT)
3. Immediate administration of broad-spectrum antibiotics IV
  - a. Metronidazole 500 mg every 8 hours *plus* ampicillin 2 g every 8 hours *plus* gentamicin 5 mg/kg body weight every 24 hours  
or
  - b. Clindamycin 900 mg every 8 hours *plus* ampicillin 2 g every 8 hours *plus* gentamicin 5 mg/kg body weight every 8 hours  
or
  - c. Piperacillin 3.375 g every 6 hours *plus* gentamicin 5 mg/kg body weight every 24 hours
4. Laparotomy
  - a. Lower abdominal incision that can be extended to the upper abdomen
  - b. Obtain specimens of infected tissue and purulent fluid for gram-staining, culture, isolation, and identification of bacteria
  - c. Remove all infected tissue: typically the woman who develops PID that progresses to tubo-ovarian abscess almost always develops bilateral tubo-ovarian abscesses
  - d. Patients who desire to retain child-bearing ability should not have the uterus removed

liquid and solid nutrition. Antibiotic therapy should then be changed to oral therapy, for example, metronidazole 500 mg every 8 hours plus levofloxacin 500 mg every 24 hours for a total of 10 days. There are no data to guide the addition of oral antibiotic therapy, but the absence of pelvic tenderness can be used as a criterion for discontinuing antibiotic therapy.

## PROGRESSION OF PELVIC INFLAMMATORY DISEASE

PID is a complex infection that ascends from the cervix to the uterus and then to the fallopian tubes. The progression is difficult to track because the initial infection and secondary infections, cervicitis and endometritis, are more often asymptomatic than not. Therefore, patients who practice high-risk sexual behavior should be suspected of having at least the initial stages of PID until proved otherwise. This is extremely important because the sequelae are devastating, and it is crucial that the patient be thoroughly evaluated. Asymptomatic, untreated, or inappropriately treated PID can result in progression of this infection.

Infection of the fallopian tubes can result in resolution without damage if antibiotic therapy is instituted early. However, women experiencing an initial episode of PID have an approximately 13% risk of becoming infertile. If the individual has a second PID episode there is a 33% chance of infertility, and the chance increases to 75% with a third episode of PID. If treatment is instituted after damage has occurred or if the infection was mild, there can be residual damage to the tube's endothelium. The damage may not be enough to leave the patient infertile but does result in a tube that does not function properly. This puts the patient at risk for ectopic pregnancy. Approximately 1.2% to 1.4% of all reported pregnancies are

ectopic.<sup>28,29</sup> Ectopic pregnancy continues to be the leading cause of maternal death during the first trimester of pregnancy as well as the cause of reduction in fertility.<sup>30-32</sup> Several factors increase an individual's risk of ectopic pregnancy (Table 20-5), with STDs that cause PID, such as *N. gonorrhoeae* and *C. trachomatis*, being the most common.<sup>33-39</sup> Even though STDs such as gonorrhea and chlamydia frequently cause PID, these bacteria tend to cause a milder form of the disease. The aerobic, facultative, and obligate anaerobic bacteria are more likely responsible for more destructive PID, for example, tubo-ovarian abscess formation.<sup>40</sup>

Once the fallopian tubes become infected, a substantial inflammatory response within the lumen of the tube as well as throughout the wall and involving the serosa of the tube occurs. This inflammatory reaction results in the formation of adhesions within the lumen of the fallopian tube and between the sera and adjacent organs. The inflammatory response also occurs at the fimbriae and results in agglutination. This intraluminal inflammatory response results in occlusion at the interstitial portion of the tube. The interstitial portion of the tube is embedded within the myometrium of the cornua of the uterus, thus preventing distention of this portion of the fallopian tube and allowing early occlusion of the proximal portion of that tube. The agglutination of the fimbriae results in occlusion of the distal end of the fallopian tube and, along with occlusion of the proximal end, results in a build-up of infected material within the lumen of the tube. There is a progressive build up of intraluminal fluid as the inflammatory process and infection progress. This intraluminal progressive build-up of fluid causes compression of the ciliated cells lining the lumen of the fallopian tube, which results in cessation of the ciliated movement. This malfunction of the cilia does not allow for migration of the fertilized egg, and the creation of false passages within the lumen of the fallopian tube, via the formation of adhesions, results in the fertilized egg becoming trapped within the fallopian tube. The development of a closed fallopian tube with contained infection is termed a *pyosalpinx* and is an abscess. The pyosalpinx can become symptomatic or undergo resolution and become a hydrosalpinx. A hydrosalpinx is, in essence, a nonfunctioning fallopian tube.

Infection involving the fallopian tubes can progress to the formation of a tubo-ovarian abscess. There are two theories with regard to the development of a tubo-ovarian abscess: (1) infectious fluid exits from the fallopian tube and enters the ovary via a ruptured follicle at the time of ovulation, and (2) the infected fallopian tube becomes adherent to the ovary and via pressure necrosis there is a breakdown of the fallopian tube ovarian walls and infected fluid from the fallopian tube enters

**Table 20-5**  
**Risk Factors for Development of Ectopic Pregnancy**

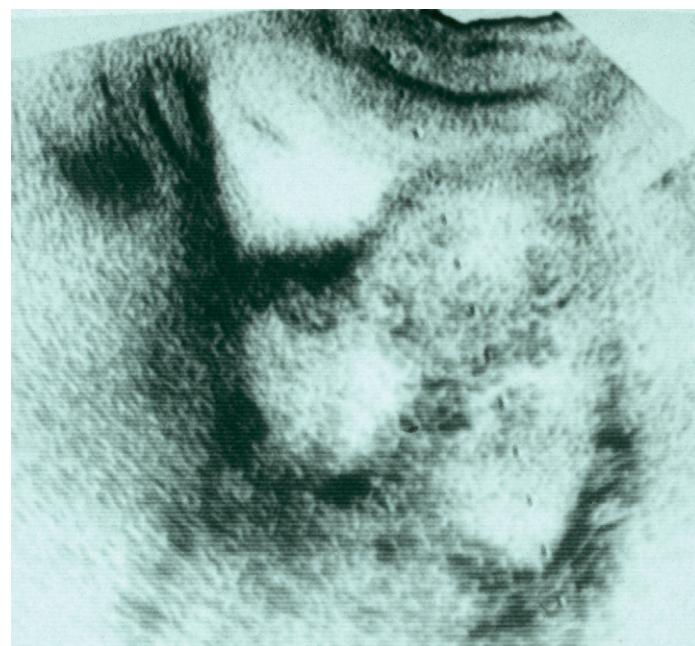

1. Previous ectopic pregnancy
2. Cigarette smoking
3. Pelvic surgery
4. Use of an IUD
5. Having had an STD that results in PID

the ovary. Typically in the absence of a foreign body, for example, an intrauterine device, tubo-ovarian abscesses that develop in association with PID are bilateral (Fig. 20-7). A tubo-ovarian abscess that develops in association with a foreign body or diverticulitis is almost always unilateral.

The diagnosis of tubo-ovarian abscesses can be established with a high-degree of certainty with the assistance of either an ultrasonogram or a CT scan. Once again, the structure of the abscess will play a role in whether the abscess is likely or unlikely to respond to antibiotic therapy. In addition, the patient with peritonitis should be suspected of having a ruptured tubo-ovarian abscess. Imaging studies that reveal the presence of fluid in the pelvis or abdominal cavity, pain with rebound tenderness, or pain, elevated body temperature, and an elevated white blood cell count should be brought to the operating room for exploratory surgery. Broad-spectrum antibiotics should be administered immediately after the diagnosis is made (Table 20-6). There should be no delay in bringing the patient to surgery because a patient with a ruptured tubo-ovarian abscess is to be considered a medical and surgical emergency with a significant potential for mortality.

If imaging studies do not indicate any degree of rupture of the abscess or abscesses, consideration can be given to medical management. The anatomic characteristics of the abscesses can be used to predict the potential success or failure of antibiotic therapy. A uniloculated, thin-walled abscess is more likely to respond to antibiotic therapy. A multiloculated, thin-walled abscess is more likely to respond positively to antibiotic therapy than a thick-walled, multiloculated abscess. A thick wall implies that the blood supply to the ovary is compromised; therefore, antibiotic levels to and into the abscess will likely be below the minimum inhibitory concentration required to kill the bacteria.

Patients being treated for PID, with or without tubo-ovarian abscesses, should be monitored closely for signs of improvement or deterioration. Patients with uncomplicated PID—without a

**Figure 20-7** Ultrasound image showing bilateral tubo-ovarian abscesses.

**Table 20-6**  
Author's Recommendations for Medical and Surgical Management  
of Patient with Tubo-ovarian Abscess

1. Laboratory tests
  - a. CBC with differential
  - b. Electrolytes
  - c. BUN
  - d. Creatinine
  - e. Glucose
  - f. Liver enzymes
2. Imaging studies
  - a. Ultrasonography
  - b. CT with contrast of the abdomen and pelvis
3. Antibiotic choices (IV)
  - a. Clindamycin (900 mg every 8 h) *plus* ampicillin (2 g every 6 h) *plus* gentamicin (5 mg/kg of body weight every 24 h; blood trough levels should be obtained prior to the third dose and repeated with every subsequent third dose to monitor for possible toxicity)
  - b. Metronidazole (500 mg every 8 h) *plus* ampicillin *plus* gentamicin
  - c. Piperacillin/tazobactam (3.375 g every 6 h) + gentamicin
  - d. Clindamycin or metronidazole *plus* levofloxacin (500 mg every 24 h)
4. Surgery
  - a. Make a vertical lower abdominal incision that can be extended to the upper abdomen.
  - b. Obtain a specimen of fluid for gram-staining and culture of aerobic, facultative, and obligate anaerobic bacteria.
  - c. If the patient does not desire future pregnancy, total abdominal hysterectomy with bilateral salpingo-oophorectomy is recommended.
  - d. If the patient wants to attempt future pregnancy, the uterus should remain in place and the tissue containing the abscesses be removed. If one ovary is not enlarged and is not cystic, it may be left in place and the fallopian tubes removed if infected.
  - e. The abdomen and pelvis should be irrigated with copious amounts (10–15 L) of either normal saline or antibiotic solution (bacitracin 50,000 units *plus* kanamycin 1 g dissolved in 1 L normal saline).
  - f. Closed drains should be placed in the pelvis, and if there was purulent fluid in the upper abdomen, drains should be placed above the liver, under the diaphragm on the left. These drains should lie along the colonic gutters and end under the diaphragm on the right and left. The drains should all be connected to suction devices (JP or Blake drains).
  - g. Drains should be used to sample the fluid exiting from the abdomen and pelvis by gram-staining and culture, especially if the patient continues to have a febrile course. The drains should be removed when there is less than 30 mL exiting from each drain over a 24-hour period.
5. Medical
  - a. Intravenous antibiotic therapy, as described above, should be continued until the patient becomes afebrile and remains afebrile for 48 hours, bowel sounds have returned, the WBC count has returned to normal, the patient tolerates oral liquids and solids, and the abdominal/pelvic examination does not reveal pain.
  - b. After the patient has been afebrile for 48 hours, the patient can be changed to oral antibiotics
    - i. Metronidazole 500 mg three times a day *plus* levofloxacin 500 mg once a day
    - ii. Clindamycin 300 mg three times a day *plus* levofloxacin
    - iii. Metronidazole *plus* ampicillin/clavulanic acid 875 mg twice a day
  - c. Imaging studies should be repeated 2 weeks after beginning oral antibiotic therapy to determine any change in the size of the mass.
  - d. The patient should monitor her oral body temperature daily, e.g., at 12, 4, and 8 PM and at bedtime. A temperature  $\geq 100.4^{\circ}\text{F}$  should be reported to her physician. The patient should also report the development of abdominal/pelvic pain.
  - e. Oral antibiotic therapy should be continued until the mass has resolved or has become asymptomatic.
6. If the patient has a persistent mass that has not been significantly reduced in size (by at least 50%) or has persistent pelvic pain, laparotomy or laparoscopy should be considered.

## Gynecologic Infectious Disease

tubo-ovarian bowel complex or abscesses—should respond to antibiotic therapy within 48 to 72 hours. They should become afebrile, WBC count and bowel function should return to normal, and their pain should be resolving. If after 48 to 72 hours of antibiotic therapy the patient's body temperature continues to be elevated, the WBC count continues to be elevated, or bowel function has not returned to normal, then the patient should be reevaluated for possible progression of PID to confirm that the initial diagnosis was correct.

In summary, a patient suspected of having PID should be treated aggressively to prevent disease progression. Patients with minimal symptoms and findings can be treated as outpatients. However, if the patient cannot be relied on to take the antibiotic therapy as prescribed, she should be hospitalized. Patients with an oral temperature of 101°F or greater, possible nausea, rebound pelvic pain, or a pelvic mass should be admitted to the hospital for treatment. Antibiotic therapy has been demonstrated to be efficacious in treating uncomplicated and suspected complicated PID.<sup>41–43</sup> Broad-spectrum antibiotics, that is, regimens providing activity against *C. trachomatis*, *N. gonorrhoeae*, and facultative and obligate anaerobic bacteria are efficacious in the treatment of both complicated and uncomplicated PID. When abscesses are suspected and documented by ultrasonography or CT scanning, broad-spectrum antibiotics are effective; however, there remains the question of whether a true abscess was present. If an abscess is suspected but it is not leaking or ruptured, antibiotic therapy can be administered with the expectation that the surgical approach can be held off. If there is any indication that the abscess is leaking or ruptured, then the combined approach of antibiotic and surgery should be taken.

## KEY POINTS

- Since one quarter of HIV-infected women are unaware of their serostatus, it is critical that HIV testing be offered to patients at risk.
- Although early in the HIV/AIDS epidemic concern was widespread that the gynecologic manifestations of HIV disease would be substantial, differences in gynecologic pathology between HIV-infected and -uninfected women are modest.
- Cervical dysplasia is more common and severe in HIV-infected patients. Pap tests should be performed twice in the year after diagnosis of HIV and then, if normal, annually thereafter.
- HIV-infected women have higher rates of intraepithelial neoplasia in the vagina, vulva, and perianal regions. These regions should be examined carefully during pelvic examinations. When colposcopy is performed, the entire lower genital tract should be evaluated.
- Diagnosis and treatment recommendations for bacterial vaginosis, vulvovaginal candidiasis, trichomoniasis, gonorrhea, and chlamydia do not differ with HIV status. However, topical therapies for candidiasis may be more effective if a 7-day course is prescribed.

## VIROLOGY AND LIFE CYCLE OF HIV

Human immunodeficiency virus-1 (HIV-1) is a member of the family of human retroviruses (Retroviridae) and subfamily of lentiviruses. Electron microscopy shows that the HIV virion has an icosahedral structure (Fig. 21-1) that contains an envelope formed mainly by the external glycoprotein gp120 and the transmembrane glycoprotein gp41. HIV infects CD4+ “helper” T lymphocytes, monocytes, and macrophages. Cells are infected after binding of the envelope glycoprotein gp120 to both the CD4 receptor and a chemokine coreceptor on the surface of target cells. This binding leads to a series of changes in the tertiary structure of the viral envelope that brings about virus-cell fusion.<sup>1</sup> After fusion of the virus with the cell membrane, the viral RNA enters the cytoplasm and reverse transcription of the viral RNA occurs by the enzyme reverse transcriptase, with production of the viral DNA copy (cDNA). cDNA is then transported to the nucleus, where integration into the host cell genome takes place through the action of the viral enzyme integrase. This provirus, which is now integrated with the

nucleus of the infected cell, may remain transcriptionally inactive (latent), or it may manifest varying levels of gene expression, up to active production of virus. Productive infection of lymphocytes results in extracellular release of virions that bud through the host cell membrane. The virally encoded protease catalyzes the cleavage of a precursor to yield the mature virion. Each step in the life cycle of HIV represents a potential target for therapeutic intervention; the processes of fusion and the reverse transcriptase and protease enzymes have been subjected to pharmacologic disruption (Fig. 21-2). Integrase and other entry inhibitors are in development.

## PATHOGENESIS AND CLINICAL MANIFESTATIONS OF HIV IN WOMEN

Infection with HIV leads to a decrease in number and function of CD4+ cells through a variety of mechanisms, including direct infection and destruction of these cells and indirect acceleration of cell death through immune activation.<sup>2</sup> The decrease in CD4+ T lymphocytes has profound effects on both cell-mediated and humoral immunity. Without treatment, HIV infection causes generalized immunodeficiency with resultant susceptibility to opportunistic infections and neoplasms that are AIDS-defining illnesses. There is generally an inverse relationship between CD4+ cell count and the amount of virus circulating in the peripheral blood. As HIV disease progresses, the CD4+ cell count gradually declines as the amount of virus increases. The typical clinical course of an untreated HIV-infected individual will lead to AIDS and death at a mean time of approximately 10 years from primary infection (Fig. 21-3). A small proportion (<5%) of HIV-infected patients are long-term nonprogressors; the viral and host determinants that contribute to this course have not been elucidated.<sup>3</sup>

Overall HIV disease manifestations are similar in women and men. The most frequent AIDS-defining opportunistic processes in both men and women in the United States have so far been *Pneumocystis jirovecii* (formerly *Pneumocystis carinii*) pneumonia, *Candida* esophagitis, and wasting syndrome. With regard to malignancies, cervical cancer, Kaposi sarcoma, non-Hodgkin lymphomas, and lung cancer are more frequent in HIV-infected women compared with uninfected women. Whereas Kaposi sarcoma is less frequent in HIV-infected women than in HIV-infected men, there seem to be differences in clinical presentation, with women demonstrating a more aggressive course and a higher incidence of noncutaneous presentation and visceral involvement including, in some cases, involvement of the female genital tract.

Rights were not granted to include this figure in electronic media.  
Please refer to the printed publication.

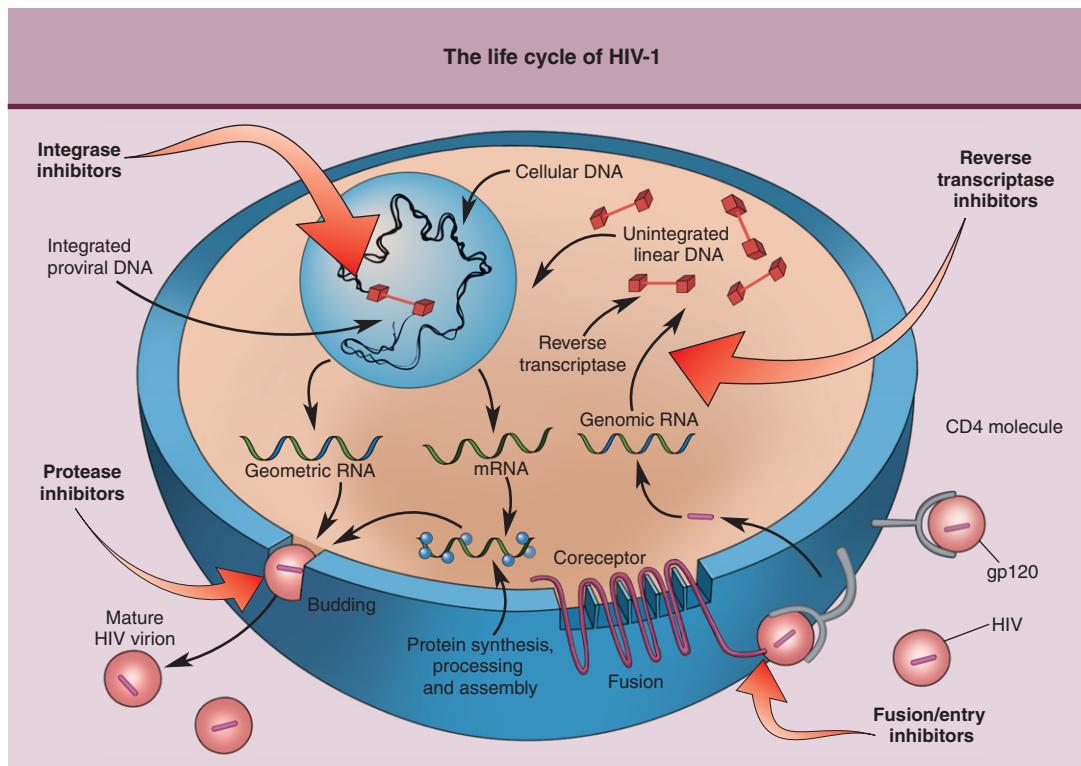

It was initially thought that HIV infection had a worse prognosis in women than in men; subsequent evidence, however, does not point to a difference in HIV disease-free survival or in response to antiretroviral therapy in women and in men. There may be, however, a mild sex influence on virus load levels, with women having a lower virus load than men, particularly in the initial stages of the disease when CD4+ T cell counts are higher.<sup>4</sup>

## EPIDEMIOLOGY AND TRANSMISSION OF HIV INFECTION

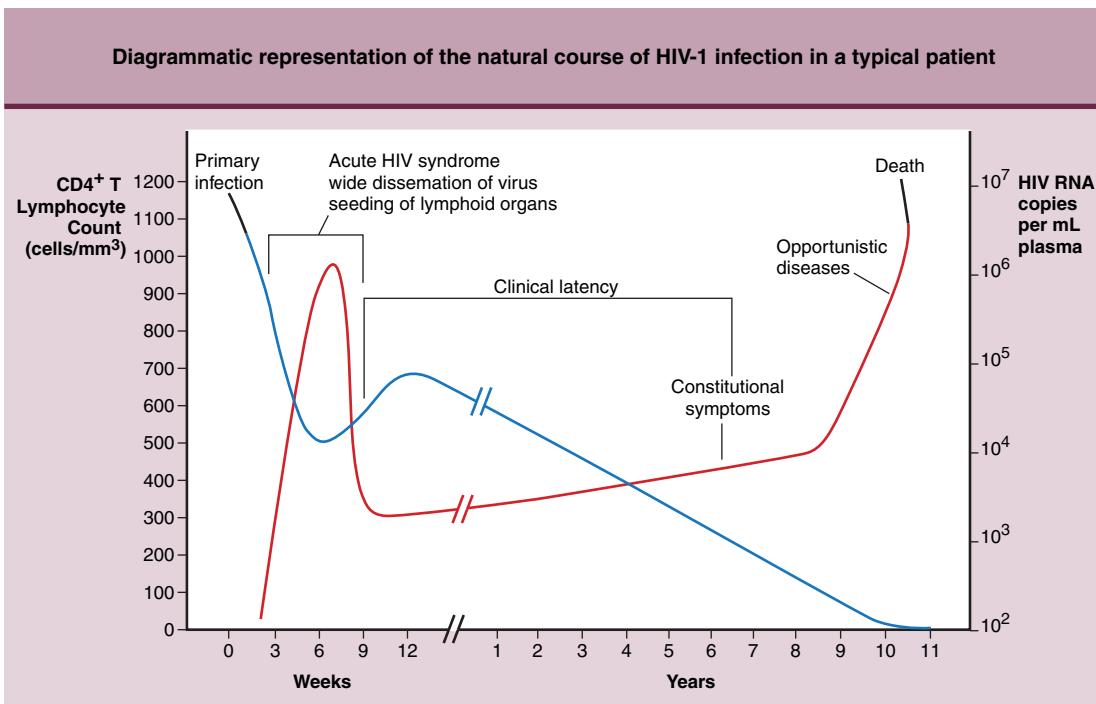

HIV is transmitted by sexual contact, percutaneous exposure to contaminated blood and blood products, and mother-to-child transmission (MTCT).<sup>5</sup> Risk factors for HIV infection among adults in the United States include exposure to blood products from 1978 to the spring of 1985, parenteral illicit drug use, multiple heterosexual or homosexual contacts, and a partner with one of these risk factors. Seroprevalence rates are highest among gay men and injecting drug users, but heterosexual transmission continues to rise. Youth (aged 13 to 24 years) and minority women are disproportionately affected by new infections. In developing countries, heterosexual contact is the most common mode of transmission among adults, and prevalence is similar in both sexes.

In the United States, women represent the fastest growing part of the population with newly acquired HIV infection. Whereas only 7% of all AIDS cases reported in the United

**Figure 21-1 Structure of the HIV virion.** The spikes projecting from the viral envelope represent glycoprotein gp120, which binds to the CD4 receptor on host cells. (Available at: <http://www.luc.edu/depts/biology/hiv.jpg>. Accessed 5/18/05.)

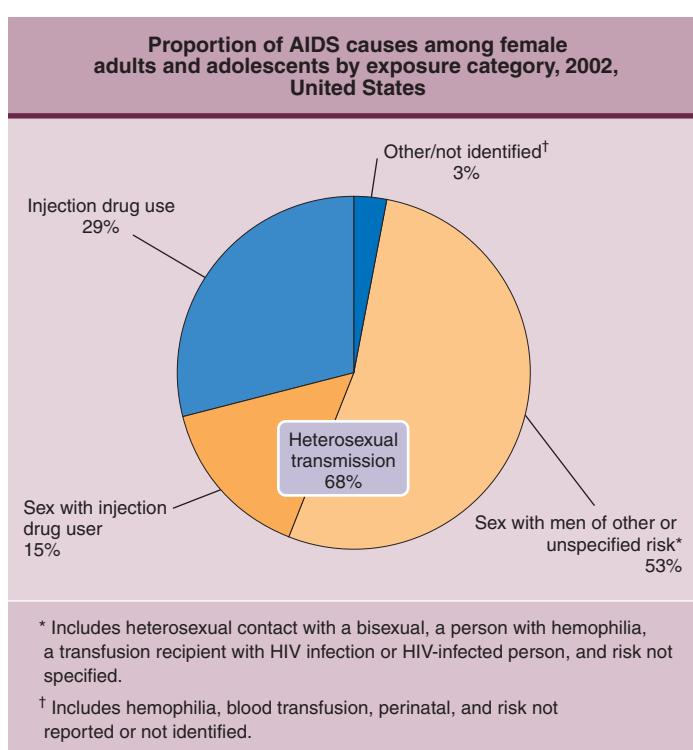

**Figure 21-2 The life cycle of HIV-1 and potential targets for antiretroviral action.** To date, fusion, reverse transcription, and protease action have been disrupted by pharmacologic agents; integrase and entry inhibitors are currently under development. (From Fauci AS: HIV and AIDS: 20 years of science. *Nat Med* 9:839–843.)

**Figure 21-3 Diagrammatic representation of the natural course of HIV-1 infection in a typical patient.** The average length of time from primary HIV infection to AIDS and death is, in the absence of antiretroviral treatment, approximately 10 years. (From Pantaleo G, Graziosi C, Fauci AS: New concepts in the immunopathogenesis of human immunodeficiency virus infection. *N Engl J Med* 1993;327–335. Copyright 1993 Massachusetts Medical Society. All rights reserved. Adapted 2006 with permission.)

States in 1985 were in women, this proportion had reached 28% in 2003. From 1990 to 1994 AIDS cases in women increased by 89%, as compared with 29% in men. Heterosexual contact accounts for most HIV acquisition in women: 53% of women acquire HIV by contact with an HIV-infected partner and 15% by contact with a partner who is an intravenous drug user (Fig. 21-4). Minorities are disproportionately affected: approximately 80% of female AIDS cases in 2002 were in black or Hispanic women (Table 21-1). By 1995 AIDS represented the third leading cause of death among women 25 to 44 years of age in the United States and the leading cause of death in African American women of the same age.<sup>6,7</sup> Some evidence points to a slower decline in HIV-related mortality in women than in men after introduction of potent antiretroviral regimens. This may be related to decreased health care access or decreased utilization of protease inhibitors in women, although the evidence is inconclusive.

While the overall efficiency of HIV transmission through a single heterosexual contact is low, evidence points to increased efficiency of HIV transmission from man to woman compared with from woman to man.<sup>8</sup> Factors associated with increased risk of sexual transmission of HIV include concurrent sexually transmitted diseases (STDs), advanced HIV disease with low CD4+ T cell counts and high RNA virus load, acute HIV infection, absence of antiretroviral therapy, sex during menses, receptive anal intercourse, traumatic vaginal intercourse, lack of barrier contraception, lack of circumcision, and cervical ectopy.<sup>9</sup> Viral subtype and host genetics also play a role (Table 21-2).

**Figure 21-4 Proportion of AIDS cases among female adults and adolescents by exposure category in the United States in 2002.** Heterosexual transmission accounts for 68% of transmission to women. (From Centers for Disease Control and Prevention, 2005. Available at <http://www.cdc.gov/hiv/graphics/images/I264/I264-2.html>.)

Reported AIDS Cases and Rates among Female Adults and Adolescents by Race and Ethnicity in the United States in 2002

### Screening for HIV: Who Should Be Tested?

HIV counseling and testing should be offered as a routine part of gynecologic care. It is estimated that 25% of persons living with HIV are unaware that they are infected. In April 2003, the Centers for Disease Control and Prevention (CDC) announced a nationwide initiative that stressed making HIV a routine part of medical care as one of four key strategies. In a study of women in whom HIV was newly diagnosed, only 17% reported that they were tested because the test was offered or recommended by a health care provider.<sup>10</sup> This illustrates the need for health care providers, including gynecologists, to be proactive about offering and recommending testing.

### DIAGNOSIS

The diagnosis of HIV infection is made by detection of antibodies against HIV or direct detection of HIV or one of its components. The standard way to diagnose HIV is via a positive

HIV antibody test produced by an enzyme-linked immunosorbent assay (ELISA). A confirmatory test, usually a Western blot, must be performed, since occasionally false-positive ELISA results occur. Rarely an infected person may fail to make antibody. This could happen in patients with low immunoglobulin levels (sometimes the result of generalized immunodeficiency) or during the "window" period of the first 2 to 8 weeks following primary infection. Tests for the presence of virus (usually nucleic acid detection, but also HIV culture or p24 antigen) are positive and should be performed if the ELISA is negative but the clinical suspicion for HIV infection is strong.

Highly sensitive detection of proviral DNA can be accomplished using the polymerase chain reaction (PCR) technology on peripheral blood mononuclear cells isolated from whole blood. The sensitivity of PCR is greater than 95% and its specificity greater than 98%.<sup>11</sup> A number of assays are commercially available for the detection and quantitation of plasma HIV RNA; these assays are used for measurement of the viral load in a patient's plasma.

The absolute number and percentage of CD4 lymphocytes decline with disease progression; CD8 lymphocyte counts usually increase. Total immunoglobulin levels are usually elevated. Routine laboratory tests (complete blood count, blood chemistry profiles) are usually normal in the absence of a secondary infection or organ system disease. As disease progresses, anemia becomes common; granulocytopenia and thrombocytopenia may also occur. Mild elevation of liver enzymes is not uncommon. Serum LDH levels may be high with *P. jirovecii* infection. With brain involvement, the cerebrospinal fluid may be normal or the protein elevated and lymphocyte/mononuclear pleocytosis may be present.

### TREATMENT IN WOMEN

Specific antiretroviral therapy can prevent HIV-induced progressive immune deterioration, and prophylactic measures can prevent opportunistic infections. HIV has a high spontaneous mutation rate, and emergence of drug resistance during treatment is well recognized. Many antiretroviral drugs select for resistant mutations in the virus within weeks to months when used as monotherapy. Thus, combinations of at least three drugs and strict adherence to the dosing regimen are critical. If viral replication is not fully suppressed, the potential for emergence of resistance exists. If increasing plasma viremia is observed after treatment in a compliant patient, viral resistance is likely and the antiretroviral regimen should be changed, if possible all three drugs at the same time. Selecting a combination of drugs appropriate for an individual patient is a complex process requiring expert understanding of antiretroviral activity, cross-resistance patterns, and drug interactions; therefore, a physician with expertise in HIV treatment should be consulted whenever possible.

Four classes of drugs have been approved by the FDA for the treatment of HIV infection, and additional drugs are under development.<sup>12</sup> The four classes are nucleoside/nucleotide reverse transcriptase inhibitors (NRTIs/NtRTIs), nonnucleoside reverse transcriptase inhibitors (NNRTIs), protease inhibitors (PIs), and fusion inhibitors. There are currently 21 FDA-approved drugs.

Table 21-2  
Factors Affecting Sexual Transmission of HIV-1

- Sexually transmitted infections (ulcerative/nonulcerative)
- Advanced HIV disease (low CD4+ T cell counts/high virus load)
- Lack of antiretroviral therapy
- Acute HIV infection
- Sexual activity during menses
- Receptive anal intercourse
- Traumatic vaginal intercourse
- Lack of barrier protection
- Lack of circumcision
- Cervical ectopy
- ?Hormonal contraception/?Pregnancy
- HIV viral subtype/phenotype
- Host genetics (deletions in the chemokine receptor gene CCR5)

NRTIs/NtRTIs are nucleoside/nucleotide analogs that block reverse transcription and production of viral DNA and thus productive infection of the cell. The first class of drugs to be developed, they vary with regard to their potency, rate of resistance development, and side effects. Zidovudine, stavudine (d4T), didanosine, lamivudine (3TC), zalcitabine (ddC), and abacavir are the best known drugs of this class. Zidovudine has moderate antiretroviral activity and a relatively long interval before development of resistance. Toxicity includes anemia, neutropenia, headache, gastrointestinal upset, myalgia, and insomnia. Stavudine has fewer side effects, the most common being peripheral neuropathy mainly seen in patients with advanced disease. Common side effects with ddI include gastrointestinal upset, pancreatitis, and peripheral neuropathy. 3TC is highly active against HIV, but resistance develops within weeks when it is used as monotherapy. Abacavir is highly active; however, approximately 10% of patients develop a hypersensitivity reaction characterized by flu-like symptoms with or without a rash. Continued treatment or rechallenge is contraindicated because the outcome may be fatal. ddC is the least potent in the class and is frequently associated with peripheral neuropathy. Emtricitabine, a newer agent in the class, is generally well tolerated; headache is an occasional side effect. Tenofovir, an agent in the NtRTI class that requires only one intracellular phosphorylation step, has a long half-life and only once daily dosing and has shown promise in preventing infection as pre- and postexposure prophylaxis in monkeys; side effects include gastrointestinal upset and headache; renal toxicity is an unusual but important side effect of this drug.<sup>13</sup>

NRTIs are known to induce mitochondrial dysfunction because the drugs have some affinity for mitochondrial γ-DNA polymerase. Toxicity related to mitochondrial dysfunction has been reported in patients receiving long-term treatment with NRTIs and generally resolves after discontinuation of the drug. These toxicities include neuropathy, myopathy, cardiomyopathy, pancreatitis, hepatic steatosis, and lactic acidosis; the last two are more common in women.

NNRTIs also inhibit viral DNA synthesis but act at a different site on the viral enzyme reverse transcriptase. NNRTIs have generally high-level antiretroviral potency, but resistance appears rapidly. The most common side effect is rash, which can be as severe as Stevens-Johnson syndrome. Evidence indicates that severe liver involvement with rash or systemic symptoms may be observed during the first weeks of treatment with nevirapine, particularly in women with CD4+ T lymphocyte counts greater than 250/mm<sup>3</sup>.<sup>14</sup> Rare deaths have been reported. It is unclear whether pregnancy confers higher risk. However, in recognition of this higher risk, nevirapine is not recommended as part of an antiretroviral regimen in a woman with CD4 count greater than 250/mm<sup>3</sup> unless benefits clearly outweigh risks. Efavirenz is associated with mild central nervous system symptoms (dizziness, confusion, strange dreams), which usually resolve after the initial weeks of use. The major concern for women is its known teratogenicity (FDA pregnancy category D). Neural tube defects have been reported both in experimental animal systems and in humans inadvertently exposed to efavirenz during the first trimester of pregnancy. Women should undergo pregnancy testing before receiving efavirenz and should be counseled regarding the risk of teratogenicity. Because of

the possibility of increased failure of hormonal contraceptives related to drug interactions with certain antiretrovirals, which may include efavirenz, alternative regimens that do not contain efavirenz should be strongly considered in women at risk for unintended pregnancy.<sup>15</sup>

PIs inhibit viral protease during assembly of the virus and result in noninfectious particles. PIs are highly active but also induce resistance within months when used as monotherapy. Common toxicities include diarrhea (nelfinavir); nausea and perioral paresthesias (ritonavir); nephropathy and nephrolithiasis (indinavir); nausea and rash (amprenavir and fosamprenavir); nausea and diarrhea (saquinavir); hyperbilirubinemia, nausea, and diarrhea (atazanavir); nausea/vomiting (lopinavir/ritonavir); and elevation of liver enzymes, hypercholesterolemia, hypertriglyceridemia, and hyperglycemia (all). PIs are metabolized by the hepatic cytochrome P-450 enzymes, resulting in many interactions with other drugs including other antiretroviral agents, so care is needed when prescribing other medications to a patient taking a PI. Regimens combining two PIs can take advantage of the drug interaction and improve the pharmacokinetic properties of the drugs.

Enfuvirtide is the only agent in the class of fusion inhibitors. It has to be administered subcutaneously, and the most common side effects are site injection reactions, diarrhea, and nausea. Increase in rate of bacterial pneumonia in patients administered enfuvirtide has been reported.

In nonpregnant adults, initiation of antiretroviral therapy is recommended for all patients with symptomatic HIV infection. In asymptomatic infected adults, recommendations concerning when to start treatment are more controversial. The most recent recommendations are to offer therapy to nonpregnant adults with fewer than 350 CD4+ T cells per cubic millimeter or a plasma viral load exceeding 100,000 copies per milliliter and to defer therapy in otherwise asymptomatic individuals not meeting these criteria.<sup>16</sup> Consideration for treatment should also be given within 6 months of seroconversion. Results of therapy are evaluated through plasma HIV RNA levels, which are expected to decrease by 1.0 log<sub>10</sub> at 2 to 8 weeks, with no detectable virus (<50 copies/mL) at 4 to 6 months after treatment initiation. Failure of therapy at 4 to 6 months might be due to nonadherence, inadequate potency of the regimen, viral resistance, or other factors. Patients whose therapy fails in spite of a high level of adherence to the regimen should have their regimen changed. Recommended combination antiretroviral regimens include two NRTIs combined with a PI or an NNRTI; an alternative combination regimen consists of three NRTIs when the other two options cannot be used as initial therapy. In women of reproductive age, regimen selection should account for the possibility of planned or unplanned pregnancy. As part of the evaluation for initiating therapy, women should be counseled about the potential risk of efavirenz-containing regimens if pregnancy occurs. These regimens should be avoided in women who are trying to conceive or who are not using effective and consistent contraception.

## PREVENTION OF HIV TRANSMISSION

The only 100% effective method of avoiding sexual transmission of HIV is abstinence or limiting sexual contact to a monogamous

## Gynecologic Infectious Disease

partner who is not HIV-infected. Condoms, when used correctly and consistently, are highly effective in preventing transmission between sexually active couples when one partner is HIV-infected. CDC provides detailed instructions on correct condom use. Use of the spermicide nonoxynol-9, which has anti-HIV activity in vitro, was shown to increase risk of epithelial disruption and genital tract inflammation, with resultant higher risk of HIV transmission, and thus is not recommended.<sup>17</sup> Prompt treatment of other STDs also reduces the risk of sexual transmission of HIV. Antiretroviral prophylaxis to prevent HIV infection in people who are exposed to HIV in a circumstance that is not likely to recur (such as sexual assault or condom rupture) is now recommended<sup>18</sup> even though the data on the efficacy of this approach are limited. CDC recommends post-exposure prophylaxis following occupational exposure, using ZDV and 3TC, with or without a protease inhibitor, depending on the degree of risk associated with the exposure and in consultation with an infectious diseases expert.<sup>19</sup>

All medical equipment that can penetrate the skin should be sterile. Infected blood and secretions should be handled according to CDC recommendations.

### **GYNECOLOGIC MANIFESTATIONS OF HIV**

Early in the epidemic, it was widely believed that there would be large differences in the clinical manifestations of HIV/AIDS between men and women. Specifically, it was thought that many gynecologic conditions such as lower genital tract dysplasia, gynecologic cancers, menstrual irregularities, and infectious conditions such as vaginitis, cervicitis, and pelvic inflammatory disease might be more common, severe, and persistent in HIV-infected women compared with uninfected women. To address these concerns, two large cohort studies of HIV-infected and uninfected women were funded, one by CDC and the other by the National Institutes of Health (NIH).<sup>20,21</sup> The CDC-funded HIV Epidemiology Research Study (HERS) beginning in 1993 enrolled 871 HIV-infected women and 439 high-risk HIV-uninfected women in four cities in the United States (New York, Detroit, Providence, Baltimore). The NIH-funded Women's Interagency HIV Study (WIHS) began in 1994 and enrolled 2058 HIV-infected women and a comparison cohort of 568 HIV-uninfected women. Findings from these studies indicate that although there are subtle differences between HIV disease in men and women, the differences are much less pronounced than originally believed. In addition, the differences between HIV-infected women and well-matched high-risk HIV-uninfected women are also much less pronounced than originally thought. The most notable gynecologic difference between infected and uninfected women is the development of cervical dysplasia.

#### **Cervical Dysplasia**

Compared with HIV-uninfected women, HIV-infected women have a markedly higher prevalence of human papillomavirus (HPV), including high-risk subtypes, and these HPV infections tend to persist longer. Furthermore, the prevalence and persistence of HPV infection among HIV-infected women increases with decreased CD4 count and increased viral load. However, the response of HPV and cervical intraepithelial neoplasia (CIN) to antiretroviral therapy remains unclear.<sup>22</sup> Although some studies

have shown increased clearance of HPV and regression of cervical dysplasia following immune reconstitution, others have failed to document a clinical response.<sup>23,24</sup>

Since HPV is more common among HIV-infected women and is the major cause of cervical dysplasia, it is not surprising that HIV-infected women have high rates of abnormal Papanicolaou (Pap) tests. In the setting of HIV infection, rates of cytologic abnormalities on Pap screening are up to 10 times greater than those observed among HIV-uninfected women. Therefore, HIV-infected women should undergo a comprehensive gynecologic examination including Pap test as part of their initial evaluation. A Pap test should also be obtained twice in the first year after diagnosis of HIV infection. If the initial Pap test results are normal, then women can begin a schedule of annual Pap tests. Pap tests are an adequate screening tool for HIV-infected women. No additional routine screening, such as colposcopy, is recommended for women with normal Pap tests.

If the results of a Pap test are abnormal, then standard diagnostic and treatment algorithms for HIV-uninfected women should be followed. As in HIV-uninfected women, the diagnosis of cervical dysplasia involves colposcope-directed biopsies. Since HIV-infected women have high rates of dysplasia, abnormal-appearing areas should be sampled liberally. Although recurrence rates are higher after treatment of cervical dysplasia among HIV-infected women, standard excisional treatment is recommended for CIN II or CIN III. Since cryotherapy has the highest rate of recurrence, it should generally be avoided. HIV-infected women may be more likely to have positive surgical margins, which may contribute to higher rates of recurrence. A randomized trial among HIV-infected women evaluated the efficacy of topical vaginal 5-fluorouracil (5-FU) maintenance therapy in preventing recurrence after standard treatment for high-grade cervical dysplasia.<sup>25</sup> Although this trial found a reduction in recurrence of CIN, the potential clinical role for 5-FU is still unclear. Because of limited clinical experience as well as concerns about mucosal toxicity and inflammation, this therapy is still investigational and can not be routinely recommended.

At 2 to 4 weeks following treatment for CIN, when the cervix is inflamed and ulcerated, there is a dramatic increase (as high as 10,000-fold) in the amount of HIV shed in the genital tract.<sup>26</sup> Therefore, abstinence should be emphasized until complete healing has occurred following treatment. Although consistent and correct condom use should always be stressed, the time after treatment of CIN may be a particularly high-risk period for sexual transmission.

#### **Vaginal, Vulvar, and Perianal Intraepithelial Neoplasia**

Since HPV disease is multicentric in nature, it is not surprising that in addition to cervical dysplasia, HIV-infected women also have higher rates of intraepithelial neoplasia in the vagina, vulva, and perianal regions.<sup>27</sup> For this reason, the vaginal, vulvar, and perianal regions of HIV-infected women should be carefully examined during routine pelvic examinations. Biopsies should be taken of suspicious areas. In addition, at the time of colposcopy for cervical dysplasia, the entire lower genital tract should be evaluated. Although there is evidence that multicentric intraepithelial neoplasia is more common in the setting of immunosuppression, HIV-infected women should continue to be followed

carefully for evidence of lower genital tract neoplasia, regardless of CD4+ count, viral load, or antiretroviral therapy.

### Gynecologic Cancers

In 1993, invasive cervical cancer was designated an AIDS-defining disorder by CDC. This was in recognition of the documented increased risk of development of cervical cancer among HIV-infected women.<sup>28</sup> However, HIV infection has not had a substantial impact on overall cervical cancer rates. No other gynecologic cancers have been consistently shown to be more common in HIV-infected compared with HIV-uninfected women.

### Menstrual Disorders

Although HIV-infected women frequently report menstrual disorders, these disorders are likely related to coexisting conditions rather than to HIV infection. Weight loss, substance abuse, immunosuppression, poor nutritional status, and use of certain antiretroviral agents may cause amenorrhea or other menstrual irregularities.<sup>22</sup> For HIV-infected women, evaluation and treatment of menstrual disorders should be similar to those in uninfected women.

### Gynecologic Surgery for HIV-Infected Women

Since women are increasingly affected by HIV infection and since gynecologic surgery is relatively common among women of reproductive age, it would be expected that a sizable number of HIV-infected women would undergo gynecologic surgical procedures such as dilation and curettage and hysterectomy. Surprisingly, however, there is little published information regarding gynecologic surgery among HIV-infected women. One retrospective review included 235 surgical procedures; 72 were major and included cesarean section, tubal sterilization, oophorectomy, and hysterectomy. They reported a higher complication rate in the HIV-infected group; major complications included postoperative fever, additional surgery, anemia requiring transfusion, and disseminated intravascular coagulation. The risk of complications was associated with immune status.<sup>29</sup> Another report reviewed 53 surgical procedures including nine hysterectomies. There was no difference in outcome between HIV-infected women and the uninfected women.<sup>30</sup> A small study from Grady Hospital in Atlanta retrospectively reviewed the hospital course of 24 HIV-infected patients who underwent hysterectomy and compared them to matched controls. Although the study was limited by small sample size, no significant differences in complication rates were found between HIV-infected and -uninfected women.<sup>31</sup> Since cesarean delivery is routinely recommended for HIV-infected women with viral loads higher than 1000 copies/mL, there is more published information about the obstetric surgical experience in the setting of HIV infection. Some but not all studies have found increased rates of postoperative infections, such as endometritis, wound infection, and pneumonia, among HIV-infected women compared with HIV-uninfected controls. From the limited available information, no differences in the clinical management of HIV-infected women undergoing routine gynecologic procedures can be recommended. Standard perioperative antibiotic prophylaxis should be used, and HIV-infected patients should be monitored closely for postoperative infectious complications.

Because HIV-infected women are living longer, healthier lives, increased numbers probably will undergo gynecologic surgical procedures for benign gynecologic conditions unrelated to HIV infection. In addition, since some conditions leading to gynecologic surgery, such as cervical dysplasia and cervical cancer, are more common among HIV-infected women, gynecologic surgery probably will increase among HIV-infected women as well.

### Cervicovaginal Infections

Early reports fueled concern that the prevalence and severity of lower genital tract infections such as vulvovaginal candidiasis might be increased in HIV-infected women. In 1992 CDC included vulvovaginal candidiasis among category B conditions—those for which clinical course or management is complicated by HIV infection. However, over time, it has become clear that the differences in vulvovaginal conditions such as bacterial vaginosis, vulvovaginal candidiasis, and trichomoniasis between HIV-infected and -uninfected women are less pronounced and more subtle than previously thought. In some cases, there are no meaningful clinical differences by HIV status.

The prevalence of vulvovaginitis associated with *Candida* is generally higher in HIV-infected women compared with uninfected women. Much of this difference can be attributed to immunosuppression; when HIV-uninfected women are compared with immunocompetent HIV-infected women, differences in prevalence rates are absent or modest. Increased rates of candidiasis are associated with declining CD4+ T cell count and increasing viral load among HIV-infected women. A longitudinal analysis from HERS found that vulvovaginal candidiasis occurred with higher incidence and greater persistence, but not greater severity, among HIV-infected women.<sup>32</sup>

In general, diagnosis and treatment of vulvovaginal candidiasis among HIV-infected women are similar to those in HIV-uninfected women. However, owing to greater persistence, topical therapies for candidiasis may be more effective if given for longer periods (e.g., 7 days). In addition, when antibiotics are given, use of prophylactic topical antifungals may be considered.

Bacterial vaginosis, a condition characterized by a shift in dominant vaginal flora, may be slightly more common among HIV-infected women compared with uninfected women, although the differences are modest. In HERS, bacterial vaginosis was more prevalent, persistent, and severe among HIV-infected women, particularly among those who were immunocompromised.<sup>33</sup> Diagnosis and treatment of bacterial vaginosis are the same in HIV-infected and -uninfected women.

In addition to the clinical significance of bacterial vaginosis among HIV-infected women, bacterial vaginosis may also be important among HIV-uninfected women at risk, since evidence suggests that bacterial vaginosis may be a risk factor for acquisition of HIV.

HIV infection does not appear to make a woman more likely to have incident, prevalent, or persistent trichomoniasis.<sup>34</sup> Diagnosis and treatment are the same as in HIV-uninfected women. Similarly, bacterial cervicitis caused by *Neisseria gonorrhoeae* or *Chlamydia trachomatis* is not more common in HIV-infected women compared with uninfected women. HIV-infected women with gonorrheal or chlamydial cervical infections should receive the same treatment as uninfected women.<sup>35</sup>

### Pelvic Inflammatory Disease

Despite early reports suggesting that HIV-infected women with pelvic inflammatory disease (PID) may have a more complicated clinical course than uninfected women, those differences are modest. Although not conclusive, there is some evidence that HIV-infected women are more likely to have a tubo-ovarian abscess. Overall, however, the presenting symptoms and response to standard therapy are similar. Whether the management of HIV-infected women with PID requires more aggressive treatment, such as hospitalization or parenteral antibiotics, has not been carefully evaluated. However, CDC guidelines for treatment of PID do not differ by HIV status.<sup>35</sup>

### CONTRACEPTION FOR HIV-INFECTED WOMEN

Preventing unintended pregnancy among HIV-infected women should be an integrated component of their gynecologic care. A wide variety of contraceptive options are appropriate for HIV-infected women.

All HIV-infected women should be counseled regarding correct and consistent condom use to decrease the risk of HIV transmission to uninfected partners. Latex male condoms are the best studied condom; they afford excellent protection when used correctly and consistently. Female condoms are also an effective barrier if intact and in place. An advantage is that they are a female-initiated method. However, cooperation and participation of the male partner are required. There are fewer data on the effectiveness of the female condom compared with the male condom, and acceptability of the female condom has been low in some populations. Although condoms provide some protection against unintended pregnancy, their effectiveness is not so high as some other methods. Therefore, some HIV-infected women may require dual protection with two different methods: a highly effective method for disease transmission prevention, such as condoms, and a highly effective method for pregnancy prevention, such as hormonal contraception.

Hormonal contraceptives can generally be prescribed according to the guidelines used for HIV-uninfected women. However, since some antiretroviral drugs may alter the bioavailability of circulating steroid levels, concomitant use of antiretroviral agents and oral contraceptives may alter the safety and effectiveness of both. It is unknown whether progesterone-only injectables are affected, since they involve much higher circulating steroid levels. For HIV-infected women taking antiretroviral therapy who desire hormonal contraception, use of an alternative or additional method of contraception is generally recommended.

In addition to concerns about the effectiveness of hormonal contraceptives, there is a theoretical concern that hormonal methods might act directly on the virus or immune system and increase HIV disease progression or severity. Limited studies suggest no such association. In addition, there is some limited evidence that hormonal contraceptives may increase genital tract shedding. Although this could have implications for sexual transmission of HIV, HIV-infected women should be advised to use condoms to protect their sexual partners from HIV and other STDs.

The World Health Organization recently revised its guidelines for the use of intrauterine devices (IUDs) in the setting of

HIV. HIV-infected women can generally use IUDs. However since the risk of infection is greatest around the time of insertion, an IUD should not be inserted in a woman with AIDS unless she is clinically well on antiretroviral therapy. The appropriateness of surgical sterilization should be assessed without regard to a woman's HIV serostatus.<sup>36</sup>

### DISCORDANT COUPLES

Since people with HIV are living longer, healthier lives, couples may wish to have their own biologic children. This raises particularly difficult decisions for couples discordant for HIV when the man is seropositive and the woman is seronegative. Because of the risk of HIV transmission with unprotected intercourse, some authors advocate artificial insemination with semen that has been processed in an attempt to remove HIV from spermatozoa. These processing techniques generally involve semen washing and gradient centrifugation, followed by a sperm "swim-up" in which only the upper layer of medium is tested and used for insemination. After semen processing, the sample is tested for viral contamination by real-time PCR. Since the risk of sexual transmission is so low, the benefit and safety of such techniques have not been conclusively proven.<sup>37,38</sup>

## KEY POINTS

- Human papillomaviruses (HPVs) are the most common sexually transmitted infection.
- Most HPV infections are asymptomatic and transient.
- HPV is a family of more than 100 closely related viral types.
- The types found in the genital tract are divided into high risk and low risk groups based on their disease associations.
- High risk HPV types are associated with anogenital cancers, particularly cervical cancer.
- Low risk HPV types are associated with genital warts and recurrent respiratory papillomatosis.
- Treatment is not directed at HPV, rather at HPV-associated disease.
- HPV testing is recommended for triage of women with equivocal Pap smear results and may be used in combination with Pap smears for cervical cancer screening in women over age 30.

## EPIDEMIOLOGY, RISK FACTORS, AND PATHOGENESIS

HPV is the most common sexually transmitted infection. In the United States it is estimated that 80% of the sexually active population will be exposed during their lifetime. The vast majority of HPV infections are transient and asymptomatic. HPV testing is used clinically to detect HPV-associated disease. HPV infection is not treated; only HPV-associated disease is treated.

Human papillomaviruses are a family of more than 100 closely related small double-stranded DNA viruses, family Papovaviridae. HPV had been known since the turn of the 20th century to cause warts, but it was not until the advent of molecular biologic techniques that their association with cervical cancer was suspected. The genome of all papillomaviruses is episomal, about 8 kb, coding for relatively few proteins with a polycistronic message transcribed from one strand only (Fig. 22-1). The limited coding potential of the virus makes it completely dependent on the host cellular machinery for crucial steps of the viral life cycle. HPV requires a differentiating squamous epithelium to provide the appropriate cellular transcriptional and translational proteins for growth and is therefore not detectable by culture methods.

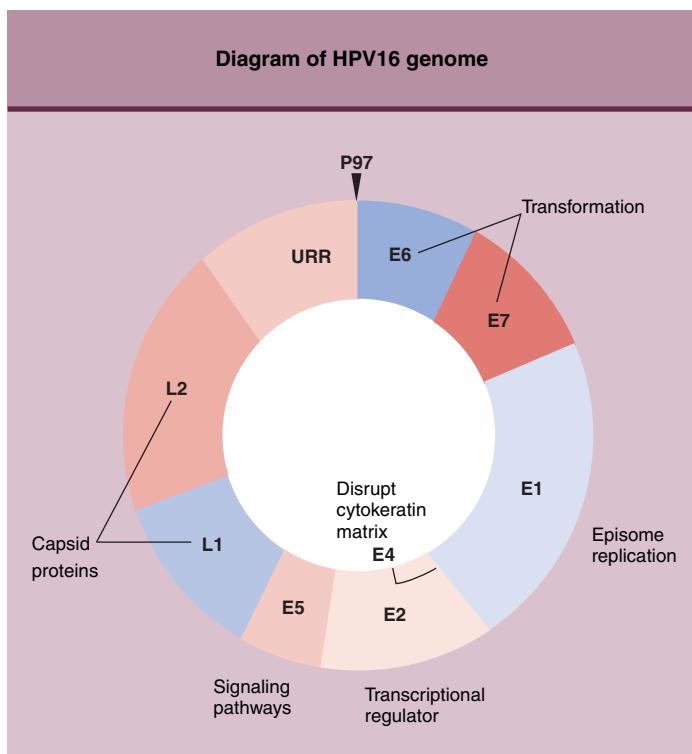

Human papillomavirus types are recognized based on their genetic sequence and are numbered in order of their discovery.

Sequence differences of more than 10% in the L1 region are recognized as another type, whereas variations of less than 2% are recognized as variants of currently numbered types. HPVs can be grouped as cutaneous or mucosal types. The cutaneous types are quite numerous and are associated with common hand and foot warts as well as a rare genetic disorder characterized by widespread warts and frequent skin cancer, erythrodermoplasia verruciformis. The cutaneous types are being investigated as risk factors for actinic keratoses, psoriasis, basal cell carcinomas, and squamous cell carcinomas. The mucosal types are those most commonly found in the anogenital region, but that may be found elsewhere, including the nail beds and oropharyngeal epithelium. The mucosal types are commonly divided into high risk and low risk groups based on their frequency of detection in malignancies. High risk types are detected in greater than 90% of cervical cancers. These types are also those most prevalent in the genital tract in the general population regardless of disease status.

The entire anogenital epithelium is exposed to HPV and may become infected during sexual contact with an infected individual. The most common site of HPV-associated neoplasia in the genital tract is the squamocolumnar junction of the cervix. Other less common sites include the squamocolumnar junction of the anus as well as the vaginal and vulvar epithelium. Most HPV infections are subclinical and do not require therapy. Detection of HPV is usually transient (median 6 to 12 months), with high risk types taking slightly longer than low risk types to clear.<sup>1</sup>

The mere presence of HPV DNA at the cervix does not necessarily define a woman as destined to develop cervical neoplasia. In general there is an interval of 10 or more years between HPV infection and detection of high grade squamous intraepithelial lesions or invasive cancer. Although poorly defined, additional cofactors interact with cervical HPV in the pathogenesis of cervical cancer. Some of these factors include smoking, parity, and oral contraceptive use,<sup>2</sup> as well as other genital tract infections, inflammation, and diet.<sup>3</sup> Persistent infection with high risk HPV is strongly linked to neoplastic progression. The host immune response, preceding cofactors, as well as viral factors such as viral load, type and variant types, multiple types, and integration may contribute to HPV persistence or interact in other ways to result in cervical carcinogenesis.

A variety of prospective studies have examined the issue of persistent cervical HPV infection. Ho and colleagues<sup>4</sup> examined the factors related to persistent squamous intraepithelial lesions among 70 women followed every 3 months for 15 months. The risk of persistent squamous intraepithelial lesions was associated

**Figure 22-1** The genomes of all human papillomaviruses (HPVs) are double-stranded DNA closed circles (episomes) with similar genetic organization. Late genes (L1 and L2) are structural proteins that make up the virus capsid. Early genes (E1, E2, E4–E7) are involved in the viral life cycle; major functions as noted on diagram. The upstream regulatory region (URR), also called the noncoding region (NCR) or long control region (LCR), contains binding sites for numerous cellular and viral transcriptional regulators. Genes are named based on relationship to bovine papillomavirus, which is why E3 is missing.

with persistent type-specific HPV infection of the cervix, with an odds ratio of 3.9 (95% CI, 1.58 to 9.65). In this study HPV persistence was defined as consecutive assessments positive for HPV. The same investigators' study of 608 college women followed every 6 months for 3 years noted a cumulative 36-month incidence of HPV infection of 43%.<sup>1</sup> The median duration of new infections was 8 months (95% CI, 7 to 10 months), but the accuracy of this estimate was limited by the every 6 month assessment. The risk of developing an abnormal Papanicolaou (Pap) smear increased with persistent HPV infection, particularly with high risk types (RR, 37.2; 95% CI, 14.6 to 94.8).<sup>1</sup>

Human papillomavirus is episomal in productive infections and in most lesions. Integration of the viral genome into host cellular DNA is found in essentially all cancers with HPV18 and most of those with HPV16. Viral integration has not been observed in all cancers, but integration clearly has implications in the perpetuation of the transformed phenotype as well as in tumor progression. HPV integration appears to be random with respect to the cellular chromosome, but nearly always occurs within the E1/E2 region of the HPV genome. Integration may be an irreversible event as a consequence of host cell genomic instability, or it may be that integration initiates a chain of events including the impairment of tumor suppressor genes

(e.g., *TP53* and *RB*), which results in genomic instability and cell immortalization.

The papillomavirus life cycle differs from that of all other virus families: infection requires the availability of epidermal or mucosal epithelial cells that are still able to proliferate.<sup>5</sup> In these cells, viral gene expression is largely suppressed, although the limited expression of specific “early” viral genes (such as E5, E6, and E7) results in enhanced proliferation of the infected cells and their lateral expansion.<sup>6</sup> Following entry into the suprabasal layers, “late” viral gene expression is initiated; the circular viral genome is then replicated, and structural proteins form. In the upper layers of the epidermis or mucosa, complete viral particles are assembled and released.

A significant role for malignant transformation can be assigned to the *E6* and *E7* genes and their respective proteins.<sup>7</sup> Initial observations revealed that *E6* interacts with *p53*, and *E7* interacts with *RB* to block the activity of these tumor suppressors. Indeed, some of the prominent functions of the *E6* protein originate from its interaction with and degradation of *p53* and the proapoptotic protein *BAK*, resulting in resistance to apoptosis and an increase in chromosomal instability.<sup>5</sup> *E7*, however, interacts with and degrades *RB*, which releases the transcription factor *E2F* from *RB* inhibition and up-regulates *INK4A*.<sup>5</sup> The resulting high *E2F* activity might lead to apoptosis in *E7*-expressing cells. Moreover, *E7* stimulates the S-phase genes cyclin A and cyclin E, and seems to block the function of the cyclin-dependent kinase inhibitors *CDKN1A* (also known as *CIP1* and *p21*) and *CDKN1B*.<sup>5</sup>

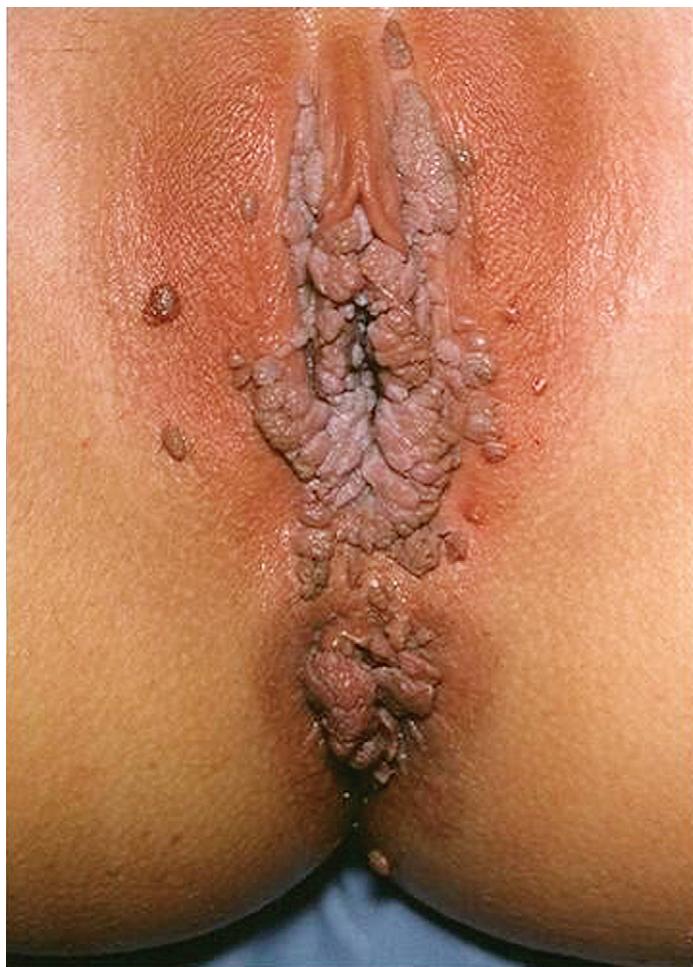

## CLINICAL FEATURES

Human papillomavirus infection is most often asymptomatic and transient. In women, HPV infection presents clinically as warts (usually on the vulva or vaginal introitus) or is detected through cervical cancer screening as a Pap smear abnormality. HPV infection may also present as a result of a positive HPV test with or without a cytologic abnormality in women over age 30 who are screened with the “DNA-Pap” (HPV DNA test and cervical cytology).

### Genital Warts

Condylomata acuminata, or external genital warts, are generally noticed by the patient as visible cauliflower-like tan or pink papillary growths. In African American women the warts are typically hyperpigmented. They are generally painless, but may be associated with itching, burning, or redness, particularly if a secondary infection occurs. Solitary lesions do occur, but multifocal presentation is the rule. Lesions can be found anywhere on the anogenital epithelium, including the vulva, perineum, and perianal skin (Figs. 22-2 and 22-3). In men, the lesions can appear anywhere on the genitalia, including the scrotum and the pubic and perirectal areas. The lesions vary from less than 1 cm in size to massive confluentes involving the entire external genitalia. These growths are benign and generally self-limited, but are treated because of cosmetic reasons or, in extreme cases, because of difficulty with ambulation. Their appearance is generally distressing to patients.

The presence of external genital warts should prompt a careful gross visual inspection, with or without magnification, of

**Figure 22-2 External genital warts.** Typical features are the symmetry and multifocality of the lesions. The entire perineum is involved, including the perianal skin and mucosa.

the entire anogenital area, as well as a Pap smear screen for coexisting HPV-associated lesions. Application of acetic acid before inspection is particularly helpful in identifying vulvar intraepithelial neoplasia and makes lesions easier to identify in men (Fig. 22-4). As with other HPV-associated diseases, condylomas can also be found in “internal” areas of the genital tract, including the vagina, cervix, and anus (Fig. 22-5). In contrast to the vulva, condylomata of the cervix are often flat (condyloma latum). Flat condylomata of the cervix are histologically indistinguishable from low-grade intraepithelial neoplasia, and the terms are interchangeable (Fig. 22-6). Condylomata of the vagina typically resemble the verrucous lesions found on the external genitalia, but may also resemble cervical warts.

Transmission generally occurs through sexual activity, and the age prevalence generally follows the age prevalence of sexual initiation and change of partners. Time from exposure to appearance of lesions varies but is on the order of several months. Transmission may occur from clinically inapparent lesions; partner tracing is not recommended. Genital warts in children are not diagnostic of sex abuse but should prompt an investigation to exclude this possibility. Testing or screening for other common sexually transmitted infections, such as *Chlamydia*, *Trichomonas*,

**Figure 22-3 Anal warts.** Large anal warts in a heterosexual woman with an intact immune function. She has severe psoriasis that involves the genital area.

**Figure 22-4 Penile lesions.** These lesions on the penile shaft were seen only after the application of acetic acid. They were not symptomatic or apparent to the patient.

**Figure 22-5 Cervical condyloma.** This colposcopic photograph depicts a cervical warty lesion. Note the dense white epithelium, its location at the squamocolumnar junction, and its papillary appearance.

**Figure 22-6 Flat cervical wart.** This colposcopic photograph depicts an acetowhite lesion characteristic of flat condyloma, indistinguishable from a low-grade cervical intraepithelial lesion (LGCIN).

gonorrhea, syphilis, hepatitis, and HIV are warranted because of the common sexual routes of transmission.<sup>8</sup>

### Pap Smear Abnormalities

Women with Pap smear abnormalities are generally completely asymptomatic. These abnormalities come to light during routine cervical cytology performed for the purpose of cervical cancer screening. Cellular samples from the transformation zone are examined for cytologic features predicting the presence of underlying lesions that require treatment. In the United States, Bethesda terminology is used to describe cervical cytology results<sup>9</sup> (Table 22-1). Other than inflammatory and reactive changes

attributable to other infections such as yeast, *Trichomonas*, *Chlamydia*, or herpes, most Pap smear abnormalities are attributable to incident or persistent HPV infection. Pap smear abnormalities are very common and generally do not reflect serious disease. Because of uncertainty regarding the nature of the underlying lesion, abnormal Pap smears require further evaluation. The degree of cytologic abnormality determines the most appropriate clinical follow-up.

The ASC diagnosis (atypical squamous cells, former terminology ASCUS, atypical squamous cells of unknown significance) may prompt repeat Pap smear testing in 4 to 6 months or HPV testing.<sup>10</sup> The goal is to avoid missing a lesion that requires treatment, but because of limitations of sampling and cytologic sensitivity may not be diagnosed. Persistent ASC, or high risk HPV-positive ASC, as well as diagnoses of atypical squamous cells—high grade squamous intraepithelial lesion cannot be excluded, atypical glandular cells, low grade squamous intraepithelial lesion, and high grade epithelial lesion, are routinely evaluated with colposcopic examinations and directed biopsies for definitive histologic diagnosis.

## DIAGNOSIS

Human papillomavirus testing is complicated because of the nature of the virus. It cannot be cultured, and antibody methods are relatively insensitive; therefore, HPV detection requires some form of nucleic acid test. The viral life cycle is restricted to differentiating epithelium; therefore, a cellular sample collected from the site of infection is required. Further, HPV is not a single virus but a family of more than 100 closely related viral types. The types are distinguished based on differences in their DNA sequence. Assays must be designed to handle the complexity introduced by the large number of HPV types.

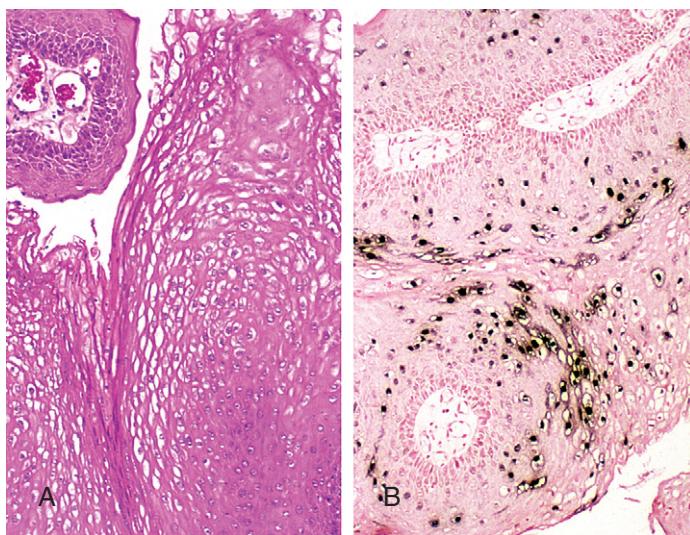

Human papillomavirus testing has been used to understand the epidemiology and natural history of the virus. The nature of the sample and the assay will frame the view of infection. Definitions of occult, persistent, or recurrent infection are complicated because of these issues. Based on association with disease, HPV types found in the anogenital tract are grouped into high risk and low risk types. High risk types are detected frequently in cancers, yet these are the most prevalent types in the general population. HPV testing is evaluated in terms of clinical sensitivity and specificity (ability to detect disease) or analytic sensitivity and specificity (ability to detect HPV). This section will focus on the analytic characteristics of HPV tests.

The only HPV test approved by the U.S. FDA for clinical use is Digene's Hybrid Capture 2 HPV DNA test (HC2). This test can be applied to cervical cells collected with the Digene Cervical Sampler (includes brush and media), cervical cells collected for liquid-based cytology, or with cervical biopsies collected in Digene Specimen Transport Medium. The current assay format uses liquid hybridization in a microarray platform. Samples are lysed to release nucleic acids and combined with the RNA probe mixture. The high risk probe mix includes 13 types (HPV16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, 68). The RNA probes hybridize to the DNA targets in liquid phase and are bound to the wall (i.e., captured) by antibodies specific for DNA-RNA hybrids. The same antibody linked to alkaline phosphatase is used to generate a signal after addition

**Table 22-1**  
**The 2001 Bethesda System Terminology**

Criteria	Categories
Specimen adequacy	Adequate Inadequate
General categorization (optional)	Negative for intraepithelial lesion or malignancy Epithelial cell abnormality
Interpretation/Result	Negative for intraepithelial lesion or malignancy Organisms, reactive changes, atrophy, etc. Epithelial cell abnormalities Squamous cell Atypical squamous cells of undetermined significance (ASC-US) ASC cannot exclude HSIL (ASC-H) Low-grade squamous intraepithelial lesion (LSIL) High-grade squamous intraepithelial lesion (HSIL) Squamous carcinoma Glandular cell Atypical glandular cells (AGC) Atypical glandular cells, favor neoplastic Endocervical adenocarcinoma in situ (AIS) Adenocarcinoma

**Figure 22-7 Histology and in situ hybridization of condyloma.**

A, Hematoxylin and eosin-stained section demonstrating expanded epithelial layers with finger-like projections and cells with enlarged nuclei and perinuclear halos (koilocytes) that are characteristic of HPV infection. B, Colorimetric in situ hybridization with biotinylated probe to HPV 6/11. Dark blue/black color in scattered nuclei, particularly koilocytes, indicates presence of HPV. The uneven signal distribution within the lesion is characteristic of episomal HPV.

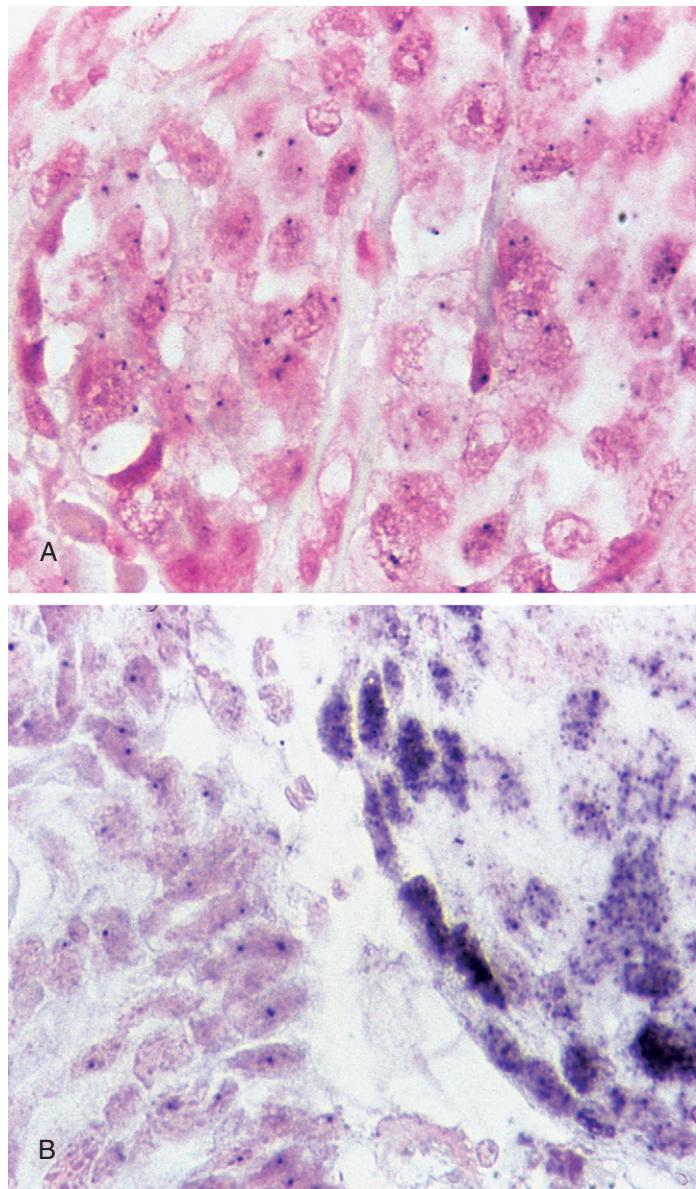

of chemiluminescent substrate. Cutoff for a positive result is determined by comparison of the intensity of sample to that of the 1 pg/mL control. The test has good interlaboratory comparisons and has been widely used in trials determining the clinical utility of HPV testing. The test does not control for sample cellularity and does not give type-specific results. Because the RNA probes are genetically complex and include the majority of the HPV genes, cross-hybridization with types not included as probes occurs. This could be advantageous for detection of other closely related high risk types. Occasionally large numbers of copies of low risk types will yield a positive result.

Type-specific polymerase chain reaction (PCR) assays for HPV are available and can be particularly useful in quantitative assessments of HPV. However, the large number of types that are of interest limit their usefulness in most studies. PCR assays that target sequences that are highly conserved are called *consensus assays*. These assays will generate a product for nearly all HPV types. Type-specific identification requires analysis using sequencing, restriction fragment length polymorphism assays, or hybridization. The three most widely used consensus PCR assays are PGMY09/11, GP5+/6+, and SPF.<sup>11</sup> All target the L1 region. They differ in the primer mix, the size of the amplified product, and the method for type identification. Results differ slightly in terms of type-specific sensitivity and specificity. Typing assays using linear arrays or strips allow for efficient detection of multiple HPV types within a sample.

Other HPV assays include serology and in situ hybridization. Serologic assays use ELISA-based detection of type-specific antibodies against L1-VLPs (virus-like particles). A positive reaction indicates past or current infection. Less than 70% of HPV-positive subjects develop detectable antibodies, and these

develop after a lagtime of several months. There is currently no gold standard for setting the threshold for positive results, and few interlaboratory comparisons are available. Competitive ELISA formats that allow titer determination are being used to follow response to HPV vaccination. The World Health Organization is developing one or more standard sera that will assist in assay standardization. In situ hybridization assays are useful for detecting virus within a morphologic context (Fig. 22-7) and can give information about integration status (Fig. 22-8). Requiring virus to be localized in abnormal cells may increase the specificity of test results, but sensitivity may be affected. The clinical utility of this format is under investigation.

In men, there is no accepted or proven method to detect HPV because the most appropriate site and method of sampling

**Figure 22-8 In situ hybridization of HPV16 in cervical carcinomas.**

## Gynecologic Infectious Disease

has not been determined. A variety of anatomic sites have been studied, including urine, penile urethra, penile shaft, scrotum, and anal area. HPV testing in men has no clinical role.

### TREATMENT

It is important to recognize that treatments are not directed toward eliminating HPV infection; rather, they are directed to elimination of disease associated with HPV. There is no treatment for HPV-positive, cytology-negative women who have no genital warts. This is one reason why patient counseling can be difficult. Without careful explanation it can be quite stressful for women to learn that they have a virus associated with cervical cancer and that there is no treatment for the virus. Patients need to understand that the detection of high risk HPV in the absence of disease indicates an increased risk for disease and that regular screening must always be followed. They should be reassured about the generally transient nature of infection and the success of regular screening in preventing cancer by the detection and treatment of cancer precursors.

Human papillomavirus-associated diseases include common skin warts, genital warts, laryngeal warts (recurrent respiratory papillomatosis), cervical neoplasia, and other anogenital neoplasias (vulvar, vaginal, anal, penile). In addition, there is evidence that HPV is associated with a subset of head and neck cancers. This chapter will only address the treatment of genital warts and cervical cancer precursors, the most common HPV-associated diseases seen in gynecologic practice.

#### Genital Warts

Therapeutic options for condylomata are based on removal of the lesions. A variety of chemicals can be applied topically to destroy the lesion or stimulate immune destruction. Lesions may also be removed by surgical approaches, including laser ablation, cryoablation, or excision. Regardless of the approach, a high recurrence rate, ranging from 35% to 52%, is the rule (Table 22-2), since the underlying HPV infection is not eradicated.<sup>11,12</sup> The choice of therapy is dictated by the size and anatomic location of the lesions, provider experience, and patient preference.<sup>13</sup>

#### External Genital Warts

Based on ease of use and low toxicity, first-line therapeutic options for external genital warts include podofilox (Condylox) or imiquimod (Aldara). Both of these agents are self-administered. Patients, particularly those with keratinized warts, are advised to bathe before application to allow better penetration of the medication. Sexual contact should be avoided for 24 hours after application.

Podofilox is an antimitotic agent that is prepared as a gel or solution. Visible warts are treated twice daily for 3 consecutive days, then discontinue for 4 consecutive days. This weekly cycle can be repeated up to four times. Podofilox can be absorbed systemically and may cause bone marrow toxicity and neurotoxicity; therefore, it should be avoided in pregnancy and should not be used to treat large lesions ( $>10 \text{ cm}^2$ ). The dose should not exceed 0.5 mL per application. The clearance rate of warts with podofilox seen in multiple randomized double-blind

**Table 22-2**  
**Summary of Therapeutic Response to External Genital Warts\***

Therapy	Patients with Clearance of Warts (%)	
	At End of Treatment	3 Months Post-treatment
Cryotherapy	70–88	63–92
Electrocautery	94	78–91
Interferon	6–90	18–62
Laser	31–86	39–86
Podofilox	32–79	22–73
Surgery	89–93	36
TCA or BCA	64–81	70
5-FU	10–50	37
Aldara	72–84	72 (Females) 33 (Males)

\*References provided in text.

placebo- or vehicle-controlled trials is 45% to 91%, with a recurrence rate of 4% to 91%.<sup>14</sup>

Imiquimod is an immune response modifier that stimulates proinflammatory cytokines locally. It is available as a 5% cream in a predosed 250-mg sachet. Imiquimod is applied at bedtime, allowing 6 to 10 hours of overnight exposure, and is removed the following morning with soap and water. The medication is used three nonconsecutive times per week for 16 weeks or until the lesion clinically clears. As with podofilox, the wart clearance rate for imiquimod seen in multiple randomized, placebo-controlled, double-blind trials ranges from 37% to 52% after 8 to 16 weeks of therapy.<sup>15–18</sup> Benefits of using imiquimod over other medical therapies include a lower rate of recurrence (9% to 19%) and a greater median reduction in size of lesion.<sup>15,19,20</sup>

Other second-line therapies generally require administration by a health care provider and therefore multiple office visits. Trichloroacetic acid or bichloracetic acid induces a chemical burn by coagulating proteins. These strong acids are not absorbed and therefore can be used during pregnancy. Treatments are applied weekly. Podophyllin resin (10% to 25%) is another option for weekly application by a health care professional. Topical 5-fluorouracil (Efudex 5%) is a chemotherapeutic agent whose use is decreasing as other agents become available. It has toxicities, including nonhealing ulcerations of the vulva and vagina. Intralesional interferon is as effective as the other second-line therapeutics but is uncommonly used because of the high frequency of systemic side effects.

Treatment of external genital warts with surgical techniques has the advantage of providing immediate clearance of the lesions; however, high recurrence rates remain problematic. Surgical interventions include ablative and excisional procedures: cryotherapy, electrosurgery, laser, ultrasonic surgical aspiration, and cold knife excision. The recurrence rates for each method vary. The recurrence rates for cryotherapy, electrosurgery, and excisional biopsy range from 19% to 29%, in contrast to laser ablation, with recurrence rates of 60% to 77%. No randomized studies have compared one modality to the other, nor has there been a study comparing recurrence by size of lesion, which

affects the recurrence rate and choice of treatment modality. For example, electrosurgery is only an option for small lesions because of the potential for third-degree skin burn.<sup>21</sup>

All surgical methods require local or regional anesthesia, depending on the surface area to be treated. Because these epithelial lesions are not invasive, only superficial excision to the depth of the epithelium (1 mm) is required. However, external genital warts may have multifocal involvement, requiring treatment of extensive areas with a greater anesthetic and analgesic requirement. In general, surgical procedures require more experience and expertise than medical therapies but have the benefit of a single visit for treatment. However, convalescence from the one-day surgical treatment may extend over a month.

Cryotherapy and electrosurgery both destroy warts by thermal-induced cytolysis (freezing or burning). Overtreatment and damage to the dermis should be avoided. Local anesthesia is required for electrosurgery and may be required for cryotherapy of extensive lesions. Carbon dioxide laser destroys the warts with the benefit of low penetration of the beam; thus, underlying dermal involvement is minimized. Cold knife excision is performed by slicing the lesion off the dermis. Hemostasis is achieved with electrosurgery. Condylomata that fail to entirely clear with topical therapies alone should be considered for an excisional biopsy for both treatment and histologic diagnosis to exclude a dysplastic lesion.

Large and multifocal vulvar condylomata measuring greater than 4 cm in greatest dimension, referred to in the past as *giant condyloma of Buschke-Lowenstein*, present a management challenge, because they usually fail to respond to medical therapy. However, excision or ablation of large vulvar lesions is very painful and is associated with delayed wound healing, increased risk of scarring, and poor cosmetic result. As an alternative, a staged medical and surgical approach may be used. Topical therapy with podofilox or imiquimod can be used to reduce the size of the lesion to one that is more amenable to surgical excision with decreased morbidity.

### **Cervical Warts**

Cervical warts are usually flat and asymptomatic; they regress spontaneously and do not require treatment. However, a high grade intraepithelial lesion must be excluded with a biopsy. If cervical warts require treatment for progressive disease, they should be treated as high grade cervical lesions, with cryotherapy or loop electrosurgical excision procedure (LEEP).

### **Vaginal and Anal Warts**

Condylomata of the vagina or the anus are usually associated with vulvar or cervical condylomata. Treatment options for vaginal and anal disease are limited. Using direct visualization with a speculum as necessary, trichloroacetic acid or bichloracetic acid may be applied. To minimize damage to adjacent tissues, the speculum should not be removed until the acid has dried and the treated tissue appears white. As with external genital warts, weekly application by a health care professional is required. Another option includes surgical removal with carbon dioxide laser or cold knife excision. Cryotherapy with a probe is not recommended due to the close proximity and potential for injury of the bladder and rectum. Topical 5-fluorouracil is not recommended because of the risk of nonhealing ulcers.

### **Cervical Intraepithelial Neoplasia**

Although only a small fraction of even high grade lesions are truly premalignant, therapeutic intervention of these lesions at the intraepithelial stage before they become invasive is responsible for the success of screening practices in cervical cancer prevention.

#### **Low-Grade Cervical Intraepithelial Neoplasia (LGCIN, CIN I)**

In deciding on management of these lesions, it's important to realize that eradication of the intraepithelial lesions does not eradicate the HPV infection in the genital epithelium. It is therefore recommended to manage the patient expectantly to allow the opportunity for spontaneous clearance of the lesion. Low grade cervical epithelial neoplasia (LGCIN), also referred to as cervical intraepithelial neoplasia grade I (CIN I) or mild dysplasia, is the histologic reflection of productive HPV infection. It is characterized by a 40% to 70% rate of spontaneous regression and a 10% to 15% rate of progression to a high grade intraepithelial lesion.<sup>22</sup>

Expectant management may consist of a repeat evaluation in 6 to 12 months, including a repeat Pap smear alone, repeat Pap smear and colposcopic examination, or HPV DNA testing in 12 months.<sup>23</sup> For persistent low grade lesions, the length of observation before intervention is at the discretion of the colposcopist. A defined period of time of at least 1 year is acceptable, but indefinite observation may be appropriate in circumstances with a motivated patient in whom it is desirable to avoid instrumentation. For example, immunocompromised women such as transplant recipients, long-term corticosteroid users, or HIV-infected women, may benefit from prolonged observation to avoid multiple procedures for frequent recurring low grade lesions.<sup>23</sup>

The decision whether to manage CIN I expectantly or to treat the lesions must also consider the patient's preference as well as her ability to comply with follow-up. Dysplasia clinics in varied locations are notorious for no-show rates of up to 50% for any one appointment. Indications for treatment of CIN include persistent or progressive disease. Progression includes increased grade or size of lesion. Persistence or progression must be documented histologically, not only cytologically or by colposcopy. Progression by size criteria is by growth of lesion to involve additional quadrants of the cervix, or histologic progression of the grade of the dysplasia from CIN I to CIN II or III.

#### **High-Grade Cervical Intraepithelial Neoplasia (HGCIN, CIN II, III)**

The success of Pap smear screening practices in decreasing the rates of invasive cervical carcinoma is most likely due to the treatment of HGCIN, the well established cancer precursor lesion. From 14% to 22% of HGCIN lesions progress, justifying immediate treatment of all HGCIN lesions with few exceptions.<sup>24</sup> Furthermore, Chang found a 20% to 30% progression of carcinoma *in situ* to invasive carcinoma within 5 to 10 years.<sup>25</sup> Before proceeding with treatment, a complete evaluation of the lesion is recommended, consisting of an adequate colposcopic examination, visualization of the entire lesion and the squamocolumnar junction, and a negative endocervical

## Gynecologic Infectious Disease

curettage. If these conditions are not met, a diagnostic conization of the cervix, which may also be therapeutic, is required.

Ablation and excision are equally efficacious treatments, with a risk of posttreatment recurrence of less than 10% for all treatment modalities: cryotherapy, laser ablation, laser conization, cold knife conization, and LEEP. Benefits of ablative procedures with cryotherapy include the broad availability of the procedure and the lack of need for anesthesia. Laser ablation of the squamocolumnar junction is also an acceptable ablative procedure.

Many colposcopists are biased toward excisional methods, in large part because these methods produce a large specimen for further pathologic evaluation, including comment on the margins of excision. Uncommonly, findings on an excision specimen upgrade the diagnosis and affect management decisions. From 4933 published LEEP specimens, 39 (0.8%) showed unsuspected microinvasive disease, 11 (0.2%) occult invasive cancers, and 14 (0.3%) adenocarcinoma in situ.

An excisional procedure is preferred over an ablative procedure for women with recurrent HGCIN or when a carcinoma is anticipated. A hysterectomy is an acceptable mode of treatment for recurrent HGCIN in a woman not interested in maintaining fertility. Hysterectomy is not an appropriate option for the primary treatment of CIN.

Cold knife conization remains the definitive treatment in select cases when the margins of excision need to be meticulously evaluated and it is felt that the submillimeter zone of cautery artifact in a LEEP specimen may compromise this evaluation. These cases include microinvasive carcinoma when a hysterectomy is not planned and adenocarcinoma in situ.

In adolescents, based on level II evidence, it is acceptable to follow a CIN II lesion with repeat Pap smear and colposcopy for 1 year, provided the examination is satisfactory and endocervical curettage is negative.

After treatment, recommended follow-up is in the form of a repeat Pap smear at 4 to 6 months, HPV testing at 12 months, or repeat Pap smear and colposcopy at 4 to 6 months.<sup>23</sup>

### **Management of Positive Margins or Positive Endocervical Curettage Results**

Many factors are to be taken into consideration in the management of patients with positive endocervical curettage results or positive conization margins. These include probability of residual cancer, which margin is positive, the degree of dysplasia at the margin or endocervical curettage, patient compliance, and fertility desires. If fertility is not an issue and a positive endocervical curettage is obtained, a repeat conization should be performed. Pap smear and colposcopy should be repeated in no later than 3 to 4 months if the patient strongly desires fertility and would prefer not to have a repeat conization, which could adversely affect obstetric outcome.

Recurrence following a conization with a negative margin is 10% compared to 26.6% if margins are positive.<sup>26</sup> Kobak and colleagues, in a record review of 104 patients with conization, found that 8 of 27 (29%) cases with positive margin and positive endocervical curettage had invasive cancer, whereas cancer was found in 0 of 37 cases with positive margin and benign endocervical curettage.<sup>27</sup> If either endocervical curettage or margin were negative, there were no cases of invasive cancer. Six of

16 patients over age 50 with positive endocervical curettage had invasive cancer (two microinvasive and four frank invasion).

The risk of recurrence of adenocarcinoma in situ is high: 40% to 70% if margins are positive and 10% to 40% with negative margins.<sup>28,29</sup> A repeat conization is warranted in cases of adenocarcinoma in situ with positive margins to rule out invasive disease. After confirmation of the pathology, a hysterectomy is indicated in the patient with adenocarcinoma in situ who is not interested in maintaining fertility.

### **Vulvar, Vaginal, and Anal Intraepithelial Neoplasia**

The entire anogenital epithelium is at risk of HPV infection. The natural history of HPV associated disease appears to be similar for the various epithelia. Similarly, low grade lesions of the vulva, vagina, and anal canal may be managed expectantly. High grade lesions share malignant potential, requiring destruction of the lesion.

### **CLINICAL COURSE AND PROGRESSION**

Infection with HPV is the most common sexually transmitted infection. The infection is most often without any symptoms or clinical manifestations. For most patients with intact immune function, the infection is transient. Koutsky and colleagues noted a 2-year cumulative incidence of CIN II/III from first positive HPV as 28% among college women.<sup>30</sup> In addition, this group noted no new cases of CIN II/III after 24 months regardless of HPV status. Moscicki and colleagues reported that most women with HPV clear it in 24 months.<sup>31,32</sup> A prospective study of young women with 6-month follow-up by Woodman and colleagues describes the incidence, persistence, and risk of HPV infection.<sup>33</sup> Among 1075 women negative for HPV and with cytologically normal cervical smears, the cumulative risk of any HPV infection over 3 years was 44%. The median duration of HPV infection by type and associated risk for developing CIN II/III are highlighted in Table 22-3. Duration was defined as one or more uninterrupted time points of HPV detection.

### **PITFALLS AND CONTROVERSIES**

#### **Human Papillomavirus Education**

Despite the overwhelming prevalence of HPV and the potential consequences of an HPV infection, several studies have demonstrated an enormous lack of awareness of the disease.<sup>34-38</sup> In a study of 263 college-aged women, 87% replied that they had either never heard of HPV or were not sure if they had heard of HPV.<sup>34</sup> Another study of university students confirmed these findings, with only 38% responding that they had heard of HPV. The same study also found that 59% of participants responded that they were unaware of how HPV could be transmitted. Ramirez and colleagues quantified HPV knowledge among young women at a local university, finding a mean knowledge score at only the 68th percentile.<sup>35</sup> Those who had heard of HPV had received information from the following sources: health professionals (30%), class (29%), clinics (23%), friends (22%), teachers (18%), and parents and boyfriends (<8%). In contrast, adolescents' knowledge of HPV and cervical dysplasia after the diagnosis of HPV was quite high.<sup>37</sup> Only one published study has examined the knowledge of adults beyond college students. Adults seen in a typical family physician's office have similarly

limited knowledge of HPV.<sup>39</sup> One tool clinicians can use to identify those with the least amount of knowledge is to ask patients how informed they are about HPV. The preferred time to receive information about HPV is before a patient becomes sexually active. However, it remains unclear whether educational intervention or knowledge changes risky behaviors.

### Psychosocial Issues Regarding Human Papillomavirus

Only one published study has examined the potential for adverse psychosexual alterations due to HPV besides an abnormal Pap smear.<sup>40</sup> This cross-sectional study was conducted with sexually active women aged 18 to 60. They had few sexually transmitted infections and few risk factors, yet 20% had unsuspected HPV infection. Psychosexual characteristics at baseline and at follow-up, as well as perceived changes in these characteristics by the women, did not differ between women with HPV infection and those without. Stratification by potential confounders, including the presence of a vaginal infection at the time of study enrollment, household income level, ethnic background, age, marital status, and sexual history, did not alter these results. However, there is potential for significant adverse psychosexual impact given the issues of an untreatable, sexually transmitted infection that increases a woman's risk for an abnormal Pap smear. More data are needed to examine the full impact.

### Human Papillomavirus Vaccines

Because HPV infection is necessary (even though not sufficient) for cervical cancer, preventing HPV infection has the potential to eliminate cervical cancer. Phase II trials of a monovalent vaccine against HPV16<sup>41</sup> and a bivalent vaccine against HPV16 and HPV18<sup>42</sup> have been essentially 100% effective at preventing persistent infection with the types included in the vaccine. The

current vaccine formulations are based on VLPs composed of L1 proteins. Vaccination has resulted in very high titers of type-specific antibodies. Phase III trials are under way and licensure can be anticipated.

Although these developments are promising, many questions must be answered before vaccine implementation. Follow-up to date has been short-term, and cancer is not the observed endpoint. Because not all viral types associated with malignancy are included in the vaccines, cervical cancer screening will not be able to be stopped. What is the most cost-effective approach to combination vaccination and screening? How long is protection maintained? What age-group should be targeted for vaccination? As a prophylactic vaccine, it should be given before exposure at the time of sexual debut. Will parents accept vaccination of their adolescent children against a sexually transmitted infection? Should both boys and girls be vaccinated? The availability of vaccine further emphasizes the need for education of the general public and health care providers about HPV.

## KEY POINTS

Sepsis should be suspected if any of these signs or symptoms are present postoperatively:

- Temperature  $\geq 100.4^{\circ}\text{F}$  ( $38^{\circ}\text{C}$ ) and tachycardia
- Elevated white blood cell count or  $> 10\%$  increase in immature neutrophils
- Pain adjacent to the surgical site that does not respond to narcotic analgesia
- Necrosis of skin in or adjacent to the surgical site
- Leukopenia and decreased urine output
- Hypotension, oliguria, tachypnea

Postoperative pelvic infections continue to be a significant cause of morbidity and mortality. In addition to postoperative pelvic infection, the gynecologic surgeon must be concerned with infections that are associated with the surgical procedure but occur outside of the pelvis. The key to reducing the morbidity and mortality associated with postoperative infection resides in predicting which patients are more likely to develop a postoperative infection and then applying appropriate measures preoperatively, intraoperatively, and postoperatively. The gynecologic surgeon can take measures to reduce the patient's risk for developing a postoperative infection.

## MICROBIOLOGY

Postoperative pelvic infections are most frequently caused by bacteria that make up the patient's endogenous vaginal microflora. The endogenous vaginal bacteria include gram-positive and gram-negative aerobic, facultative, and obligate anaerobic bacteria listed in Table 23-1. The status of the vaginal ecosystem, that is, whether it is in a healthy state (*Lactobacillus*-dominant) or in an altered state, appears to be of primary importance with regard to the patient's potential risk for developing a postoperative pelvic infection. When the patient's microflora is dominated by *Lactobacillus*, the species of *Lactobacillus* is important, for the species must produce a significant amount of organic acids, including lactic acid, hydrogen peroxide, and lactocin. When the ecosystem is dominated by *Lactobacillus*, the number of lactobacilli is at least  $10^6$  bacteria/mL of vaginal fluid, whereas other bacteria are present in a concentration less than or equal to  $10^3$  bacteria/mL of vaginal fluid. This ratio of lactobacilli to other bacteria is maintained by a vaginal pH below 4.5; the presence of hydrogen peroxide, which is toxic to those bacteria that lack catalase (i.e., obligate anaerobic bacteria); and the production of lactocin.<sup>1-3</sup>

When the pH of the vaginal environment begins to rise, the lactobacilli are suppressed. The bacterium that gains dominance will determine the state of the altered vaginal microflora. If *Gardnerella vaginalis* gains dominance, its growth results in either a continued decrease in the hydrogen ion concentration or a rise in pH and a reduction in the oxygen concentration. These physiologic changes in the environment cause the continued growth of *Gardnerella* and an increase in the growth of the obligate anaerobic bacteria. In addition, the facultative bacteria switch from an aerobic metabolism to an anaerobic metabolism. When this occurs, both *Gardnerella* and the obligate anaerobic bacteria dominate ( $\geq 10^6$  bacteria/mL), and the facultative anaerobic bacteria are present in a concentration between  $10^3$  and  $10^6$  bacteria/mL of vaginal fluid. A microflora dominated by obligate anaerobic bacteria is known as *bacterial vaginosis*. Typically, bacterial vaginosis is defined as a vaginal condition in which a shift in the bacteriology of the vagina has occurred, the lactobacilli have lost dominance and the obligate anaerobes assumed dominance, and there is an absence of white blood cells (WBC). The patient's microflora can become dominated by a gram-negative facultative bacterium (e.g., *Escherichia coli*, a virulent bacterium that has been involved in pelvic infections). Patients who develop an endogenous vaginal microflora dominated by *Streptococcus agalactiae* can develop symptomatic vaginitis, but this microflora is not a risk factor for the development of a postoperative pelvic infection. However, if the patient has a significant chronic illness (e.g., insulin dependent diabetes [IDDM]) or significant immunosuppression, Group B streptococci (GBS) will place the patient at risk for infection morbidity.

The significance of an altered endogenous microflora with regard to the potential development of postoperative infection resides in two important characteristics. Infection requires that the inoculum be sufficient to overcome the host defense mechanisms. This allows the bacterium to adhere to the epithelium, invade to deeper tissues, and reproduce. The organisms that make up bacterial vaginosis contain many virulent bacteria, such as the facultative and obligate anaerobic bacteria. Many of these bacteria are gram-negative, and therefore contain lipopolysaccharide (LPS), which is responsible for initiating the pro-inflammatory response. In addition to the presence of virulent bacteria, some of these bacteria act synergistically to initiate the development of abscess formation (e.g., *E. coli* + *Bacteroides fragilis*, *E. coli* + *Prevotella bivia*, and *Enterococcus faecalis* + *P. bivia*).<sup>4</sup> The activity of these bacteria combinations explains why some patients who appear to have an uncomplicated hysterectomy develop a postoperative pelvic abscess. The synergistic activity of bacteria may contribute to the production of virulence factors (collagenases, proteinases, fibrinases, enzymes to break down immunoglobulins) as well as the

Adapted from Faro S: Vaginal microflora. In Faro S (ed): Sexually Transmitted Diseases in Women. Philadelphia: Lippincott Williams & Wilkins, 2003, p. 98.

production of nutrients required by a co-colonizing bacterium. This activity allows for the growth and reproduction of the co-colonizing bacterium, thereby enabling it to achieve a population that permits it to become a co-infecting bacterium.

The endogenous microflora, not bacteria introduced from the exogenous environment, appears to be a significant factor and is the principal reason why patients who undergo hysterectomy are at risk for the development of a postoperative pelvic infection. Women with a *Lactobacillus*-dominant endogenous vaginal microflora who are undergoing a hysterectomy are at extremely low risk for the development of postoperative pelvic infection. In a study, 200 women undergoing abdominal or vaginal hysterectomy were analyzed with respect to the status of their endogenous vaginal microflora and the development of postoperative infection. The results showed that only those with bacterial vaginosis had a significant rate of infection compared to those patients who had either a *Lactobacillus*- or GBS-dominant endogenous vaginal microflora.<sup>5</sup>

## RISK FACTORS FOR INFECTION

For patients undergoing pelvic surgery the risk increases significantly when the vagina is entered during the course of the operation. Entry into the vagina provides a source of bacterial contamination of the pelvis. This contamination source is not limited to the pelvic peritoneum and pelvic organs; it can also allow these bacteria to colonize the abdominal incision. In cases where the vagina is not grossly entered, the presence of suture in the vaginal apex provides a conduit for bacteria to gain entrance to the pelvis. Both the grossly opened vagina and the vagina that is only penetrated by suture allows for bacteria to seed the pelvic cavity and colonize the vaginal apex as well as the

pelvic cavity continuously. Frequently, there is a collection of serum or blood at the vaginal apex, plus necrotic tissue and suture, thus providing a culture medium for the bacteria that gain entrance to this area. The suture acts as a foreign body and lowers the size of the inoculum required for infection to develop de novo. The combination of these factors allows for the reproduction of bacteria within an environment conducive to the growth of both facultative and obligate anaerobic bacteria. If the tissues at the surgical site are significantly devascularized so that the oxygen concentration and reduction potential are significantly reduced, this can result in inhibition of phagocytosis. Additionally if the area is significantly devascularized, suitable levels of antibiotic will not be achieved and both cellular and humoral host antibacterial agents will be unable to arrive at the site of bacterial colonization.

Patients with chronic illness (e.g., IDDM, severe hypertension, and immunosuppression) are at risk for postoperative infection. Patients with IDDM and severe hypertension can have peripheral vascular disease; during the operative procedure the surgical areas can experience hypoxia and are thus susceptible to infection.

Morbidly obese patients pose significant problems to the gynecologic surgeon performing a laparotomy or vaginal hysterectomy. The difficulties encountered in this instance begin with the abdominal wall; with a lower abdominal vertical incision, a significant amount of subcutaneous fatty tissue is encountered. The depth of subcutaneous fatty tissue is proportional to the amount of dead space, which allows for the collection of serum and blood. Incising the subcutaneous tissue involves cutting through lymphatic vessels and arterioles as well as venules. The pressure exerted by retraction, a decrease in blood pressure and spasm of the lymphatic vessels, arterioles, and venules results in cessation of the exiting of blood and serum. Postoperatively, the return to preoperative blood pressure and relaxation of the vessels causes the development of a seroma or hematoma. Repeated trauma to the cut surfaces of the abdominal wall occurs when the hands of surgeons and assistants brush over the exposed tissues. Bacteria can colonize the surface of the exposed tissues. Small lacerations occur in the subcutaneous fatty tissue and muscle secondary to the manipulations that occur during the operative procedure. When the abdominal incision is closed, removal of the retractors relieves the pressure from the abdominal wall and allows the serum and blood to enter the dead space of the closed incision. Bacterial colonization occurs, and this closed space with serum and/or blood serves as culture medium and an incubator. Operating in the pelvis of the morbidly obese patient is also difficult because the surgeon must operate through a thick abdominal wall. Additionally, the fatty tissue in the pelvis often hampers visualization of the operative field. There is also a significant opportunity for seepage of serum and blood around the vaginal apex. This creates a situation similar to that observed with the abdominal wound except there is a greater opportunity for bacterial colonization of the vaginal cuff. Bacteria from the vagina can gain entrance to the pelvis and cause pelvic cellulitis. If a hematoma or a seroma develop and bacteria gain entrance, an abscess can form. The microbiologic makeup of a postoperative infection that occurs in the pelvis differs from one that occurs in an abdominal surgical incision. However, the microbial pathophysiology, events that occur

during the operative procedures, and host factors are probably similar.

## PREVENTION

Prevention of postoperative infection in gynecologic surgery begins with knowing the patient's past history of infection, her current status with regard to inherent risk factors, and what preventive measures were taken during the operative procedure. If the patient had surgery in the past and developed a postoperative infection, she may have an inherent defect in her immune system or a chronic subclinical infection (e.g., gingivitis) or an altered vaginal microflora. Therefore, reviewing her history may raise the need for further evaluation before performing an elective operation.

Risk factors inherent to patients fall into three categories: chronic illness (e.g., IDDM, severe chronic hypertension, immunosuppressive diseases, morbid obesity, smoking, abuse of alcohol), altered vaginal microflora syndromes, and recent antibiotic therapy.

Patients with chronic illness should be evaluated to ensure that the illness is properly managed and controlled. The diabetic patient's blood glucose should be under control weeks before the operative procedure is performed. Both severe diabetes and chronic hypertension have significant effects on the peripheral circulation. The presence of hyperglycemia in any tissue involved in the operative procedure will suppress phagocytic activity. The tissue supplied by the peripheral circulation is compromised and therefore not well perfused and oxygenated. Combine this with the mechanical effects of the operative procedure and these tissues will experience a degree of hypoxia. In addition to the hypoxia there is a decrease in antibiotic that will be perfusing this tissue. Therefore, the patient must be well oxygenated during the procedure. If the patient uses tobacco products, nicotine will also have an effect on the peripheral vascular system as well as impairing lung function. The patient should have pulmonary function studies performed to determine if there is decreased lung function. The patient should be instructed to quit smoking or using tobacco products 3 weeks before admission to the hospital for her surgery. Before surgery the patient should also be instructed in the use of incentive spirometry. The morbidly

obese patient should be evaluated for hyperglycemia, hypertension, the presence of altered vaginal microflora, and nasal carriage of *Staphylococcus aureus*, as well as have pulmonary function studies, a chest x-ray, and a consultation with a pulmonologist if the pulmonary functions are abnormal.

All patients undergoing an operative procedure involving the vagina, regardless of the degree of involvement, should have an assessment of the lower genital tract microflora to determine if it is altered. This is easily accomplished by determining the color of the discharge, the pH, and whether an odor is present, and by taking a wet preparation (Table 23-2). If microscopic examination of the vaginal discharge reveals the presence of an altered vaginal microflora or bacterial vaginosis and the presence of WBCs, the physician should evaluate the patient further for the possible existence of an associated infection (e.g., *Trichomonas vaginalis* or cervical infection with *Chlamydia trachomatis*, *Neisseria gonorrhoeae*, herpes simplex virus, or human papillomavirus). Patients with an altered vaginal microflora who are going to have elective vaginal surgery are at risk for the development of a postoperative pelvic infection. These patients are at great risk for postoperative pelvic infection even after receiving antibiotic prophylaxis before the operative procedure.<sup>5</sup> Although antibiotic prophylaxis has been shown to reduce the risk of postoperative infection, patients with altered vaginal microflora may derive only partial benefit from antibiotic prophylaxis.<sup>6-9</sup>

Antibiotic prophylaxis is recommended for patients who are not infected. Patients with an abnormal vaginal microflora should be considered to have a subclinical or clinical infection because the number of pathogenic bacteria in the vaginal microflora is in excess of  $10^6$  bacteria/mL of vaginal fluid. It can be hypothesized that this amount of bacteria is too high for surgical prophylaxis to overcome.

Patients designated to receive antibiotic prophylaxis should receive a single dose within 1 hour of beginning the operative procedure. If the patient has a clinically apparent or subclinical infection she should receive therapeutic doses of antibiotic. If the operative procedure is associated with more than 1500 mL of blood loss or lasts longer than 3 hours, a second dose of antibiotic should be administered. The antibiotic should be given to noninfected patients scheduled for an operative

**Table 23-2**  
Assessment of the Vaginal Microflora

Character of Discharge	Healthy	Bacterial Vaginosis	Altered Vaginal Flora	Trichomonas	Candida
Color	White to slate-gray	Dirty gray	Gray, green-yellow, green	Dirty gray	Gray
Odor	No	Yes	No	Possibly	No
pH	<4.5	>5	>5	>5	<4.5
Whiff test	Negative	Positive	Negative	Possibly negative	Positive
Clue cells	No	Yes	No	Maybe*	No
WBCs	No	No	Maybe†	Yes	Maybe†
Lactobacillus dominant	Yes	No	No	No	Possibly

\*Clue cells may or may not be present.

†White blood cells may or may not be present.

**Table 23-3**  
**Indications for Antibiotic Prophylaxis**

Procedures with a Definite Indication	Possible Indications (no data available)
Total vaginal hysterectomy	Laparoscopic hysterectomy
Elective abortion	Tension-free and subobturator urethral sling
Abdominal hysterectomy	Retropubic urethral suspension Colposacropexy

procedure that has been associated with a significant risk for development of a postoperative infection (Table 23-3).

Antibiotic administered prophylactically should not be given without a definite indication because of its impact on the endogenous vaginal microflora. Several investigators have demonstrated that even a single dose of antibiotic can cause changes in the endogenous microflora. Cephalosporins will select for the enterococci, even when a single dose is administered.<sup>10</sup>

## DIAGNOSIS AND MANAGEMENT

The clinical signs of infection are an elevated body temperature and tachycardia. These two findings should alert the physician to initiate a physical examination, including a pelvic examination, in the postoperative patient regardless of the amount of time that has elapsed since completion of the operative procedure. Additional findings indicative of infection are elevated WBC count, an increase (>10%) in immature polymorphonuclear leukocytes, an increased pulse rate that parallels the temperature, pain at the operative site that is not relieved by the prescribed analgesic, and a persistent ileus. In addition, both the patient's abdominal and vaginal incisions should be inspected.

The clinical findings that indicate that a patient may have an infection in the incisions are erythema, swelling, edema, increased temperature in the tissue surrounding the incision, pain, and drainage from the incision. The incision should be carefully inspected; if any of the above is present, the incision should be examined via ultrasonography. If a pocket of fluid is observed, it should be aspirated and Gram stain and culture of the fluid for bacteria should be performed (Table 23-4). Once the pocket of fluid has been aspirated, it should be placed into appropriate transport media for isolation of aerobic and anaerobic bacteria and mycoplasmas (*Mycoplasma* and *Ureaplasma*). The incision should then be opened and completely drained, all necrotic tissue should be débrided, and the incision packed with gauze moistened with 0.025% acetic acid. The dressing should be changed three to four times a day. If there is no evidence of infection after 48 hours of wound management, the incision can be closed. If there was documented infection or necrotic tissue, this wound management protocol should be continued until a complete layer of granulation has formed. Once this layer of tissue has formed, the incision can be closed with suture or Steri-Strips or by gradual closure. Alternatively the wound could be allowed to close by secondary intention. When initially evaluating the incision for possible infection, it is important to

ensure that the infection has not progressed to necrotizing fasciitis (as discussed in Chapter 18).

After the abdominal incision has been evaluated, the patient should be thoroughly examined. It is critical to determine if the patient has an infection outside of the pelvis. The surgical patient is at risk for developing a variety of infections because of the anesthetic, the use of peripheral lines, and an indwelling (Foley) catheter. Each of these systems must be evaluated to ensure that infection has not occurred. Once the examination is complete, an assessment of the pelvis should be performed. The vaginal discharge should be examined for the presence of pus, its origin, and the presence of erythema at the vaginal apex. The vaginal apex should be palpated to determine if the tissue is hot to the touch. A bimanual and rectal examination should also be performed to determine if a mass is present. If there is evidence of purulent fluid draining from the cuff, a needle should be inserted through the incision at this point and the fluid aspirated. Gram stain and culture for aerobic, facultative, and obligate anaerobic bacteria should be performed on the fluid.

If a mass is detected, an ultrasonogram should be obtained to determine if there is a pelvic mass and its location. If a pelvic mass is present, ultrasonography can reveal its characteristics: whether its wall is thin or thick; whether septations are present; and where free fluid is present in the pelvis. If a definitive mass is present at the vaginal cuff, it can be completely drained by gently opening the cuff. If the mass is not adjacent to the vaginal cuff, the patient should be taken to the operating room so the mass can be drained vaginally under anesthesia. Once the mass has been drained, a drain (e.g., a Foley catheter, or a mushroom or similar drain) should be attached to a suction device and should remain in place until only minimal drainage accumulates over a 24-hour period.

As soon as a diagnosis of infection is suspected, the patient should be administered intravenous broad-spectrum antibiotics (Table 23-5). If the patient received a prophylactic antibiotic, this should be considered when choosing an antibiotic regimen for treatment. Cephalosporins are the most commonly used antibiotics for prophylaxis and can select for resistant bacteria. In addition, most pelvic infections are polymicrobial; therefore, empiric antibiotic therapy should provide coverage against gram-negative and gram-positive aerobic, facultative, and obligate anaerobic bacteria. Thus, it may be prudent to initiate treatment

**Table 23-4**  
**Evaluation of the Infected Wound**

Fluid Color	Gram-stain Characteristics	Action
Serous and clear	Few WBCs, no bacteria	Drain
Serous and cloudy	WBCs >5/hpf, no bacteria	Culture for <i>Mycoplasma</i> and <i>Ureaplasma</i>
Seropurulent	WBCs >5/hpf, bacteria +	Culture for aerobes and anaerobes
Serosanguineous	Few WBCs, no bacteria	Drain
Bloody	WBCs >5/hpf, bacteria +/-	Culture for aerobes, anaerobes, <i>Mycoplasma</i> and <i>Ureaplasma</i>

**Table 23-5****Antibiotic Choices for Treatment of Postoperative Pelvic Infections**

Piperacillin/tazobactam 3.375 g IV q 6 hr
Ampicillin/sulbactam 3 g IV q 6 hr
Piperacillin/tazobactam or ampicillin/sulbactam + gentamicin 5 mg/kg of body weight q 24 hr or 2 mg/kg of body weight as a loading dose followed by 1.5 mg/kg of body weight q 8 hr
Metronidazole 500 mg IV q 8 hr + gentamicin + ampicillin 2 g q 6 hr
Metronidazole + levofloxacin 500 mg q 24 hr
Levofloxacin 500 mg or 750 mg q 24 hr
Clindamycin 900 mg IV q 8 hr + gentamicin + ampicillin
Clindamycin + levofloxacin
Imipenem 1 g IV q 12 hr
Invanz 1 g IV q 24 hr

with broad-spectrum penicillin or combination therapy (see Table 23-5).

When gentamicin is administered, serum levels should be obtained. If once-a-day dosing is used, a trough level should be obtained before administration of the third dose. If dosing every 8 hours is used, trough and peak serum levels should be obtained at the third dose. If the trough levels are elevated, there is an increased risk for ototoxicity and/or nephrotoxicity; peak levels will determine if a therapeutic level of gentamicin is achieved at the dose being administered.

Specimens should be obtained for culture, isolation, and identification of any bacteria. If a possible infection site is identified, a specimen should be obtained for microbiologic analysis. Venous blood should be obtained for the possible identification of bacteremia. A urine specimen should also be obtained for analysis, Gram stain, culture, identification, and sensitivity. If the surgical incision is intact, the abdominal wall should be examined via ultrasonography to determine if there is fluid collection. If there is a collection of fluid, the area should be aspirated and the fluid processed for detection and identification of bacteria (i.e., Gram stain and culture for aerobic, facultative, and obligate anaerobic bacteria). If the incision has spontaneously opened, opens easily, or is necrotic, tissue should be sent for culture of aerobic, facultative, and obligate anaerobic bacteria.

After the patient has received antibiotic therapy for 48 hours, she should show a positive response. If the patient does not demonstrate improvement (Table 23-6), consideration should be given to additional diagnostic tests and the addition of new antibiotics to broaden the range of therapy to cover the possibility of an emerging resistant bacterium. If the physical examination does not reveal anything significant and laboratory tests are not helpful, a change in antibiotic therapy may be indicated as well as more diagnostic tests (e.g., abdominal/pelvic ultrasonography and/or computed tomography [CT] scan). Choosing additional or new antibiotic therapy without microbiological data is difficult, and the antibiotic chosen often results in redundancy. The most likely bacteria to emerge as resistant to current antibiotic therapy are gram-negative facultative anaerobes (e.g., members of Enterobacteriaceae) and possibly gram-positive bacterium (e.g., *Enterococcus*). If metronidazole is being administered there is probably no need to change to another agent, such as clindamycin, because there is the possibility of

a resistant obligate anaerobic bacterium emerging within the immediate 48-hour postoperative period. If an aminoglycoside is not being administered, it should be given in place of any other antibiotic, providing coverage for possible involvement of gram-negative facultative bacteria. If gentamicin or tobramycin is being administered, it should be discontinued and amikacin initiated. Penicillin should be administered to provide activity against gram-positive bacteria and synergy with the aminoglycoside against enterococci and streptococci. Initial empiric antibiotic therapy must be broad-spectrum because the infection is frequently polymicrobial, involving gram-positive and gram-negative facultative and obligate anaerobic bacteria (Table 23-7).

The patient who continues to have an elevated body temperature but has a normal pulse rate should be considered as possibly having drug fever. Physical examination of the patient with drug fever is typically negative. It is important to perform a complete examination, including a urinalysis, urine Gram stain, urine culture, chest x-ray, CT scan of the abdomen and pelvis, complete blood count with WBC differential, and blood glucose. Once the patient's evaluation is completed and there is no focus of infection, all antibiotic therapy can be discontinued. All medication should be reviewed and consideration given to discontinuing nonessential medications. If after discontinuing antibiotic therapy and nonessential medications the patient does not become afebrile within 24 to 48 hours, re-evaluation is necessary to determine if a focus of infection (e.g., pelvic or intra-abdominal abscess, wound infection, bacteremia, or endocarditis) should be sought.

**Table 23-6**  
**Clinical Findings Consistent with Ongoing Postoperative Infection**

Recent peak body temperature that is above or equal to the previous peak temperature
WBC count that remains elevated and has not shown a downward trend; WBC count dropping below the preoperative WBC count
Low blood sugar
An elevated pulse rate that continues to parallel the temperature
Persistent ileus
Level of abdominal/pelvic pain unchanged or worsening
Persistent tachypnea
Evaluation of the surgical site
Increasing erythema
Advancing margin of erythema (cellulites)
Increased intensity of erythema
Differential of pain
Areas of intense pain, typically distant from the incision site
Areas of anesthesia at the surgical site
Characteristics of drainage
Serous
Serosanguineous
Bloody
Dark brownish or gray-greenish
Frank pus
Integrity of the incision
Intact
Spontaneous separation
Necrosis

<b>Table 23-7</b> <b>Antibiotic Choices for the Treatment of Postoperative Pelvic Infection</b>	
Initial empiric choices	
Piperacillin/tazobactam 3.375 g IV q 6 hr	
Ampicillin/sulbactam 3.1 g IV q 6 hr	
Ticarcillin/clavulanic acid 3 g IV q 6 hr	
Clindamycin 900 mg IV q 8 hr + gentamicin 5 mg/kg of body weight IV q 24 hr	
Metronidazole 500 mg IV q 8 hr + gentamicin 5 mg/kg of body weight q 24 hr	
Clindamycin or metronidazole + gentamicin + ampicillin 2 g IV q 6 hr	
Clindamycin or metronidazole + levofloxacin 500 mg IV q 24 hr	
Ertapenem 1 g IV q 24 hr	
Imipenem 500 mg IV q 6 hr	
Meropenem 1 g IV q 8 hr	
Cefotetan 2 g IV q 12 hr	
Alteration in antibiotic therapy for patients who fail initial therapy (after the patient has been re-evaluated and the presence of an abscess or septic pelvic vein thrombosis) is discovered	
Patient is taking a penicillin: add gentamicin to increase gram-negative facultative antibacterial activity	
Patient is receiving clindamycin or metronidazole + gentamicin: add ampicillin 2 g IV q 6 hr	
Patient is on clindamycin or metronidazole + gentamicin + ampicillin: delete gentamicin and add amikacin 15 mg/kg. (The rationale is that it is highly unlikely that the patient has a resistant obligate anaerobic bacterium or a resistant gram-positive aerobe.)	
Patient is receiving ertapenem, imipenem, or meropenem: discontinue and begin clindamycin + gentamicin + ampicillin	
Patient is receiving cefotixin or cefotetan: discontinue and begin piperacillin/tazobactam + gentamicin	

## ETIOLOGY OF SEPTIC SHOCK

Failure to respond aggressively to the postoperative patient with infection leads to progressive deterioration and evolution to septic shock. Once the bacteria initiate the cytokine cascade, down-regulation of the system is prevented, thereby resulting in the production of tumor necrosis factor (TNF- $\alpha$ ). This cytokine cascade results in adverse effects on multiple organs. The initial response to infection is stimulation or up-regulation of the pro-inflammatory system. Once the patient enters the path to septic shock and with failure of aggressive intervention, progression to septic shock is rapid and often results in death. The mortality rate from septic shock varies from 20% to 80% and is related to the severity of the sepsis and the underlying disease.<sup>11–13</sup> In many cases of sepsis, the presence of microorganisms or toxins (i.e., LPS) in the blood cannot be established. This led to the establishment of the definitions listed in Table 23-8.

The patient undergoing gynecologic surgery who develops septic shock following the development of a postoperative infection may initially be a healthy individual with no particularly significant underlying illness. The patient develops an infection, which is frequently polymicrobial and involves gram-positive and gram-negative facultative and obligate anaerobic bacteria, with production and liberation of toxins that are disseminated by the bloodstream throughout the body. The patient has an exaggerated and overwhelming response to the infection and bacterial toxins occurs by release of macrophage-derived cytokines, which act on receptors of a variety of host organs. There are two classes of mediators—primary and secondary

(Table 23-9). Primary mediators—cytokines—stimulate the release of secondary mediators; together these responses have been termed the systemic inflammatory response syndrome (SIRS).

The host's initial response to infection is orderly and occurs in stages; however, if this goes unchecked, the result is severe damage to the host's organs. Stage I (pro-inflammatory response) is the release of the cytokines interleukin-1 and interleukin-6 (IL-1, IL-6) and TNF- $\alpha$ , and the secondary mediators eicosanoids and platelet-releasing factor at the site of infection. This is the host's initial response to limit the infection and repair any damaged tissue. If these mediators are left unchecked or remain up-regulated, they can cause damage. If the system is to be down-regulated, the host or body initiates release of compensatory anti-inflammatory agents (i.e., IL-4, IL-10, IL-11, IL-13, soluble TNF receptors, IL-1 receptor antagonists, and TNF- $\beta$ ).<sup>14–16</sup> These anti-inflammatory compounds inhibit the expression of the major histocompatibility complex class II, impair antigen presentation, and reduce the host cell's ability to produce inflammatory cytokines. The cytokines can even down-regulate their own production.<sup>17</sup> Pro-inflammatory and anti-inflammatory mediators can reach high concentrations and are localized to the site of infection.

If the initial infection is severe, a systemic inflammatory response occurs (Stage II). In bacteremic or septic patients, both bacterial toxins and anti-inflammatory mediators appear in

<b>Table 23-8</b> <b>Definitions for Sepsis and Septic Shock</b>	
Condition	Definition
Bacteremia	Positive blood cultures
Sepsis	Clinical evidence of infection, tachypnea (>20 breaths/min), tachycardia (>90 beats/min), hyperthermia, or hypothermia
Septicemia	Presence of microbes or microbial toxins in the bloodstream
Systemic inflammatory response syndrome	Patient response to disseminated infection or toxins Two or more of the following: fever (>38°C); tachypnea (>24 breaths/min); tachycardia (>90 beats/min); leukocytosis (>12,000/ $\mu$ L); leukopenia (<4000/ $\mu$ L)
Sepsis syndrome	Sepsis plus hypoxemia or elevated plasma lactate levels or oliguria
Severe sepsis	Sepsis plus one or more signs of organ dysfunction: metabolic acidosis, acute anencephalopathy, oliguria, hypoxemia, DIC, or hypotension
Early septic shock	Sepsis syndrome plus hypotension
Septic shock	Sepsis syndrome plus hypotension in the presence of adequate volume resuscitation

**Table 23-9**  
**Components of the Systemic Inflammatory Response Syndrome**

Primary Mediators (Cytokines)	Secondary Mediators
Interleukin-1 (IL-1)	Platelet-activating factor
Interleukin-2 (IL-2)	Eicosanoids: Leukotrienes B <sub>4</sub> , C <sub>4</sub> , D <sub>4</sub> , E <sub>4</sub> Thromboxane A <sub>2</sub> Prostaglandins E <sub>2</sub> , I <sub>2</sub>
Interleukin-4 (IL-4)	Interferon-γ
Interleukin-6 (IL-6)	Granulocyte-macrophage colony-stimulating factor
Interleukin-8 (IL-8)	Endothelium-derived relaxing factor
Tumor necrosis factor-α (TNF-α)	Endothelin-1 Complement fragments C3a, C5a Polymorphonuclear cells Toxic oxygen radicals Proteolytic enzymes Adhesion molecules Endothelial-leukocyte adhesion molecule 1 Intracellular adhesion molecule 1 Vascular cell adhesion molecule 1 Platelets Transforming growth factor-β <sub>1</sub> (TNF-β <sub>1</sub> ) Vascular permeability factor Macrophage-derived procoagulant and inflammatory cytokines Bradykinin Thrombin coagulation factor Fibrin Plasminogen-activator inhibitor Myocardial depressant factor β-endorphin Heat shock protein

the host's circulatory system. If the local infection is severe, the pro-inflammatory mediators may achieve high concentrations at the site and leak into the systemic circulation, thus initiating SIRS.<sup>18</sup> Initially the pro-inflammatory response acts as a normal response to infection. This results in the recruitment of neutrophils, T cells, B cells, platelets, and coagulation factors to the site of infection. If this response is left unchecked then SIRS will develop and the pro-inflammatory agents will stimulate an anti-inflammatory response.

Failure to down-regulate the pro-inflammatory response results in a massive systemic inflammatory response (Stage III). The clinical characteristics of SIRS (i.e., body temperature <36°C or >38°C; tachycardia >90 beats/min; tachypnea; a PaCO<sub>2</sub> <32 mmHg; and an elevated WBC count[<12,000/μL] or leukopenia (<4,000/μL) develop (Table 23-10). The patient can develop edema of organs secondary to damage to endothelial cells, thereby allowing microvascular leakage.<sup>19,20</sup> The patient also develops sludging within the circulatory system along with increased platelet aggregation, which results in the formation of thrombi within the microcirculation and blood being diverted from tissues and organs. This results in tissue and organ ischemia,

which can result in reperfusion injury and the induction of heat shock protein.<sup>21-24</sup>

Once thrombosis begins activation of the coagulation system, the patient can deplete the store of coagulation factors and develop disseminated intravascular coagulation (DIC). Consumption of coagulation factors leads to bleeding. DIC can produce concurrent thrombosis that results in serious hypoperfusion of tissues, leading to gangrene, acrocyanosis, and skin necrosis. The bleeding associated with DIC leads to the development of petechiae, purpura, and ecchymosis.

Significant systemic inflammation can alter the vasodilatory and vasoconstrictive mechanisms, typically resulting in vasodilation. This causes transudation of fluids from the vascular compartment to tissues and changes blood flow. This leads to shock, organ dysfunction, and death.

Individuals who survive septic shock may, in turn, experience excessive immune suppression (Stage IV). This overcompensatory reaction results in immune suppression, "immune paralysis," or a "window of immunodeficiency."<sup>25,26</sup> This syndrome occurs in patients who develop shock secondary to severe burns, hemorrhage, or trauma. This may explain why gynecologic and obstetric patients who develop shock secondary to hemorrhage become infected.

The final stage in SIRS (Stage V) is referred to as immunologic dissonance and precedes multiple organ dysfunction syndrome. The presence of both SIRS and multiple organ dysfunction syndrome is the result of an overwhelming concentration of pro-inflammatory mediators. If this up-regulation cannot be reversed, the patient is at increased risk for death. Organ failure occurs in steps, the first organ to fail is the lungs, followed by the liver, then the gastrointestinal tract, and finally the kidneys.

Septicemia rates more than doubled in the United States between 1979 and 1987, resulting in approximately 250,000 deaths each year.<sup>13,27</sup> The proportion of infections caused by gram-negative bacteria ranges from 30% to 80%; those caused by gram-positive bacteria, from 6% to 24% of the total number of septic cases.<sup>28</sup> Sepsis secondary to gram-positive bacteria, especially *S. aureus* and *S. epidermidis*, rose in the 1990s and accounted for more than 50% of the cases of septicemia.<sup>29,30</sup> Bacterial infection is often mild or moderate but can be severe, leading to sepsis, bacteremia, or both. One key bacterial factor leading to septic shock is the endotoxin of gram-negative bacteria, LPS. The gram-negative bacterial cell wall is complex. It consists of a capsule, the outermost layer, an outer membrane that consists of LPS, a lipid bilayer, a peptidoglycan, and an inner cell membrane.<sup>31</sup> When LPS is contained within the bacterial cell wall, it is not toxic. However, when LPS is released (e.g., during bacterial cell multiplication) bacterial cell death or lysis disruption

**Table 23-10**  
**Clinical Manifestations of Systemic Inflammatory Response Syndrome**

Body temperature <36°C or >38°C
Tachycardia (90 beats/min)
Tachypnea (>20 breaths/min)
PaCO <sub>2</sub> <32 mmHg
WBC count <400/μL or >12,000/μL or >10% increase in immature polymorphonuclear leukocytes

## Gynecologic Infectious Disease

of the cell wall occurs, and the toxic moiety, lipid A, is exposed to immune cells and initiates an inflammatory response.<sup>32,33</sup> The gram-positive bacterial cell wall contains a compound similar to LPS—lipoteichoic acid (LTA)—as well as other lipid components (e.g., diglucosyldiacylglycerol, phosphatidylglycerol, diacylglycerol, and lysylphosphatidylglycerol).<sup>34,35</sup>

When bacteria enter the human body, two defensive systems come into action: the humoral (i.e., complement) system of antibodies and acute phase proteins and the cellular system of monocytes, macrophages, and neutrophils. Under normal physiologic conditions, the immune cells are continuously exposed to low levels of LPS from the bacteria in the gastrointestinal tract that gain entrance into the body via the portal circulation.<sup>33</sup> It is currently hypothesized that the continuous challenge of bacterial constituents is necessary to maintain the immune system in a ready state to infection.<sup>36–38</sup> Once a significant concentration of LPS or LTA is introduced into the body (i.e., infection is established), the pro-inflammatory response is triggered. If the host cannot contain the infection with or without the assistance of antimicrobial agents and the cytokine system cannot be down-regulated, the patient will progress into septic shock.

### MANAGEMENT OF SEPTIC SHOCK

Infection in the postoperative gynecologic patient should initially be considered polymicrobial (i.e., involving both gram-positive and gram-negative bacteria). Therefore, initial therapy should be with intravenous administration of broad-spectrum antibiotics (Table 23-11). Piperacillin/tazobactam, clindamycin, or metronidazole will provide excellent coverage against the obligate anaerobic bacteria. Although clindamycin does have activity against many gram-positive bacteria such as staphylococci and streptococci, gentamicin will provide slightly better activity against staphylococci and ampicillin will provide more comprehensive activity against streptococci. Gentamicin will provide broad coverage against gram-negative facultative bacteria. The combination of gentamicin and ampicillin will provide synergistic activity against enterococci and streptococci.

Patients developing, or suspected of developing, septic shock should be monitored very closely. A Foley catheter should be inserted to monitor urine output. A Swan-Ganz catheter should be placed to monitor pulmonary artery wedge pressure and cardiac output as well as to calculate oxygen delivery and utilization.<sup>39,40</sup> Both cardiac output and peripheral vascular resistance are important; for antibiotic therapy to be effective it must reach the site of infection and be equally distributed throughout the circulatory system. Therefore, the tissues must be adequately perfused and oxygenated. The patient's airway

must be maintained and the lungs adequately oxygenated. Volume expansion and correction of hypovolemia are critical in maintaining adequate blood pressure and, in turn, tissue perfusion. A significant decrease in blood pressure will result in poor tissue and organ perfusion, which will then be manifested by increased peripheral resistance, a decrease in kidney perfusion and urine output, and an increase in interstitial fluid or edema. If increases in fluid replacement do not result in increased urine output and cardiac output, the patient will require pressor agents. Initially, dopamine, with both alpha- and beta-adrenergic effects, is administered.<sup>41</sup> Doses smaller than 5 µg/kg/min are associated with increased blood flow to the kidneys and mesentery. Doses between 5 and 20 µg/kg/min primarily result in more effective myocardial contraction, increased cardiac output, and a resultant increase in myocardial oxygenation. Doses in excess of 20 µg/kg/min result in primarily alpha effects (i.e., in increased vasoconstriction and decreased tissue perfusion). Dopamine is usually administered in a dose of 2 to 5 µg/kg of body weight/min to achieve an increased blood flow (cardiac output) to the kidneys and increase urine output.<sup>42</sup>

Alternatives to dopamine are dobutamine and norepinephrine. Dobutamine increases cardiac output and oxygenation and improves tissue perfusion by decreasing systemic vascular resistance.<sup>43</sup> Dobutamine is frequently used in combination with dopamine to maintain renal perfusion and improve cardiac output. Epinephrine increases cardiac output, oxygenation, and blood pressure. However, although the patient may appear to have improved oxygenation, there is a decrease in tissue oxygenation, increased cardiac work, and greater myocardial oxygen requirements.<sup>44,45</sup>

If vasoconstriction becomes profound and tissue perfusion is significantly impaired, cells become hypoxic and acidotic. This leads to cell death. Arterioles cannot respond to histamine and bradykinin.<sup>46</sup> Immunologic complexes form and cause significant tissue injury, especially in the lung. These complexes develop within the vasculature of the lung and lead to the development of adult respiratory distress syndrome (ARDS) and within the tubules of the kidney.<sup>47</sup> ARDS results in a further oxygen deficit and increased tissue hypoxia. Systemic tissue hypoxia results in microscopic injury to bowel mucosa, allowing for translocation of bacteria and toxins across the bowel wall, thereby worsening septic shock.<sup>48,49</sup> Failure to reverse septic shock results in the development of anaerobic metabolism, which in turn leads to lactic acidosis, multiple organ dysfunction, and death.<sup>50</sup> Oxygen must be delivered until the concentration of lactic acid returns to normal, tissue perfusion is improved, and organ dysfunction is reversed.

Thus, the patient who develops sepsis must be regarded as on the verge of developing septic shock because this is the greatest opportunity to treat the patient and reverse the course to septic shock. The initial response of the physician is to administer broad-spectrum antibiotics and insert a Foley catheter and a Swan-Ganz catheter if there is a decrease in urine output and blood pressure. If the pulmonary wedge pressure is normal, volume replacement must be initiated; if it is decreased, dopamine should be administered. The patient should be transferred to an intensive care unit and a critical care specialist consulted.

**Table 23-11**

#### Antibiotic Therapy for Postoperative Infection in the Septic Patient

Piperacillin/tazobactam 3.375 g q 6 hr + gentamicin 5 mg/kg of body weight q 24 hr
Clindamycin 900 mg q 8 hr + gentamicin + ampicillin 2 g q 6 hr
Metronidazole 500 mg q 8 hr + gentamicin + ampicillin

## TREATMENT

Administering antibiotic therapy to patients having undergone gynecologic surgery and subsequently develop a pelvic infection and/or surgical site infection is based on the following principles:

- Most patients receive antibiotic prophylaxis.
- The most frequently administered antibiotic is a cephalosporin, which can select for *Enterococcus*.
- Postoperative pelvic infection is typically due to the endogenous vaginal microflora.
- Surgical site infection is due to *S. aureus* and endogenous vaginal microflora.

Therefore, the antibiotic regimen chosen for pelvic infection should provide coverage against the following:

- Gram-positive aerobic bacteria (e.g., *Streptococcus agalactiae*, *Enterococcus faecalis*)
- Gram-negative facultative anaerobic bacteria (e.g., *E. coli*, *Enterobacter* sp., *Klebsiella pneumoniae*)
- Obligate anaerobic bacteria (e.g., *Prevotella*, *Peptostreptococcus*, *Fusobacterium*, *Bacteroides*)
- Surgical-site infection, whether caused by gram-positive aerobic bacteria (e.g., *S. aureus* (MRSA), *Streptococcus* sp.) or a mixed polymicrobial infection

The initial choice of antibiotic for pelvic infection should provide broad antimicrobial coverage (Table 23-12).

Patients can initially be treated with a single agent, piperacillin/tazobactam, which provides activity against most bacteria that cause pelvic cellulitis and vaginal cuff cellulitis. If the patient does not demonstrate improvement after 48 hours of antibiotic therapy, gentamicin should be added to increase the gram-negative facultative anaerobic coverage. If the infection began within the first 24 to 48 hours postoperative, the dominant bacteria involved in the infection are gram-positive and gram-negative facultative anaerobes. If the patient continues to fail to respond, repeat the physical examination and obtain imaging studies (i.e., ultrasonography or CT scan of the abdomen and

pelvis). It is important to rule out the presence of infected hematoma or abscess.

Alternatively, therapy can be initiated with either clindamycin or metronidazole, understanding that there is a significant difference between clindamycin and metronidazole. Clindamycin has activity against both obligate anaerobic bacteria and gram-positive aerobes (i.e., *S. aureus*, including some strains of MRSA, and *S. agalactiae*), whereas metronidazole only has activity against obligate anaerobes. Therefore, neither clindamycin nor metronidazole has activity against enterococci. Thus, patients treated with either of the above antibiotics and not responding should have ampicillin and gentamicin added to the regimen. The addition of ampicillin acts synergistically with gentamicin and increases activity against streptococci and enterococci. Another advantage of clindamycin and gentamicin is that this antibiotic combination provides a relatively good degree of activity against MRSA.

Surgical site infections can be divided into two categories—cellulitis and abscess. One aid in the management of surgical site infection is ultrasonography, which can delineate a collection of fluid. If fluid is present, aspiration can be performed with ultrasound guidance. A Gram stain of this fluid can assist in choosing appropriate antibiotic therapy. For example, if gram-positive cocci in chains are present, a broad-spectrum penicillin would be used; if the cocci are in clusters, clindamycin and gentamicin, which will provide coverage against MRSA, are the proper choice. If the Gram stain reveals a polymicrobial infection, piperacillin/tazobactam + gentamicin or clindamycin can be administered. If an abscess is present, the incision should be opened, the abscess drained, and any necrotic tissue present should be débrided. Aggressive management of surgical site infection can result in a speedy recovery and prevention of necrotizing fasciitis.

## Section 4 Urogynecology

# Chapter 24

# The Anatomic Basis of Normal and Abnormal Pelvic Support

Robert M. Rogers, Jr., MD

### KEY POINTS

- Learn normal pelvic support anatomy by paying attention during pelvic examination of the nulliparous patient.
- Intact, fully functioning pelvic floor muscles and their innervations are more important in pelvic organ support than intact visceral support connective tissues.
- Pelvic support defects are seen as stretched and attenuated vaginal epithelium and peritoneum. What is not seen or appreciated are the breaks in the visceral connective tissues between these two layers.
- The keys to successful reparative vaginal surgery are the reconstruction of the pericervical ring and the reconstruction of the perineal body.

A directed clinical examination of the normal, nulliparous young woman teaches the clinician pelvic support anatomy. This exercise requires training and guidance as to what to observe, why, and how; and what to palpate, why, and how. This experience is further enhanced with appropriate observations during various surgeries and directed cadaver dissections. During examination of patients with existing pelvic support defects, such as high cystocele or low rectocele, often the examiner can be confused as to the specific anatomic reasons for the various observed bulges in the vagina and their associated movements on Valsalva maneuver. Even the terms *cystocele* and *rectocele* mislead the observer as to the etiology of the observed vaginal support weaknesses. We can only appreciate that which we have been trained to understand, as we process our observational and tactile input.

This chapter presents the reader with a working, hands-on overview of our present understanding of female pelvic support anatomy. This anatomy teaching is from observations from reparative vaginal surgeries and cadaver dissections by knowledgeable, anatomically minded clinicians and surgeons. This information is then correlated with clinical findings to help explain female pelvic visceral support, both normal and abnormal. This chapter explains normal vaginal support findings and anatomy, and then discusses various pelvic support defects. These include anatomic descriptions to explain the various clinical findings. Although the information offered in this chapter is basic, it should be sufficient. The goal is to give the clinician and reparative vaginal surgeon practical knowledge that can be applied

immediately in the examination room and in the operating room. However, the reader must first be forewarned. This information requires the ability to think and conceptualize in three dimensions. This must first be accomplished while reading words and sentences, and observing photographs and illustrations, on two-dimensional pages. This is challenging, even for the most experienced gynecologic anatomists and surgeons. The structural anatomy of the female pelvis is difficult to orient in one's mind. The understanding of pelvic support anatomy is even more challenging.

### EXAMINATION OF THE PATIENT WITH NORMAL PELVIC SUPPORT

Vaginal support anatomy is best learned and understood by performing focused and educated pelvic examinations on young, nulliparous patients.<sup>1</sup> This is most commonly performed during the patient's annual well visit, with the patient in the dorsal lithotomy position. The clinician should be professional and ask the patient for her permission to examine her after explaining the purposes of the examination. The physician will need at hand an appropriate bivalve speculum, or vaginal retractor such as a Sims' retractor, as well as a long Allis clamp or single-toothed tenaculum. Remember, these patients do not have vaginal support problems. Therefore, any feel of the tissues or movement upon patient straining or with pelvic muscular contraction gives the physician a feel for the norm. The examiner should have already been instructed about what to observe and what to palpate, with the expected findings in the nulliparous patient. The focused examination for learning pelvic support anatomy begins with observations of the vaginal area and associated movements and is followed by palpation of these organs and tissues at rest and with various movements.

#### Observation of the Perineum

With the patient in the dorsal lithotomy position, the clinician should simply observe the labia, vaginal introitus, perineal body, and anus. Astute observation demands self-questioning to focus the examiner's mind to ensure that systematic observations are noted in order so as not to overlook a particular observation. This process is obviously facilitated by practice and experience. The clinician needs to establish a pattern and sequence of examination, including both observation and palpable feel of the tissues. Noting the appearance and feel of these structures gives the examiner a reference on which he/she can judge what is

## Urogynecology

normal and what is not normal in all the patients examined in the office. This information on vaginal support must be correlated with patients' complaints and symptoms. The physician must adapt his/her learning to what the patients teach him/her, not to what books teach. And these observations must be correlated and integrated with newer anatomic studies and clinical reports. The learner must always question himself/herself.

### Speculum Examination

Once the external features are observed, the labia should be separated with the fingers. Note the shape and the function of the vaginal introitus. Ask the patient to squeeze your fingers. Note the action and strength of the surrounding muscles. What happens when the patient is asked to "bear down, as if having a bowel movement?" Gently insert the bivalve speculum. In what direction does the speculum travel? Is there a change in direction from the lower portion of the vagina to the upper portion? Note the cervix and surrounding vaginal fornices. Are the fornices flat or concave? Where? Describe. Ask the patient to bear down. What is the movement of the cervix? Does the cervix move down into the vagina more? Do the fornices—lateral, anterior, posterior—bulge out? What is their movement? What happens when the patient contracts her pelvic and para-vaginal muscles? Place a long Allis clamp gently on the cervix. What lateral movement does the cervix show? How much? To what extent?

Slowly remove the speculum as the patient rests, as she contracts or "squeezes" her pelvic muscles, and as she bears down. What happens with the vagina? Do the vaginal walls demonstrate rugae? Where? What do they look like? What happens to the anterior vaginal wall? What happens to the lateral vaginal wall? What happens to the posterior vaginal wall? What happens as the speculum moves down toward the vaginal introitus? Do the walls demonstrate any longitudinal ridges or clefts? The bivalve speculum can be separated and the lower blade used to observe the anterior vaginal wall while retracting the posterior vaginal wall. Likewise, the posterior vaginal wall can be examined while retracting the anterior vaginal wall with the lower blade of the speculum. Pay attention and note these findings, answering these and other questions. Correlate these findings with the understood vaginal support anatomy. Why are these findings observed anatomically and physiologically?

### Palpation of Vaginal Tissues

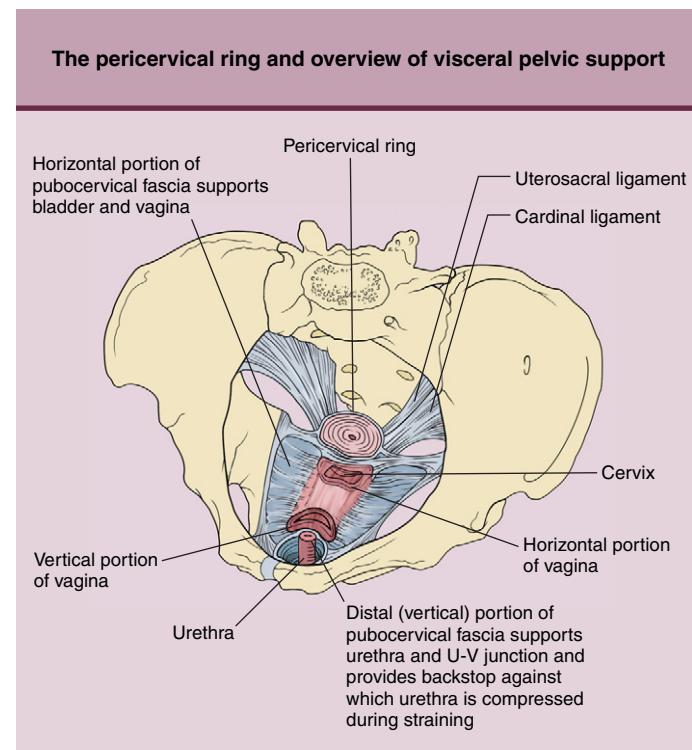

Perform the bimanual examination and learn from palpation with the fingers through the lubricated glove. Note the tactile thickness and feel of the various areas of the vagina and surrounding viscera. Again, this is done systematically with self-directed questions. The examiner palpates the cervix, uterus, and adnexae; the four vaginal fornices; the four walls of the vagina; the lower third of the vagina underneath the urethra; laterally to feel the muscles of the levator hiatus; and posteriorly to feel the perineal body. Palpate the sidewall and the arcus tendineus fasciae pelvis, the "banjo string" traveling from the ischial spine to the pubic arch. Gently place a lubricated cotton-tipped swab in the urethra. Ask the patient to cough or bear down. How far does the cotton-tipped swab move up? Palpate the paraurethral tissues. Can you feel the pubic bone? How thick are the paraurethral tissues?

Place an Allis clamp on the cervix and gently pull while palpating posteriorly for the uterosacral ligaments. Where are they? How thick and strong are they? How far do they stretch? Be gentle. Perform a rectal examination to assess the strength of the levator ani muscles, the anal sphincter muscle, and the integrity of the perineal body. Perform this examination without and with the patient straining, and without and with the patient "squeezing" your finger. Assess the levator plate, which is easily palpable just under the posterior rectal wall. What does the anal canal feel like? How long is it? What does the rectum feel like? What is the shape of the perineal body? In what orientation are they? What happens to these areas when the patient is at rest; with contraction of the surrounding pelvic muscles; with straining? After many patients, the examiner will develop a "normal" pattern for these examinations.

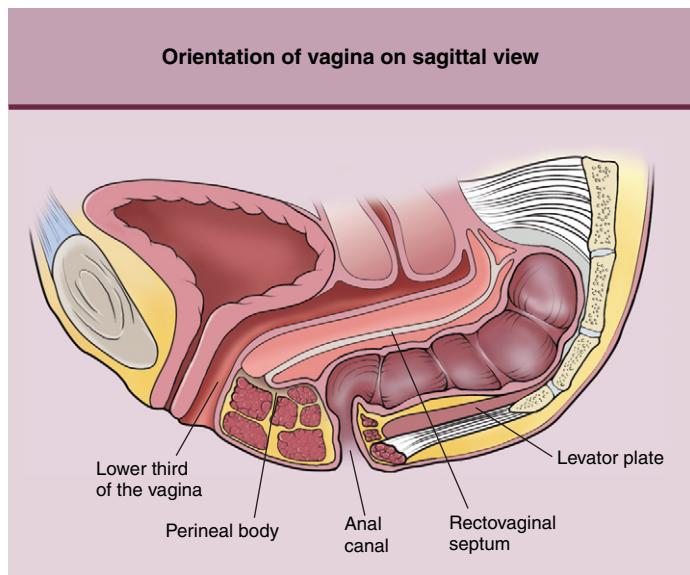

### ANATOMY OF NORMAL PELVIC SUPPORT: CLINICAL CORRELATIONS

#### Pericervical Ring and Levator Plate

As the "normal" findings are registered in the examiner's mind and assimilated, a discussion of the relevant pelvic support structures must be included. The uterosacral–cardinal ligament complexes on each side attach to the lateral and posterior aspects of the pericervical ring of visceral connective tissue (Fig. 24-1). This occurs at the level of the ischial spines, but slightly anterior to the interspinous diameter due to the pull of the upper portion

**Figure 24-1 The pericervical ring and overview of visceral pelvic support.** The pericervical ring is formed by the cardinal–uterosacral ligament complexes and pubocervical fascia. (From Retzky SS, Rogers RM: Urinary incontinence in women. In Clinical Symposia. Summit, NJ, Ciba-Geigy, 1995;47[3], from Plate 3, p 7. Netter illustrations used with permission of Elsevier, Inc. All rights reserved.)

**Figure 24-2 Orientation of the vagina.** A sagittal section through the normally oriented female pelvis. The upper portion of the vagina, the cervix, and rectum are suspended over the muscular levator plate, which dynamically contracts to entrap these pelvic organs in the pelvis on patient Valsalva straining. Note the orientation of the perineal body. (Original owned by Robert M. Rogers, Jr., MD, used with permission.)

of the cardinal ligament. The pericervical ring is located around the supravaginal portion of the cervix, which is located in the middle third of the transverse vaginal apex. Into this fuses the rectovaginal fascia posteriorly, the uterosacral ligaments posterolaterally, the cardinal ligaments laterally, and the pubocervical fascia anteriorly. The upper pelvic supports of the uterosacral–cardinal ligament complexes suspend the cervix and upper vagina over the levator plate. The active levator plate acts as a backstop against which the upper vagina and cervix are entrapped and thus prevented from prolapsing when the patient strains down<sup>2</sup> (Fig. 24-2). Therefore, when the patient strains, movement of the cervix down the vaginal axis is limited. In addition, the uterosacral–cardinal ligaments also secure the lateral vaginal fornices, thus giving them their upper concavity. On patient straining, the lateral fornices will flatten somewhat. However, the anterior vaginal fornix does not flatten because of the thickened attachment of the pubocervical fascia to the pericervical ring. The posterior vaginal fornix is supported by the rectovaginal fascia centrally and the uterosacral ligaments posterolaterally. Straining by the patient will allow the posterior vaginal fornix to bulge out a little. The extent must be observed and noted by the examiner.

### Anterior Vaginal Wall

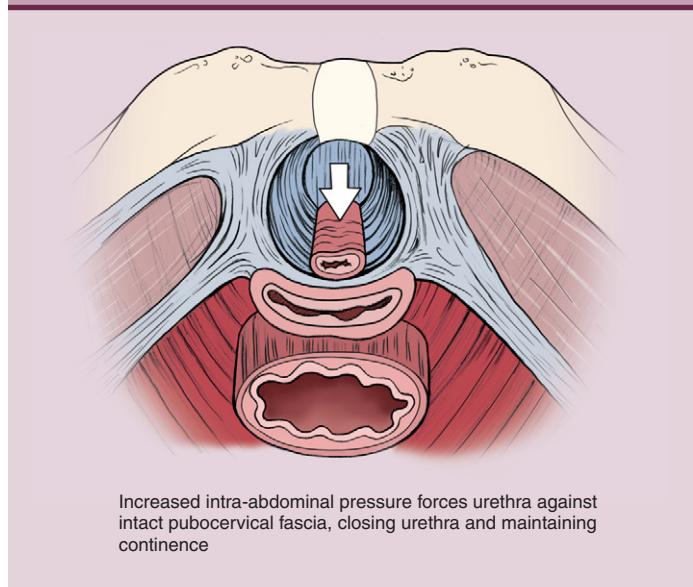

Because the cardinal ligaments have a lateral attachment to the pelvic sidewall near each ischial spine<sup>3</sup> and because the pubocervical fascia also has lateral attachments to each arcus tendineus fasciae pelvis, which ends at the level of the ischial spine, the examiner finds limited lateral excursion of the cervix when moved with an Allis clamp (see Fig. 24-1). Also because of the lateral attachments of the pubocervical fascia mentioned, the anterior wall of the vagina exhibits an anterolateral sulcus on

each side. On straining, these sulci do not disappear but remain visible and intact while the anterior wall does move down a little. The bladder rests on the upper two thirds of the vagina, with the trigone overlying the middle third of the vagina. The urethra travels on the lower third of the anterior vaginal wall. The urethra has limited movement on Valsalva straining. Remember, the urethra is supported by a “hammock” of pubocervical fascia attached laterally to each arcus tendineus fasciae pelvis<sup>4</sup> (Fig. 24-3). This hammock also prevents the examiner’s finger from moving around the side of the urethra to the back of the pubic bone. In addition, the distal portion of the urethra is supported by the pubourethral ligaments. The urethra also passes through the perineal membrane, an anatomic concept, which traverses between the inferior ischiopubic rami. The extent of movement in each portion of the vagina must be learned by observation. The pubocervical fascia is physiologically active and is responsible for the transverse rugations found in the well-estrogenized anterior vaginal wall (Fig. 24-4).

### Posterior Vaginal Wall

The posterior vaginal wall is supported by the rectovaginal fascia in the upper two thirds, while the lower third of the vagina is supported by its fusion with the perineal body. The rectovaginal fascia is between the rectum and just underneath the upper two thirds of the vagina, traveling from the apex of the perineal body to the iliococcygeal fascia bilaterally, and then to the uterosacral ligaments and posterior vaginal fornix. Laterally, the rectovaginal

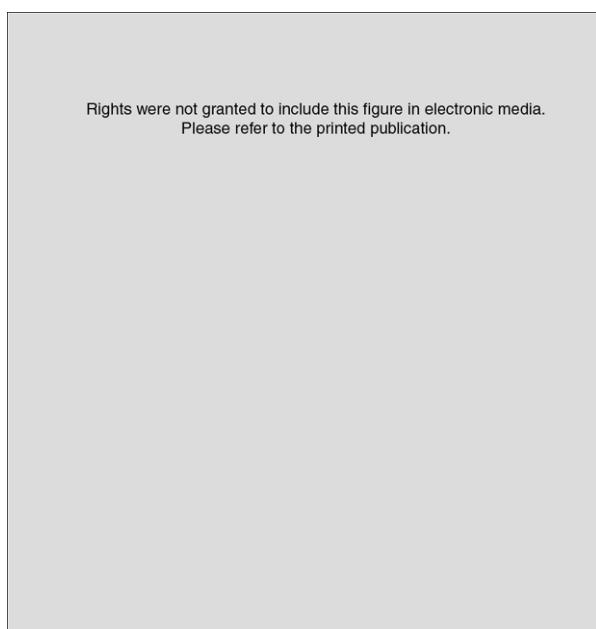

### DeLancey hammock of urinary continence

Increased intra-abdominal pressure forces urethra against intact pubocervical fascia, closing urethra and maintaining continence

**Figure 24-3 DeLancey hammock of urinary continence.** The “hammock” of pubocervical fascia underneath the urethra functions as a backstop against which the urethra is compressed on Valsalva straining. This is one of the urinary continence mechanisms in the female patient. (From Retzky SS, Rogers RM: Urinary incontinence in women. In Clinical Symposia. Summit, NJ, Ciba-Geigy, 1995, Plate 6, p 12, bottom left. Netter illustrations used with permission of Elsevier, Inc. All rights reserved.)

Rights were not granted to include this figure in electronic media.  
Please refer to the printed publication.

**Figure 24-4 The transverse rugations of the anterior vaginal wall.**  
Seen also is a bilateral paravaginal defect. (From OBG Management 2004;16[5], fig. 2, p 20; www.obgmanagement.com.)

fascia attaches to each arcus tendineus fasciae rectovaginalis, which fuses with the arcus tendineus fasciae pelvis as it travel toward the ischial spine<sup>5</sup> (Fig. 24-5). Therefore, posterolateral sulci also can be seen in the middle third of the posterior vaginal wall. The fibromuscular connective tissue coat surrounding the

posterior vaginal wall and the rectovaginal fascia are physiologically active and are responsible for the transverse rugations found in the well-estrogenized posterior vaginal wall.

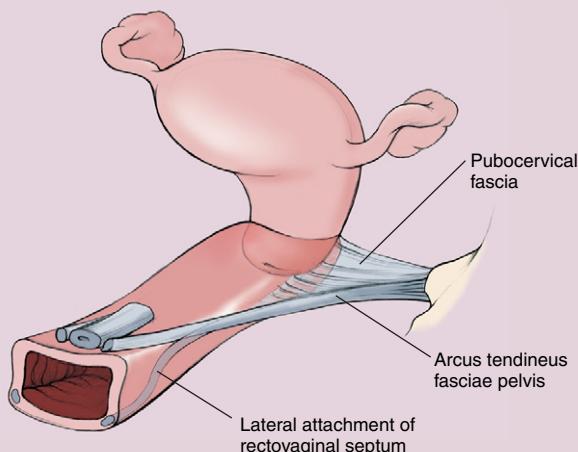

### Shape of the Vagina

In the unexamined vagina, the anterior and posterior vaginal walls rest against each other, and the lateral vaginal walls are tethered to the pelvic sidewalls by the more anterior arcus tendineus fasciae pelvis and the more posterior arcus tendineus fasciae rectovaginalis. Therefore in the resting state, the vagina in the middle third is shaped like the letter H. When the patient performs a Valsalva manuever, the anterior and posterior vaginal walls exhibit some movement, but the lateral sulci remain intact, with little movement.

### Perineal Body

The base of the perineal body is slightly concave upward because of its attachment to the rectovaginal septum, which is tethered to the hollow of the sacrum by its attachments to the uterosacral ligaments. The base is approximately 4 cm square and is almost parallel to the floor in the standing woman. The anal canal and the lower one third of the vagina fuse with the perineal body. Therefore, the apex of the pyramid-shaped perineal body is found at the junction of the lower third and middle third of the vagina. The anus, therefore, is located 1 to 2 cm above the level of the ischial tuberosities. Excursion of the perineal body by the examiner's fingers or the patient's Valsalva manuever should be approximately 1 cm and no more. The pubococcygeal muscles surround the lower third of the vagina and close off the vaginal introitus when contracted.

### Lateral attachment of the rectovaginal fascia

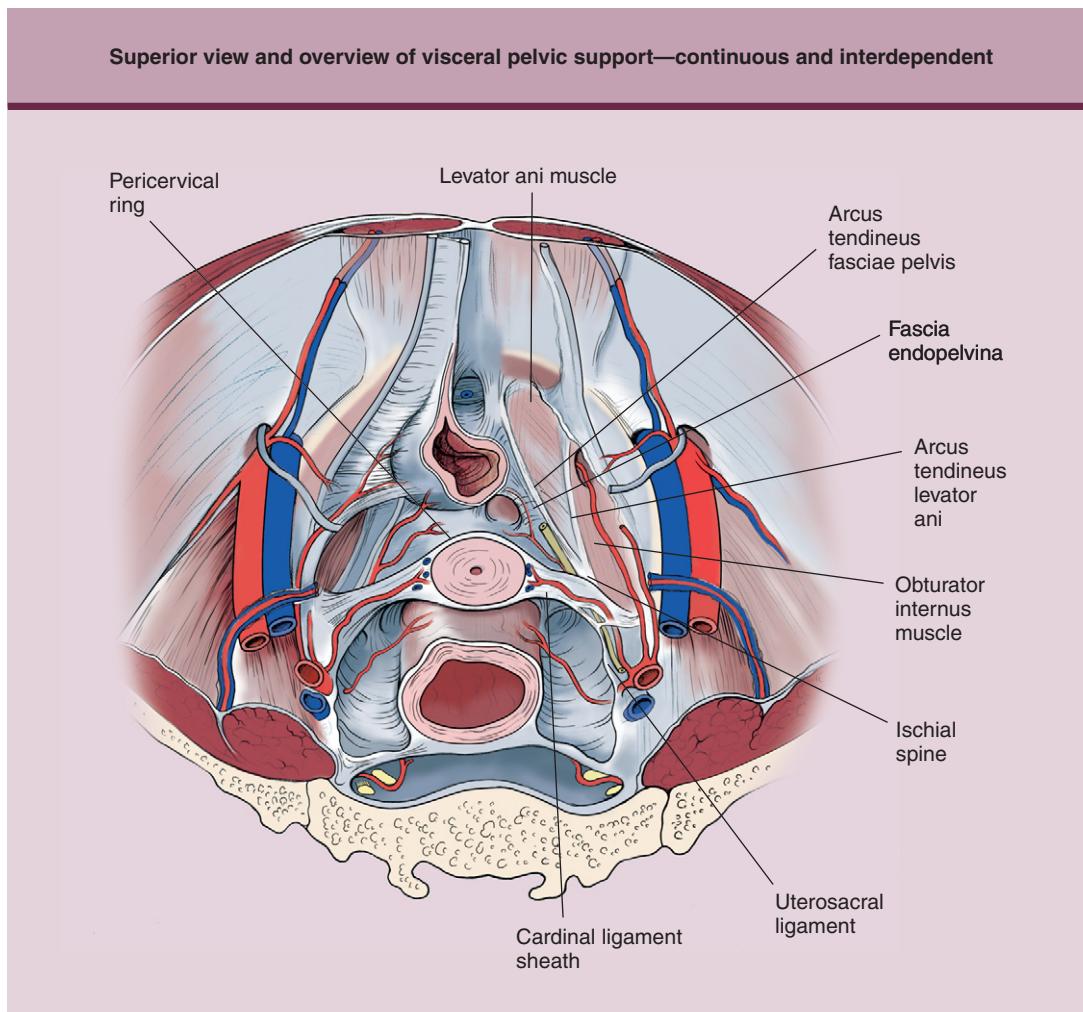

**Figure 24-5 Lateral attachment of the rectovaginal fascia.** Arcus tendineus fasciae pelvis (ATFP) of the pelvic sidewall. PCF, pubocervical fascia; RVS, rectovaginal septum, which inserts onto the arcus tendineus fasciae rectovaginalis. (From Leffler KS, Thompson JR, Cundiff GW, et al: Attachment of the rectovaginal septum to the pelvic sidewall. Am J Obstet Gynecol 2001;185:43.)

### Pelvic Visceral Support System

With the normal pelvic examination described and the important support structures correlated with these findings, more description is now offered to deepen the reader's understanding and appreciation in three dimensions.<sup>2,3,6,7</sup> The pelvic visceral support system is continuous and interdependent from the pelvic brim, along the back wall, the sidewall, and, finally, the outlet of the vagina (Fig. 24-6). Therefore, one defect in this network causes one or more defects in other areas of the network. The visceral connective tissues in the pelvis are found between the peritoneum, both visceral and parietal, and the parietal fascia covering the skeletal muscles of the pelvic basin. These visceral support tissues envelope and act as conduits for the visceral arteries, veins, nerves, lymph channels and nodes, and ureters. Visceral connective tissue is constructed of loose, meshlike collagen; some elastin; and smooth muscle. This tissue is physiologically alive, adapting to local stresses, and forms the vaginal rugae seen in the well-estrogenized vaginal epithelium.

This tissue is formed in sheets, which fuse around the contained vasculature to form sheaths (cardinal–uterosacral sheath), septa (the lateral attachments of the pubocervical fascia and rectovaginal fascia to the lateral pelvic sidewall), and even dense, direct connections with the adjacent parietal fascia (fusion of the lower third of the vagina and anal canal with the

**Figure 24-6 Superior view and overview of the female pelvic visceral suspensory system, formed by the continuous and interdependent network of visceral connective tissues.** As seen after the peritoneum has been removed. (From Netter FH, Dally AF [eds]: Netter's Atlas of Human Anatomy, 2nd ed. Novartis, 1997, Plate 341. Netter illustrations used with permission of Elsevier, Inc. All rights reserved.)

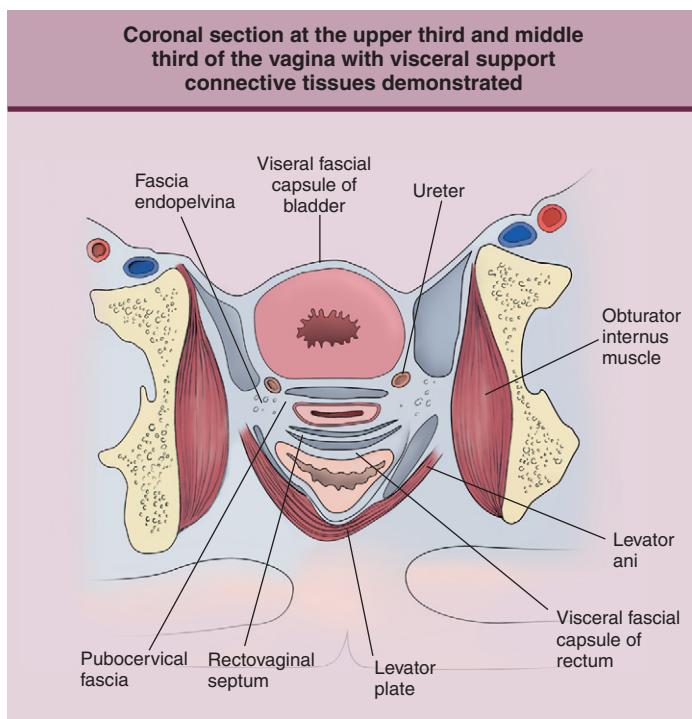

perineal body and the pubococcygeal fascia). The cardinal ligament sheath is anchored to the parietal fascia of the pelvic brim, sacrum, piriform muscle, anterior border of the greater sciatic foramen, and near the ischial spine. The sheets of visceral connective tissue coalesce and fuse around the internal iliac vessels and are led by the uterine vessels to the pericervical ring. In the standing patient, the internal iliac (hypogastric) artery and vein course in a vertical manner, along the anterior border of the greater sciatic foramen.

The visceral connective tissues also form capsules around the cervix and vagina, bladder and urethra, and the rectum and anal canal. The horizontal, lateral septa from these visceral capsules include the pubocervical fascia, rectovaginal fascia, and support pillars from the bladder and rectum. These lateral wings of visceral fascia fuse to form the medial edge of the fascia endopelvina (Fig. 24-7). The lateral edge of the fascia endopelvina inserts into the arcus tendineus fasciae pelvis, which is more horizontal in the standing patient. Remember, this travels from near the pubic arch to the ischial spine, a distance of 7.5 to 9.5 cm.<sup>8</sup>

### Pelvic Musculature

The pelvis is actually a basin of muscles, not bones (Fig. 24-8). There is no top to this open bowl-like form. The back wall is the sacrum centrally and the two piriform muscles laterally, one passing straight through each greater sciatic foramen to insert onto the greater trochanter of each femur. The front wall is the back of the pubic bone. The two sidewalls are bounded by the obturator internus muscles, which tail posteriorly and inferiorly to take sharp angles underneath the ischial spines and pass through the lesser sciatic foramina to insert onto the greater trochanters. The floor is formed by the levator ani and the coccygeal muscles. These latter muscles travel from the sides of the lower part of the anterior sacrum and narrow down to insert onto the ischial spines. This is also the same course as the sacrospinous ligaments, on top of which they travel. The course of direction of these is lateral and posterior. In the postmenopausal patient, the coccygeal muscles are atrophic and fibrous, appearing as part of the sacrospinous ligaments.

The levator ani muscles have an anterior portion—the pubococcygeus and puborectalis muscles—and a posterior

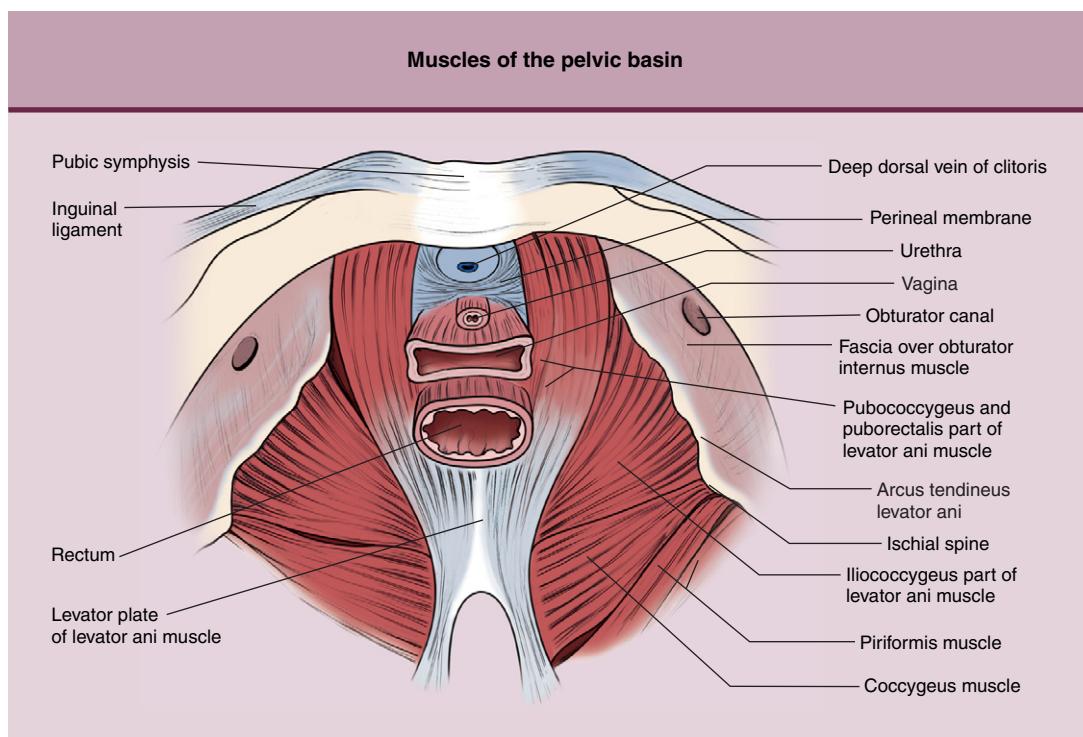

**Figure 24-7** Frontal section through the junction of the middle third and upper third of the vagina, demonstrating the visceral suspensory connective tissues and muscular support of the pelvic floor and sidewalls. Note the relationship of the fascia endopelvina to the fascial white line and the more medial tissue septa emanating from the capsules of the pelvic organs and the rectovaginal fascia. (Adapted from Peham HV, Amreich J: Operative Gynecology, Vol. 1. Philadelphia: Lippincott, 1934, p. 194.)

portion—the iliococcygeus muscles. The anterior portion forms the levator hiatus, through which passes the urethra, lower third of the vagina, and the anal canal. The pubococcygeus muscles produce the right angle of the rectoanal junction, which is essential for continence of solid stool. The muscles of the levator hiatus originate from the back of the pubic bone and the anterior part of the obturator internus muscles. The iliococcygeus muscles originate from the rest of the obturator internus muscles and sling down toward each other to form a common tendon between the rectoanal junction and the coccyx. This is the levator plate. This dynamic plate of tendon and muscle is responsible for entrapping the vagina and rectum horizontally at the time of downward pressures to help prevent vaginal prolapse.

#### “The White Line”

The muscles of the pelvic basin are skeletal and innervated by somatic rather than visceral nerves. These nerves are derived from the lumbar and sacral plexuses. These muscles are covered by parietal fascia, which is strong, flat, and firm in contrast to the looser and more flexible visceral connective tissues. The arcus tendineus levator ani is a thickening of the parietal fascia covering each obturator internus muscle and is the origin of each portion of each levator ani muscle (see Fig. 24-8). The arcus tendineus levator ani muscle travels from the lateral aspect of the back of the pubic bone toward the ischial spine in a curvilinear course.

The arcus tendineus fasciae pelvis (*the white line*) is a thickening of the parietal fascia of the levator ani muscles and is the attachment of the pubocervical fascia and rectovaginal fascia via the fascia endopelvina (see Fig. 24-6). The arcus tendineus fasciae pelvis courses linearly from near the pubic arch to the

**Figure 24-8** The muscles of the female pelvic basin. (From Netter FH, Dalley AF [eds]: Netter's Atlas of Human Anatomy, 2nd ed. Novartis, 1997, Plate 333, upper illustration. Netter illustrations used with permission of Elsevier, Inc. All rights reserved.)

## The Anatomic Basis of Normal and Abnormal Pelvic Support

ischial spine. In some cases of paravaginal defects, the most common cause of anterior vaginal wall prolapse, this arcus tears away from the parietal fascia with the fascia endopelvina and attached pubocervical fascia and the rectovaginal fascia. This leaves a bare strip of muscle along the sidewall of the pelvis.

### Site-Specific Defects

Important to our present-day concepts of pelvic visceral support, the visceral connective tissues can only stretch or attenuate within a small range. Further stretching results in distinct breaks of these support tissues. Today's concepts of reparative vaginal surgeries are based on finding, diagnosing, and repairing these site-specific defects<sup>9,10</sup> that result in the various prolapses. The realization of this concept is difficult because the visceral connective tissues lie between the vaginal epithelium and the peritoneum, both of which can stretch endlessly. Therefore, the clinician sees redundant vagina and large protrusions of peritoneum with no intervening visceral fascia. Previously, the gynecologic surgeon assumed that the unseen visceral fascia was so attenuated that it should be plicated. Today, the gynecologic surgeon repairs the disruptions and breaks in the continuous and interdependent network of visceral supporting connective tissues.

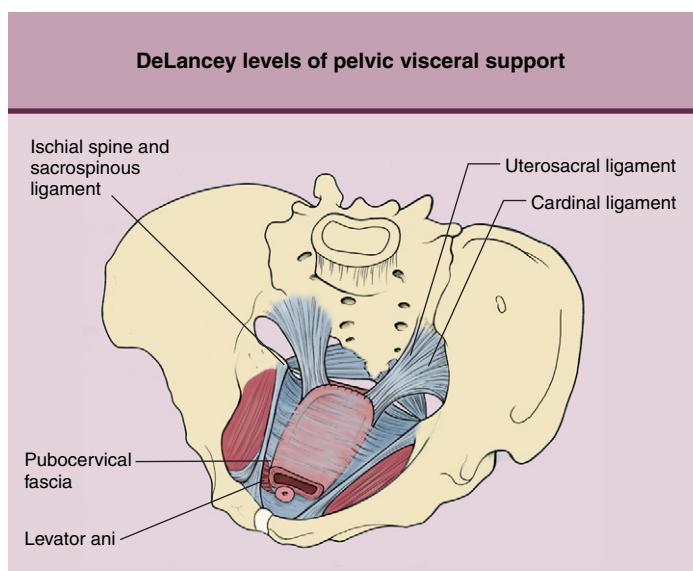

Unfortunately, we cannot operate to repair the damaged and compromised muscles and somatic nerves, which are also crucial elements in the pelvic support system. This concept is often underplayed, underappreciated, and seldom discussed or studied. Remember, the pelvic support network of connective tissue sheaths and septa simply position the urethra and bladder, vagina and cervix, and anal canal and rectum within and over the pelvic musculature. The skeletal muscles of the pelvis are ultimately responsible for the mechanical support of the pelvic viscera. These muscles are active in reacting to the various pressure changes and other conditions presented within the pelvis. Even if the visceral support connective tissues remain intact, compromise of the pelvic musculature and its innervations can result in vaginal prolapse symptoms and signs.

### Upper Vertical Supports of Level I

The pelvic support system of visceral connective tissues is artificially described by anatomists and clinicians in distinct segments. DeLancey level I,<sup>11</sup> or the superior hypogastric sheath (Uhlenhuth,<sup>3</sup> Peham and Amreich<sup>6</sup>), simply describe the suspensory function of the cardinal–uterosacral sheaths (Fig. 24-9). The cardinal and uterosacral ligaments simply suspend the cervix and upper third of the vagina over the levator plate. This allows the active levator plate to counter the downward pressures generated by the patient in a Valsalva movement, such as coughing, exercising, lifting, or having a bowel movement. This flap-valve action is believed to prevent vaginal prolapse.<sup>2</sup> The levator plate, which occurs anatomically between the rectoanal junction and coccyx, is very strong. The levator plate and levator ani muscles should be palpated and appreciated in the young, nulliparous patient by gentle rectal examination.

### Horizontal Supports of Level II

The transition from the cardinal–uterosacral ligaments into the more horizontal supports (DeLancey level II)<sup>11</sup> of the pubocervical fascia and the rectovaginal fascia occurs at the level of

**Figure 24-9 DeLancey levels of pelvic visceral support.** (From DeLancey JOL: Anatomic aspects of vaginal eversion after hysterectomy. Am J Obstet Gynecol 1992;166:1719.)

the ischial spines via the pericervical ring of visceral connective tissue (see Fig. 24-9). The pubocervical fascia is simply the thickened fibromuscular coat of visceral connective tissue surrounding the vaginal epithelium.<sup>12,13</sup> It is tethered to the pelvic sidewall by connective tissue septa or wings via the fascia endopelvina to the arcus tendineus fasciae pelvis. The rectovaginal septum inserts onto the pelvic sidewall in a similar manner. In cadaver dissections, the pubocervical fascia and rectovaginal fascia, along with visceral septa from the bladder and rectum, fuse and form the medial edge of a structure called the fascia endopelvina.<sup>3</sup> The lateral edge of the fascia endopelvina inserts onto the entire length of the arcus tendineus fasciae pelvis. Therefore, a paravaginal defect is a tearing away of the fascia endopelvina, with the attached pubocervical fascia and rectovaginal fascia, from the arcus tendineus fasciae pelvis. In some cases, the arcus and fascia endopelvina detach together from the muscular sidewall, thus leaving bare muscle tissue with no overlying parietal fascia.

### Lower Vertical Supports of Level III

The transition of the horizontal supports (DeLancey level II) to the lower vertical supports (DeLancey level III)<sup>11</sup> occurs at the apex of the perineal body. The perineal body is described as a pyramid with its base parallel to the floor and its apex vertically oriented (see Fig. 24-2). Fused to this is the anterior part of the anal canal and the posterior part of the lower third of the posterior vaginal wall. Also, the urethra is oriented vertically and is anchored to the pubic arch via its passage through the perineal membrane. This occurs as the middle third of the urethra follows into its distal third. The perineal membrane is more complex around the urethra and includes musculature and visceral connective tissues also.<sup>14</sup> In the younger patient, especially at vaginal childbirth, the structures of the perineal body can be seen—superficial transverse perineal muscles, anal sphincter muscle, rectovaginal fascia, bulbocavernosus muscle,

and lower rectal layers. However, in the older, postmenopausal patient, these structures are atrophic, fibrotic, and thus obliterated and usually cannot be seen. Nevertheless, the perineal body must be reconstructed at the time of reparative vaginal surgery, with the base positioned just above the level of the ischial tuberosities.

### **EXAMINATION OF THE PATIENT WITH DEFECTS OF PELVIC SUPPORT**

Disruption of these visceral connective tissues along any portion of the continuous network of pelvic support, along with concomitant injury and dysfunction of the pelvic musculature and somatic innervation, leads to the various defects in vaginal support.<sup>1</sup> The most common causative events are vaginal childbirth, repetitive straining as with constipation and heavy lifting, and aging.<sup>15</sup> Other factors—genetic, environmental (such as cigarette smoking), and nutritional—also affect connective tissue integrity. These support defects include uterine/cervical prolapse, various degrees of anterior and posterior vaginal wall prolapse, vaginal apical prolapse with accompanying cul-de-sac herniation, hypermobile urethra, and perineal descent with gaping vaginal introitus.

These pelvic support defects are seen as prolapse of the vaginal walls and apex in various areas, especially with the patient straining. The examiner must have a baseline appreciation of the “normal” rugated appearance and movements of the vaginal walls in the young, nulliparous subject. The clinician must also have a three-dimensional mindset and understanding of the vaginal support structures. This allows the examiner to visualize the site-specific anatomic disruptions that are responsible for the vaginal bulges. This understanding allows the reparative vaginal surgeon to address and repair the several specific defects at the time of surgery.

Patients present with various complaints associated with pelvic floor/vaginal defects. The most common include vaginal pressure and the feeling of sitting on objects such as a “golf ball” or “tennis ball.” Other complaints include urinary incontinence, urine retention, incomplete evacuation of the rectum with bowel movement, and lower back pain/pressure. With posterior vaginal wall prolapse (rectocele), some patients push on the perineal body or put a finger in the vagina to more fully empty the rectum and finish the bowel movement. The physician should listen and allow the patient to describe her symptoms. At this time, vaginal wall defects can only be appreciated and clinically diagnosed by physical examination. The office diagnoses are further confirmed and refined at the time of surgery. Physical examination with description and documentation of the findings is the standard at this time for diagnosis of pelvic support defects.<sup>10,16</sup> From these findings, the surgeon can then formulate a surgical plan that fits the patient and her specific vaginal defects. This is in contrast to former practices, in which all types of cystoceles were repaired by the same operation—central anterior colporrhaphy—and all types of rectoceles were repaired by posterior colporrhaphy. Most embarrassing of all, enteroceles (cul-de-sac hernias) were repaired by the plication or “purse stringing” of peritoneum and not visceral fascia!

Examination of the patient with vaginal support defects mirrors the same sequence with the same instrumentation and

the same maneuvers as the examination of the normal patient without such defects. However, there is one addition. A uterine dressing forceps or straight ring forceps will assist in the evaluation of the anterior vaginal wall. In the dorsal lithotomy position, observe the perineum, labia, introitus, perineal body, and anus. What differences are seen compared to the nulliparous patient? Notice the tone, laxity, and dimensions of these structures. What is observed when the patient contracts the vaginal opening? What happens when the patient bears down? Is there descent of the perineal body and anus? Normally, the perineal body and the anus are located just above the level of the ischial tuberosities. Spread the labia. Is there gaping of the introitus? What bulges are noticeable at the introitus? Is the vagina well or poorly estrogenized? Are rugations present? Measurements in centimeters can be taken at this time.

Take the bivalve speculum and gently insert it into the depths of the vagina. What does the cervix look like? Where is it located? How far down the vaginal length does the cervix prolapse with Valsalva straining? With an Allis clamp gently placed on the cervix, how much lateral movement is allowed? Describe the vaginal fornices at rest and with the patient straining. Look at the anterior vaginal wall. Are there rugations? Where is the wall resting? What happens when the patient bears down? Are anterolateral sulci present? Do they bulge down and disappear when the patient performs a Valsalva maneuver? Now place the uterine dressing forceps, curve up, or the ring forceps in the vagina with the tips placed at the level of the ischial spines. Open the forceps so that the arms rest against the pelvic sidewall and re-create the anterolateral sulci. What happens to the anterior vagina wall when the patient bears down? Describe. Does the anterior wall stay put?

Remember the forceps were originally described to correct the paravaginal defects and allow for diagnosis of a central vaginal wall defect, indicating a central defect of the visceral connective tissue underneath the bladder, as opposed to a lateral paravaginal defect. However, more importantly, the tips of the forceps also re-create the attachment of the upper edge of the pubocervical fascia with each uterosacral ligament. This action in itself significantly corrects a high cystocele. Keep this in mind when planning reparative surgery. The re-creation of the pericervical ring and its reattachment to each uterosacral ligament at the level of the ischial spines is a key element in successful repair of anterior vaginal wall prolapse (cystocele). Perform the Q-tip test. Is the urethra hypermobile?

Look at the posterior vaginal wall. Are there rugations? Where is the wall resting? What happens when the patient bears down? Are posterolateral sulci present in the middle third of the vagina? What happens when the patient bears down? Is posterior vaginal wall prolapse (rectocele) present? Anterior wall site-specific defects are usually well diagnosed and characterized in the office. In contrast, the diagnosis of posterior vaginal wall defects may be better evaluated and defined in the operating room after posterior colpotomy has been performed, and the rectovaginal septum dissected out and seen.

After the preceding observations have been made, perform the palpation portion of the examination. Place the lubricated gloved fingers in the vagina. What do the vaginal walls feel like? Can you feel the banjo string of the arcus tendineus fasciae pelvis? How do the underlying visceral connective tissues feel?

## The Anatomic Basis of Normal and Abnormal Pelvic Support

Can you feel the break of the pubocervical fascia away from the sidewall? What weaknesses in support do you notice? Can you feel the uterosacral ligaments inserting into the cervix or vaginal cuff? Place an Allis clamp on the cervix and feel again for the uterosacral ligaments. On rectovaginal examination, can you feel any distinct breaks in the rectovaginal fascia? When the patient squeezes your fingers, how strong are the levator ani muscles? How strong and functional is the levator plate? On rectal examination, move the finger laterally. Is the levator ani muscle intact and connected to the lateral pelvic sidewall? How does this examination compare to your composite “normal” patient? Describe and record in the patient’s chart.

### **ANATOMY OF DEFECTS IN PELVIC SUPPORT: CLINICAL CORRELATION**

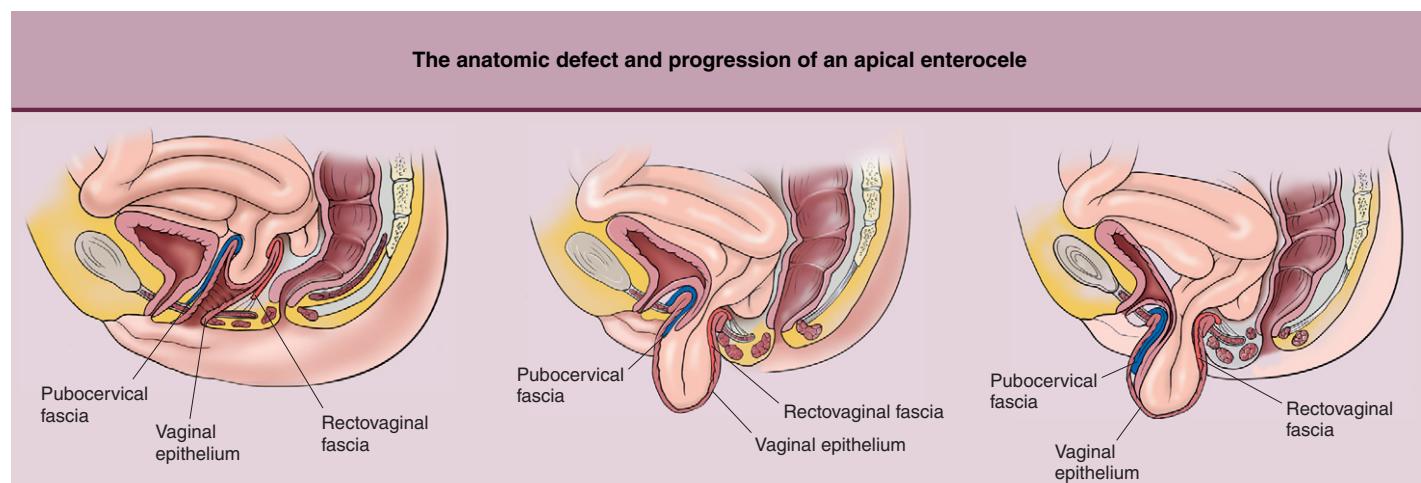

Our present knowledge of pelvic support anatomy allows the following correlations. Disruption of the cardinal–uterosacral ligaments from the pericervical ring is a crucial event that starts the evolution of uterine prolapse/vaginal vault prolapse. Continued disruption of the pericervical ring, especially the tearing of the pubocervical fascia away from the rectovaginal fascia, opens the apical fascial defect that results in enteroceles. An enterocele or cul-de-sac hernia is the protrusion of the cul-de-sac peritoneum, which can stretch endlessly, through the pericervical ring defect<sup>9</sup> (Fig. 24-10). Apical prolapse is usually a combination of both disruption of the pericervical ring (allowing the herniation) and pericervical detachment from the cardinal–uterosacral ligament complexes. As the apex is pushed distally down the vaginal length, each lateral edge of each fascia endopelvina of the pubocervical fascia and rectovaginal fascia is torn away from its sidewall insertion, thus resulting in varying degrees of severity of anterior and posterior vaginal wall prolapse.

Significant injury and compromise in function to the levator ani muscles and their somatic innervations are associated with most, if not all, pelvic support defects. This loss of real muscular

support to the pelvic viscera accelerates the formation of vaginal prolapse. Without adequate muscular support, the shearing forces on the visceral connective tissues are increased, thus increasing the visceral fascial breaks. It is important to remember that reparative vaginal surgery can only attempt to repair the integrity of the network of supporting visceral connective tissues. This surgery will not rehabilitate poorly functioning muscles and nerves.

Anterior vaginal wall prolapse (cystocele) is most commonly the result of apical support defect with concomitant paravaginal defects.<sup>17</sup> The paravaginal defects can be a partial or complete detachment of the pubocervical fascia (via the fascia endopelvina) from each sidewall, either unilateral or bilateral, usually near the ischial spines. This is based on observations at the time of surgery and in unembalmed cadavers, especially via laparoscopic observations. The apical defects are most commonly transverse detachments of the cardinal–uterosacral ligaments from the cervix or vaginal vault apex. By observations and palpation, the detachment of the cardinal–uterosacral ligaments occurs at the points of insertion to the cervix or vaginal cuff at the level of the ischial spines. The breaks do not occur at the origin of the uterosacral ligaments to the sacrum nor at the midportion of these support tissues.<sup>18</sup>

The other transverse tear seen is the detachment of the pubocervical fascia away from the anterior portion of the pericervical ring, with the uterosacral ligaments still attached to the pericervical ring posterolaterally. The paravaginal defects have been observed to be a detachment of the pubocervical fascia (via the fascia endopelvina) from the arcus tendineus fasciae pelvis in most cases. Other observed cases involve the pulling away of the arcus tendineus itself from the muscle belly of the levator ani muscle. Therefore, the pelvic sidewall shows a strip of bare muscle with no overlying parietal fascia. Muscle will not hold support sutures. Many times, a “central” defect is actually the central protrusion seen anteriorly, resulting from the detachment of the cardinal–uterosacral ligaments from the middle third of the vaginal cuff or from the cervix, which is

**Figure 24-10** The anatomic defect and progression of an apical enterocele. Note the separation of the pubocervical fascia of the anterior vaginal wall from the rectovaginal fascia of the posterior vaginal wall. Progression from small enterocele to complete vaginal prolapse. (From Richardson AC: The anatomic defects in rectocele and enterocele. J Pelvic Surg 1997;1:214–221.)

## Urogynecology

anatomically found in the middle third of the vaginal apex. Repair of the pericervical ring with reattachment of the uterosacral ligaments at the level of the ischial spines repairs this “central defect.” By far, anterior vaginal wall prolapse is caused by detachments at the edges of the pubocervical fascia (via the fascia endopelvina) and not by tears within the pubocervical fascia.

In many cases, this same observation is true in posterior vaginal wall prolapse (rectocele) and the rectovaginal fascia. The upper edge of the rectovaginal fascia detaches from the cardinal–uterosacral ligaments, causing the posterior wall prolapse to progress, resulting in the detachment of the upper, lateral edges of the fascia endopelvina (rectovaginal fascia) from the sidewall iliococcygeus fascia. Many of these defects are found with enteroceles. Therefore, repair of the enterocele also begins the repair of the high rectocele.

Because of the disruption of the perineal body during vaginal childbirth, distal posterior vaginal wall defects can also result from detachment of the rectovaginal fascia from the perineal body. This same defect also causes perineal descent as well as disruption of the rectoanal canal. The perineal body in the multiparous, aging patient is filled with scar tissue centrally and even laterally, with thinning of the fibromuscular structures. The fibers of the superficial transverse perineal and anal sphincter muscles are rarely seen or appreciated.

The perineal body should be reconstructed at the time of reparative surgery. Reconstruct the perineal body as a pyramid with the apex 3 to 4 cm high. Then, attach the rectovaginal fascia to the perineal apex. Be sure to restore the normal diameter of the vaginal introitus by bringing the bulbocavernosus muscles into the perineal body. However, be sure to allow for a vaginal opening three fingers in diameter to facilitate comfortable penile entry during sexual intercourse.

### Goals of Reparative Vaginal Surgery

Reconstruction of the perineal body also restores the integrity of the rectoanal canal and the posterior wall of the lower third of the vagina. This brings the anus into its normal position just above the level of the ischial tuberosities. Thus, the first goals of perineal reconstruction are to correct perineal descent and to restore a more functional vaginal introitus. The second goal is to form a second backstop to assist the weakened levator plate in resisting downward Valsalva pressures that stress the restored visceral support network, just constructed during the surgery. Thus, the reconstructed pelvic outlet helps relieve the stress pressures on the upper vaginal supports, especially on the uterosacral ligaments and the reconstructed pericervical ring.

After anatomically correct reparative vaginal surgery, the lower third of the vagina should be horizontal and well supported by the perineal body in the patient in the dorsal lithotomy position. The diameter of the vagina should be three fingers. The upper two thirds of the vagina should then slope down to the ischial spines, with the apex at or slightly above the level of the ischial spines. The surgeon should be able to feel thickened visceral connective tissues underneath the vaginal epithelium with excellent peripheral attachments. This should be found anteriorly, apically, and posteriorly. At times, appropriate reinforcement of vaginal repairs with autologous, cadaveric, animal-derived tissues, or plastic meshes may be indicated. This

controversial and fast-evolving clinical area of study is not addressed in this chapter. The goals of reparative vaginal surgery are to restore normal vaginal diameter and length, while also restoring more normal support and function to the bladder, urethra, vagina, rectum, and anal canal. Our understanding of pelvic support anatomy and defective vaginal support issues continues to evolve. As new knowledge and concepts appear, the clinician must integrate this knowledge into his/her understanding to better serve the many patients with pelvic floor dysfunction and prolapse.

# Chapter 25

# Nonsurgical Treatment of Urinary Incontinence

Rony A. Adam, MD, and Peggy A. Norton, MD

## KEY POINTS

- Many women with urinary incontinence may benefit from a trial of nonsurgical management.
- Pelvic floor muscle training and duloxetine are useful in the treatment of stress incontinence.
- Devices for the treatment of stress incontinence have not been well studied but show some benefit.
- Anticholinergic medications are effective at treating overactive bladder symptoms, including urge incontinence.

In women, treatment of urge urinary incontinence (overactive bladder) is primarily pharmacologic and behavioral. Although stress urinary incontinence can be treated surgically, many women choose nonsurgical options such as intravaginal devices and newer pharmacologic treatments. Both types of urinary incontinence may benefit from lifestyle interventions, physical therapy, biofeedback, bladder retraining, and behavioral modifications. Mixed urge and stress incontinence is sometimes treated as two separate entities with their respective treatments, although there is increasing evidence that both components may respond to treatments aimed at a single type of incontinence, such as anticholinergics/antimuscarinics for urge incontinence. A consensus conference on urinary incontinence was sponsored by the World Health Organization in 2001, and levels of evidence for many nonsurgical treatments were summarized by Wilson and colleagues.<sup>1</sup>

## GENERALIZED TREATMENTS FOR URINARY INCONTINENCE

### Lifestyle Interventions

Modest lifestyle changes are often suggested by practitioners, although much of the evidence for their use is based only on expert opinion (Table 25-1). Weight loss in morbidly obese women has been shown to decrease urinary incontinence (Level II evidence). Heavy occupational work and physical activity may be associated with urinary incontinence, but it is unknown whether cessation of these activities is beneficial or advisable (Level II evidence). Although smoking is associated with urinary incontinence, there is no data on smoking cessation in the management of incontinence. Excessive fluid intake may play a role in a minority of women, but adjustment of fluid has had conflicting results in the literature. Constipation appears to be a risk factor for urinary incontinence, but management of consti-

pation has not been studied for its effect on urinary incontinence. Other management interventions include decreasing lower extremity edema, treating pulmonary conditions such as cough, and utilizing a bedside commode for nighttime incontinence.

### Behavioral Modification

Behavior modification for urinary incontinence is a program of education, where skills are learned to improve urinary control. It emphasizes correct habits and frequency of voiding, urge suppression techniques, and in some cases scheduled voiding. Behavioral modification is often discussed in conjunction with pelvic floor muscle training (PFMT) because these muscles are an important part of urge suppression and bladder neck support during increased abdominal pressure. Despite its broad clinical use, a Cochrane review of timed (scheduled) voiding, showed insufficient quality and quantity of data to provide evidence for or against its use as a treatment for urinary incontinence.<sup>2</sup> This strategy continues to remain popular due to its low cost, ease of implementation, and lack of adverse effects.

Another Cochrane review determined that bladder training is better than no treatment. The reviewers cautioned, however, that such a conclusion is tenuous due to the scarcity of adequately designed studies. Regarding comparison of bladder retraining with medication for urge incontinence, the reviewers found that bladder retraining was favored over either oxybutynin or imipramine with flavoxate. Again, caution was advised in the interpretation based on the limited data found. Based on a single study reviewed for this meta-analysis, adding bladder retraining to a regimen of PFMT and biofeedback was better than PFMT or biofeedback alone when assessing patient perception of improvement and quality of life immediately after treatment. These benefits, however, were not sustained after 3 months.<sup>3</sup> One study found that in women with urge incontinence older than age 55, the combination of behavioral modification and oxybutynin was better at reducing incontinence episodes than either therapy alone at 8 weeks' follow-up.<sup>4</sup> Completion of a simple voiding diary can greatly assist in setting realistic goals for behavioral modification, and if a fluid intake/output record is kept, a better assessment of appropriate fluid management and typical voided volumes is available.

### Pelvic Floor Muscle Training

This intervention focuses on improving the strength and response of the pubococcygeal muscle to voluntary contraction. Although its role in the treatment of stress incontinence is well established, pelvic floor contraction is also a useful technique for urge suppression. In women with stress or mixed incontinence, PFMT

Table 25-1 Efficacy of Lifestyle/Behavior Treatments for Urinary Incontinence			
	Efficacy	Effort	Evidence
<b>Lifestyle interventions</b>			
Weight loss	Moderate	High	Level II
Active lifestyle, lifting	Assoc risk only		Scant II-III
Smoking cessation	Assoc risk only	High	Level IV
Fluid intake, caffeine	Moderate	Low	Scant II-III
Constipation	Assoc risk only	Low	Level II-III
Postural change (crossing legs)	Mod to high	Low	Level II
<b>Behavior modification</b>			
Bladder retraining	Moderate	Moderate	Level I
Bladder retraining w/pelvic floor muscle training	Conflicting evidence	Moderate	Level I
Bladder retraining w/medication	Conflicting evidence	Moderate	Level I-II
<b>Pelvic floor muscle training</b>			
"Intensive" better than "standard"	Moderate	Moderate	Level I
Adding biofeedback	Moderate (short-term only)	Moderate	Level I
Adding weighted cones	No additional benefit	High	Level I
	No additional benefit	Moderate	Level I

Summarized and updated from Wilson D, Hay-Smith J, Bø K: Outcomes of conservative treatment. In Cardozo L, Staskin D (eds): Textbook of Female Urology and Urogynaecology. London: Isis Medical Media, 2001, pp 325-332.

was found to be better than no treatment or sham treatment in a Cochrane review. It could not, however, be shown to be any better or worse than other conservative therapies. Adding biofeedback to PFMT shows no advantage, and the review also concludes that the role of PFMT in patients with urge incontinence remains unclear. Great heterogeneity was noted in the content of reported training programs, such as number of contractions, duration of each contraction, and number of exercise sessions per day, with no ability to determine which regimen is preferred.<sup>5</sup> The long-term success of PFMT depends on adherence to the exercise regimen. In a follow-up study of a randomized trial of home PFMT compared to intensive PFMT, the marked short-term benefit of intensive training did not persist after 15 years. The authors found that only 28% of subjects exercised at least once a week, 36% periodically, and 36% never, with no difference noted based on the original group assignments.<sup>6</sup> Obstetricians and gynecologists are in a unique position: the obstetrician sees firsthand the damage to the pelvic floor muscles during childbirth, and the gynecologist has an opportunity to teach improved muscle control every time he or she performs a digital examination of the vagina.

## URGE INCONTINENCE TREATMENTS

Although this chapter is devoted to women with incontinence, it should be noted that many women are bothered by overactive bladder symptoms without incontinence (urgency, frequency, nocturia) and may be treated for these bothersome symptoms in the absence of incontinence. Most patients with urge incontinence have some form of behavioral management included in their care, including urge suppression techniques, scheduled voiding, and fluid management. Urge suppression includes the "freeze and squeeze" technique of *not* rushing to the bathroom, contracting the pelvic floor muscles (possibly while crossing legs), and imaging the bladder contraction going away. Patients

are taught to avoid provocative situations, such as arriving home with a full bladder. A voiding diary with voided volumes recorded in a simple plastic "hat" can distinguish the patient who voids 50 to 100 mL 20 times a day from the patient who voids 400 to 600 mL 10 times a day. Both may complain of urgency, but the first will be treated with scheduled voiding and pharmacologic agents, whereas the second needs to normalize her voided volumes to a reasonable 200 to 300 mL, mostly by consuming less fluids.

Pharmacologic management of urge incontinence has good evidence for efficacy, although all of these randomized, controlled trials had significant placebo effects, probably because patients keep voiding diaries as part of these trials (Table 25-2). Newer-generation medications have sustained formulations that minimize the major side effect of dry mouth, and although all seem to have similar efficacy, the side effects seen in any individual patient may direct the medication selected. At present, differences in cognitive function in the elderly, constipation, and dry mouth are reported with several medications used to manage incontinence, but few head-to-head comparisons exist. Effects should be seen within 2 to 4 weeks of treatment, and the cost is approximately \$70 to \$100 per month. Generic oxybutynin 5 mg three times daily may be the cheapest option but has considerable side effects that may compromise compliance.

Extended-release oxybutynin given once daily appears to have similar efficacy as immediate-release oxybutynin, but with significantly fewer side effects.<sup>7</sup> Most studies show a reduction in urge incontinence episodes of approximately 70%.<sup>7-9</sup>

Transdermal oxybutynin is given twice a week and shows similar efficacy to oxybutynin and tolterodine, but with fewer anticholinergic side effects; the incidence of dry mouth did not differ from placebo. The primary side effect of transdermal oxybutynin is mild to moderate local skin reactions. Erythema occurs in about half the subjects, with 3% of those subjects having severe erythema and up to 17% associated pruritus.<sup>10-12</sup>

Table 25-2 Pharmacologic Treatment of Overactive Bladder/Urgo Incontinence*		
Generic/Brand Name	Dose	Citations
Tolterodine/Detrol LA (oral)	2,4 mg PO once daily	Dmochowski et al., 2003, <sup>12</sup> Drutz et al., 1999, <sup>14</sup> Van Kerrebroeck et al., 2001, <sup>15</sup> Diokno et al., 2003 <sup>16</sup>
Oxybutynin/Ditropan XL (oral)	5, 10, 15 mg PO once daily	Anderson et al., 1999, <sup>7</sup> Gleason et al., 1999, <sup>8</sup> Appell et al., 2001, <sup>9</sup> Diokno et al., 2002 <sup>16</sup>
Oxybutynin/Oxytrol (transdermal)	3.9 mg/day applied twice weekly	Davila et al., 2001, <sup>10</sup> Dmochowski et al., 2002, <sup>11</sup> Dmochowski et al., 2003 <sup>12</sup>
Trospium/Sanctura (oral)	20 mg PO twice daily	Frohlich et al., 2002, <sup>17</sup> Halaska et al., 2003, <sup>18</sup> Zinner et al., 2004 <sup>19</sup>

Solifenacina/Vesicare (oral)	5, 10 mg PO once daily	Cardozo et al., 2004, <sup>22</sup> Chapple et al., 2004, <sup>23</sup> Kelleher et al., 2005 <sup>24</sup>

\*Medications available in the United States.

Tolterodine, in its immediate- and extended-release formulations, has been shown effective in the treatment of overactive bladder in numerous randomized, controlled trials.<sup>13–15</sup> One study compared the long-acting formulations of oxybutynin with tolterodine. Results suggest that both had similar ability to reduce the number of incontinence episodes; there was slightly more dry mouth in the oxybutynin group but no difference in discontinuation rates.<sup>16</sup>

Several new drugs have recently been approved by the Food and Drug Administration and appear to have similar efficacy to those already marketed<sup>17–24</sup> (Table 25-3). Some of these newer medications have been shown to have little effect on cognitive function. One study compared the effects of oxybutynin, tolterodine, and trospium on sleep and cognitive skills in healthy volunteers older than age 50. There was significant reduction

of rapid eye movement (REM) sleep with oxybutynin and tolterodine, but trospium showed REM sleep similar to that subjects experienced while on placebo. No differences were noted in cognitive skills or subjective reporting of sleep variables with any of the three medications tested, compared to placebo.<sup>25</sup> Another study showed no effect on cognitive function when darifenacin was compared to placebo in subjects age 65 or older.<sup>26</sup> A few older drugs have either higher side effects (propantheline bromide) or have not had efficacy established (hyoscyamine, flavoxate).

## STRESS INCONTINENCE TREATMENTS

Pharmacologic treatment of stress incontinence was previously focused on alpha stimulation of the urethral smooth muscle with ephedrine-like agents, mainly those containing phenylpropanolamine, which were removed from the market due to concerns about hemorrhagic stroke. Estrogen seemed likely to help stress incontinence due to its effects on urethral mucosal coaption and vascularity. A Cochrane review from 2003 concluded that estrogen can improve or cure incontinence, both stress and urge types,<sup>27</sup> but more current Level I evidence shows that oral conjugated equine estrogen with or without progestin is not useful in the treatment or the prevention of urinary incontinence—stress, urge, or mixed.<sup>28</sup> The role of vaginal estrogen either by cream or intravaginal device is still unclear due to lack of available studies. Duloxetine, a combined norepinephrine/serotonin reuptake inhibitor, has been shown to improve stress and mixed incontinence in multiple randomized, controlled trials (see Table 25-3). The action of the drug is unknown, but it may augment normal urethral tone without compromising voiding function. A randomized, blinded, doubly controlled trial showed that 40 mg twice a day of oral duloxetine was better than no treatment and than PFMT alone. It further showed that duloxetine and PFMT combined was better than duloxetine alone.<sup>29</sup> Duloxetine is approved for use in stress incontinence in Europe, but is only approved for the treatment of depression and diabetic peripheral neuropathic pain in the United States as of December 2005.

Pelvic floor muscle training has long been recognized in the treatment of stress incontinence and is based on the idea that a

Table 25-3 Device/Pharmacologic Treatment for Urinary Incontinence			
	Efficacy	Effort	Evidence
<b>Continence devices</b>			
Intravaginal (pessary-like) devices	Moderate to high	Low to moderate	Scant I-II
Occlusive urethral devices (not currently marketed)	Moderate	Low to moderate	Level III-IV
Intraurethral devices (not currently marketed)	High	Moderate	Level II-III
Pharmacologic treatment of overactive bladder	Moderate	Low but expensive	Level I
Pharmacologic treatment of stress urinary incontinence	Moderate	Low, no cost estimates	Level I
Pharmacologic treatment of mixed urinary incontinence	Moderate	Low	Level I

**Table 25-4**  
**Devices for Stress Urinary Incontinence**

Device	n	Indication	Follow-up	Outcome
Smith-Hodge pessary <sup>34</sup>	30	Stress incontinence	None	Cough pressure profile 24/30 patients continent
Randomized controlled trial of super tampon and Hodge pessary <sup>35</sup>	18	Exercise-induced stress incontinence	None	36% pessary users continent; 58% tampon users continent
Bladder neck support prosthesis <sup>36</sup>	77	Stress and mixed incontinence	12 weeks	Subjective pad test; 29% continent, 51% decreased severity by more than half; 81% combined subjective/objective some or maximum benefit
Bladder neck support prosthesis <sup>37</sup>	70	Stress or mixed incontinence	4 weeks	53/70 completed trial; significant improvement on pad tests, diaries; high subjective improvement and quality of life
Continenence ring pessary <sup>38</sup>	38	Stress incontinence	1 year	6/38 continued device use long term; improved scores in pad test, voiding diary
Various continence pessaries <sup>39</sup>	100	Stress and mixed incontinence prolapse	11 months	59% patients continued use long term, with significant reduction in incontinence
Various continence pessaries <sup>40</sup>	119	Stress incontinence	6 months	89% successful device fitting; over half continued usage for 6 months

Summarized and updated from Wilson D, Hay-Smith J, Bø K: Outcomes of conservative treatment. In Cardozo L, Staskin D (eds): *Textbook of Female Urology and Urogynaecology*. London: Isis Medical Media, 2001, pp. 325–347.

strong and fast contraction of the pubococcygeal muscle will press the urethra against the back of the symphysis pubis, thus creating a mechanical rise in urethral pressure. In general, patients should be assessed for their ability to perform a correct contraction; and contact with a health care provider at regular intervals may improve the effect of PFMT. One immediate benefit of PFMT may be to alert the patient to the use of a contraction before an anticipated increase in intra-abdominal pressure (the “knack”). A variety of regimens is recommended, making comparisons difficult (see Table 25-1). In most regimens, the patient is taught to perform three sets of 8 to 12 slow maximal voluntary contractions sustained for 6 to 8 seconds. These three sets should be performed three to four times a week, preferably daily, and benefit may not be appreciated until 15 to 20 weeks. Patients should expect to continue this training long term or lose its benefit.

Intravaginal devices work by creating a “backstop” at the level of the bladder neck. Devices that have been studied include a short super tampon inserted just inside the vagina, a Hodge pessary placed backward and upside down, and a variety of continence devices manufactured by companies that also manufacture pessaries for prolapse<sup>30–36</sup> (Table 25-4; see also Table 25-3). Additionally, there are several disposable intravaginal devices exist that are not currently available for use in the United States. These devices are easy to use and seem to have moderately good efficacy, especially for the woman who has predictable stress incontinence, such as with exercise or during a bad cold. Use among urogynecologic practices is variable; some specialists offer these devices to all women with stress incontinence, but others do not include intravaginal devices in their practice. The devices have not been well studied; these are low-cost, modest-volume devices whose manufacturers do not have research funds and there are no sham devices for randomized, controlled trials.

Intra-urethral devices work through occlusion of the urethra. They are removed for voiding and most cannot be reinserted.

Trials of several products have been conducted with favorable efficacy (79% of patients were completely dry) and low risk of side effects, but intra-urethral devices are less comfortable than the intravaginal devices.<sup>37,38</sup> These intra-urethral devices have failed to gain popularity with patients and physicians, and currently no intra-urethral device is marketed in the United States.

Occlusive extra-urethral devices or patches have been reported to significantly reduce incontinence episodes and increase quality of life.<sup>39,40</sup> Despite this, acceptance from physicians and patients has been poor and the devices are not currently marketed in the United States.

## KEY POINTS

- Multiple factors are associated with stress urinary incontinence.
- Women who have delivered a child, whether vaginally or by cesarean section, have higher rates of stress urinary incontinence.
- Nulliparous women have the lowest rates of stress urinary incontinence.
- Multichannel urodynamic testing may be useful as a diagnostic tool, but it is an imperfect test with limited reproducibility.
- Pelvic exercises rarely cure stress incontinence, but they can allow some patients to achieve a level of improvement they find acceptable.
- Treatment of stress urinary incontinence is mainly surgical; the usual methods used are retropubic suspension or midsuburethral slings.
- The selection of the type of surgery performed is based more on subjective factors such as a surgeon's taste, habits, and experience as well as by the aggressive marketing of a procedure by surgical instrument companies.

Stress urinary incontinence is defined by the International Continence Society as a symptom, a sign, and a condition. The symptom is the patient complaint of involuntary loss of urine with physical exercise. The sign is the observation of loss of urine from the urethra immediately upon increasing intra-abdominal pressure (e.g., from running, coughing, and sneezing). The condition is the social unacceptable involuntary loss of urine.

It is estimated that at least 8.5% of women suffer from some form of urinary incontinence and 37% of elderly women may have urinary incontinence.<sup>1</sup> It is estimated that at least 10 million adult Americans suffer from incontinence at an estimated annual cost of \$10.3 million.<sup>2</sup> Government studies indicate that there are now 3 million adults age 85 or older who suffer from urinary incontinence; it is expected that in the next decade that number could double.<sup>3</sup> Urinary incontinence of a significant degree can have a major influence on a woman's life. Emotional stress is placed on a family when they must care for an incontinent member of the household. Health care workers are also psychologically affected as the hospitalized or institutionalized patient who is incontinent of both urine and feces requires more nursing time, is aesthetically unpleasant, and is more likely to spread certain pathogens. The social implications and the economic impact of incontinence are considerable given the enlarging elderly population and the prevalence of incontinence, which approaches 50% in the aged.

Incontinence refers to any involuntary loss of urine and is defined by the following:

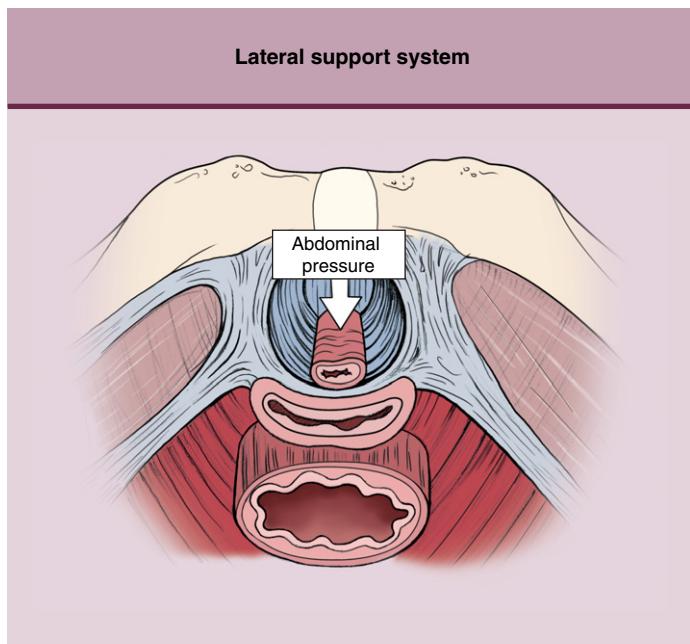

- *Stress urinary incontinence* is involuntary leakage of urine on effort or exertion or on coughing or sneezing. The sign of stress urinary incontinence must occur at the start of coughing and end with the coughing.
- *Urge incontinence* is the strong desire to urinate. The patient may sense a degree of urgency if voiding occurs despite the desire not to void.
- *Genuine stress incontinence* is involuntary leakage of urine during increased abdominal pressure in the absence of detrusor contraction during urodynamics.
- *Functional incontinence* is involuntary leakage despite normal bladder and urethral function in patients with dementia or disorientation.
- *Total urinary incontinence* occurs when the bladder is unable to store urine because the resting urethral pressure is so low that no resistance is present for the passage of urine.

Three theories have been developed to explain the continence mechanism:

1. DeLancey's hammock hypothesis
2. Ulmsten and Petros' integral theory
3. Shafik's common sphincter mechanisms

DeLancey studied the spatial relationship and the histologic nature between the arcus tendineus fasciae pelvis, the levator ani muscles, and the fascia endopelvina.<sup>4</sup> A hammock-like layer on which the bladder and the urethra rest is formed by the anterior vaginal wall and the fascia endopelvina. The stability of this layer depends on the layer's intact attachment to the arcus and the levator muscles. The urethra is compressed during stress between the downward forces of intra-abdominal pressure rise and the resistance of this hammock-like supportive suburethral layer (Fig. 26-1). DeLancey believed that the stability of this layer, rather than the intra-abdominal position of the bladder neck and proximal urethra, determines urinary continence during stress. Further support for this theory was offered by the observation that operations that stabilize the pelvic fascia to the arcus tendineus fasciae pelvis have proven to be more successful and cause less voiding dysfunction than high retropubic suspension procedures.

According to the theory of Ulmsten and Petros, female stress and urge incontinence have a common etiology.<sup>5</sup> Laxity of the anterior vaginal wall or its supporting ligaments allows activation of stretch receptors in the bladder neck and proximal urethra, which allows an inappropriate voiding reflex that may result in detrusor instability and urgency, frequency, and nocturia. Thus,

**Figure 26-1** The urethral support system, after the urethra and vagina have been transected just below the vaginal neck. The arrow represents the force generated by increased abdominal pressure. (From DeLancey JOL: Structural support of the urethra as it relates to stress urinary incontinence: the hammock hypothesis. Am J Obstet Gynecol 1994;170:1713–1723. Copyright 1994, Elsevier Science.)

the anterior vaginal wall does not efficiently transmit the closure pressure that would otherwise be caused by three separate closure mechanisms. They observed three opposing muscle forces during videoradiologic studies combined with dynamic urethral pressure measurements, surface electromyography, and digital palpation. The anterior pubococcygeal muscle acts in a forward direction to lift the anterior vaginal wall to compress the urethra; two opposing muscle groups controlled by the levator ani and the longitudinal muscle of the anus move backward, which closes the bladder neck. The pelvic floor muscles, under voluntary control, lift the hammock in a cephalad direction, closing the bladder neck. This upward motion is the mechanism used in pelvic floor exercises. Thus, the overall laxity of the anterior vaginal wall or its supporting ligaments causes a dissipation of the forces, and stress incontinence occurs.

According to Shafik, the pelvic floor consists of two muscle structures, each with a different origin and innervation.<sup>6</sup> The puborectal muscle is considered the common pelvic organ sphincter. Contraction of the levator ani opens the bladder neck and initiates voiding and bowel evacuation. Reflex contraction of the puborectal and striated urethra muscle, mediated through the pudendal nerve, controls urinary continence.

Two of the three theories are complementary because they underline the stability of the fascia endopelvina and its intact connection to the pelvic floor muscles, which appear to be essential for adequate urethral closure during stress. The integral theory suggests a more active role for the pelvic muscles in the maintenance of continence.

This chapter reviews the most recent high-quality evidence regarding the etiology and management of urinary incontinence

in women. The data sources selected focus on the etiology or treatment of urinary incontinence in adult women and included searches in the Excerpta Medica Database (EMBASE), Medline, The Cochrane Library, and the American College of Physicians (ACP) Journal Club. Studies of treatment included only randomized, controlled trials or systematic reviews of randomized, controlled trials. Articles to determine the etiology of incontinence were found by reviewing cohort studies, case-control studies, and cross-sectional studies along with reviews of these types of studies.

Multiple factors have been found to be associated with urinary incontinence. Women who developed stress incontinence during the first pregnancy and especially those who developed stress urinary incontinence during the first 6 weeks' postpartum were found to have an increased risk of having incontinence 5 years' postpartum.<sup>7</sup> Increased parity was independently associated with urinary incontinence and subsequent stress incontinence surgery.<sup>8</sup> Women who were nulliparous had lower rates of stress incontinence than those who had either vaginal deliveries or cesarean sections.<sup>9</sup> Forceps delivery was associated with a higher risk of stress urinary incontinence than spontaneous vaginal delivery.<sup>10</sup> Vacuum delivery, vaginal laceration or episiotomy, and length of the second stage of labor were not found to be risk factors for developing stress urinary incontinence, whereas forceps delivery was an independent risk factor.<sup>11</sup> There appears to be an independent association between high birth weight and subsequent surgery for stress urinary incontinence.<sup>12</sup>

Hysterectomy in women age 60 or older was associated with a higher risk of developing urinary incontinence. This was not true for women younger than age 60.<sup>13</sup> After adjusting for age, parity, and educational level, a cross-sectional study demonstrated that hysterectomy was associated with urge incontinence but not stress incontinence.<sup>14</sup> There appears to be no association between the method of hysterectomy (abdominal or vaginal) and urge or stress incontinence.<sup>15</sup> The presence of a cystocele and/or the absence of the vesicourethral fold with uterine prolapse is independently associated with urinary incontinence.<sup>16</sup> Prolapse surgery is independently associated with urinary incontinence.<sup>17</sup>

Recurrent urinary tract infection appears independently associated with urge and mixed incontinence but not stress incontinence.<sup>18</sup> Certain medications have been independently associated with urinary incontinence, including diuretics,<sup>19</sup> estrogen,<sup>20</sup> tranquilizers, antidepressants, laxatives, and antibiotics.<sup>20</sup> The association between alcohol and urinary incontinence is not clear.<sup>20</sup> Smoking may be independently associated with urinary incontinence.<sup>21</sup> High caffeine intake (400 mg/day) was associated with urge incontinence.<sup>22</sup>

Specific diseases found to be independently associated with urinary incontinence include diabetes, stroke, elevated blood pressure, cognitive impairment, parkinsonism, arthritis, and back problems.<sup>21,23,24</sup>

Advancing age is associated with urge and mixed incontinence but not with stress incontinence.<sup>25</sup> African American women had lower rates of moderate and severe urinary incontinence but only after adjusting for educational attainment, financial assets, functional status, age, stroke, body mass index, smoking, alcohol use, and parity.<sup>26</sup> Increasing body mass index is associated with increasing rates of urinary incontinence.<sup>26</sup>

Higher level of educational achievement is associated with mild incontinence and stress incontinence.<sup>26</sup>

## **NONPHARMACOLOGIC CONSERVATIVE MANAGEMENT**

### **Pelvic Floor Muscle Training**

A Cochrane review that included studies of stress, urge, and mixed incontinence found that pelvic floor muscle exercises were more effective than no treatment or placebo.<sup>27</sup> When pelvic floor training was combined with a comprehensive clinic-based program it was found to be more effective than using a self-help booklet.<sup>28</sup> The combination of pelvic floor muscle training and bladder training was equally effective when administered as individual therapy or group therapy.<sup>29</sup> Studies that compared pelvic floor muscle training to surgery (open retropubic colposuspension, vaginal repair, or a combination) for stress urinary incontinence found no significant difference in the rates of self-reported cure or improvement, but pelvic floor training resulted in fewer self-reported cures. The surgery group had a significantly greater reduction in the number of leakage episodes.<sup>30</sup>

### **Vaginal Cones**

Therapy with vaginal cones appears to be inferior to pelvic floor muscle training.<sup>31</sup> Patients who have good levator tone with a substantial increase in tone with voluntary contractions may have limited benefit from vaginal cones. Small series have reported an improvement with cone therapy such that patients delayed or canceled their bladder suspension surgery. In general, cone therapy is indicated for women who are able to generate some pelvic muscle contraction.

### **Vaginal Pessaries**

In patients with mild to moderate cystoceles vaginal pessaries may increase urethral closure and urethral functional length. The mechanism of continence appears to be increased urethral pressure, possibly from obstruction of the urethra, or elevation of the proximal urethra into the abdominal pressure zone. A new pessary developed by Biswas (incontinence dish), with two extension arms to support the urethra has reported promising results, but more long-term studies are needed. Patients who have difficulty in using or retaining pessaries are more satisfied with definitive surgery.

### **Bladder Training**

Bladder training techniques involve strategies to increase the time interval voids using progressive voiding schedules. Bladder training was not significantly better than pelvic floor muscle training, but the combination of bladder training with pelvic floor muscle training was more effective than either alone.<sup>32</sup>

### **Electrical Stimulation**

The effectiveness of electrical stimulation may depend on the type of urinary incontinence. The addition of pelvic floor electrical stimulation to an extensive pelvic floor muscle training program did not significantly reduce the frequency of incontinence episodes.<sup>32</sup> Patients with moderate or severe incontinence with marked hypermobility of the urethra and vesicourethral descent do not respond to electrical stimulation. In general,

electrical stimulation is associated with 30% to 60% improvement in stress incontinence and is most effective in patients with mild incontinence with poor pelvic muscle tone. Electrical stimulation is indicated for women who are unable to generate a pelvic muscle contraction.

### **Summary**

Pelvic floor exercises may be most helpful by improving the feeling that the patient can derive some benefit (positive incentive) through pelvic exercise, which improves her self-perception and sense of well-being and may minimize the patient's feeling of helplessness. These exercises rarely provide a cure for stress urinary incontinence but can achieve a level of improvement some patients find acceptable.

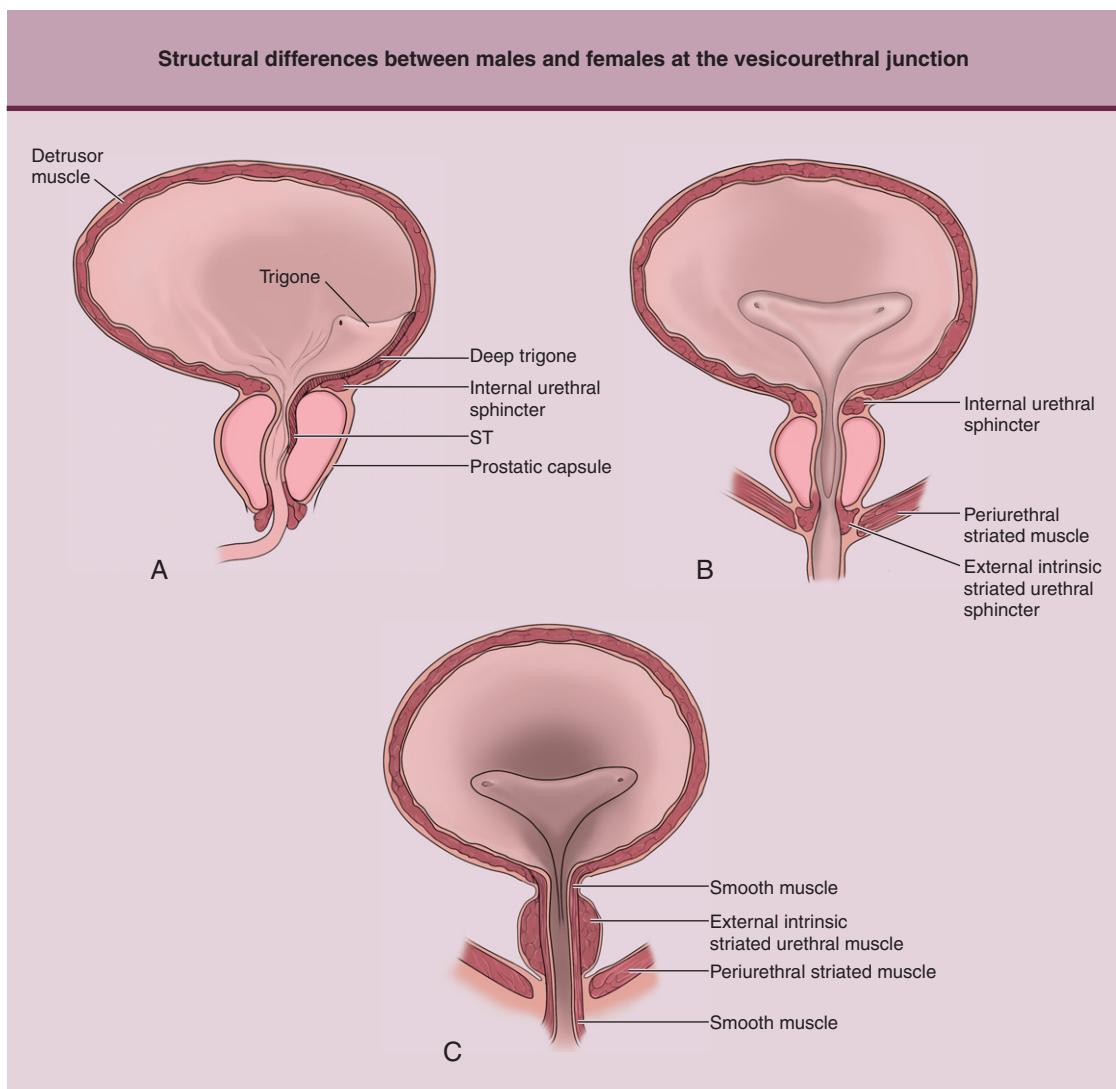

## **PHARMACOLOGIC CONSERVATIVE THERAPY**

A Cochrane review of anticholinergics for urge incontinence found anticholinergics were better than placebo in subjective cure or improvement rates.<sup>33</sup> In direct comparison trials, oxybutynin and tolterodine did not differ in outcomes; however, the risk of dry mouth was higher with oxybutynin than with tolterodine.<sup>34</sup> When extended-release oxybutynin was compared with tolterodine, there were higher mean numbers of weekly incontinence episodes with tolterodine.<sup>30</sup> Trospium chloride is the newest medication for urge incontinence. The effect is at least equal to the other anticholinergics, but the medication may have fewer side effects.

Magnesium hydroxide may reduce spontaneous detrusor contractions and may be effective treatment for urge incontinence. A small placebo-controlled study indicated some subjective improvement of urinary incontinence but transient diarrhea was a noted adverse effect.<sup>35</sup> Because of their effects on the contractile response of the urethra and bladder neck, alpha- and beta-adrenoceptor agonists have been used in the treatment of stress urinary incontinence. Likewise, ephedrine, norephedrine, and phenylpropanolamine have also been tried. However, because of the problems with hypertension from the increased vascular tone produced by these medications, their role has been diminished. Phenylpropanolamine was also found to be a risk factor in the development of hemorrhagic stroke, which has reduced the enthusiasm for alpha-adrenergic agonists.<sup>30</sup> Imipramine, because of its relaxing effect on the detrusor, has been used with some success. Serotonin and norepinephrine agonists have putative continence-promoting properties through parasympathetic suppression and enhancement of sympathetic and somatic activity. Dicyclomine hydrochloride is a muscotropic/antimuscarinic agent more commonly used for the management of irritable bowel syndrome. It is a less potent agent than oxybutynin and has fewer adverse side effects. When oxybutynin is intolerable to some patients, this medication deserves consideration.

### **Summary**

New drug therapy that augments urethral resistance by inhibiting the reuptake of neurotransmitters, which are thought to make a key contribution to micturition may soon be available to treat stress urinary incontinence. The basis for this therapy is studies that suggest inhibition of serotonin and norepinephrine

**Figure 26-2 Structural differences between male and female bladders at the vesicourethral junction.** A and B, Male bladder. C, Female bladder.

at the level of the nucleus of the pudendal nerve, which can increase signal transmission through the pudendal nerve to the urethral sphincter. This led to the development of duloxetine, a dual reuptake inhibitor, which could become the first approved medical therapy for stress urinary incontinence.

It is generally believed that the primary components that prevent stress incontinence in the female are the internal sphincter mechanism, the external urethral sphincter, and the proper anatomic support of the urethra, including the vesicourethral junction. Some researchers believe that urinary continence depends on an intact strong internal sphincter and a reactive sympathetic activity. There is a distinct structural difference between males and females at the vesicourethral junction (bladder neck). At the female bladder neck there is no comparable anatomic sphincter of smooth muscle (Fig. 26-2). Unlike the circular-oriented preprostatic smooth muscle of the

male, most of the muscle bundles in the female bladder neck extend obliquely or longitudinally into the urethral wall (see Fig. 26-1). It is doubtful that active contraction of this area plays a significant role in the maintenance of urinary incontinence in females. Due to the fact that the bladder neck and proximal urethra contain large quantities of elastin within their walls, passive elastic resistance offered by the urethral wall may be the most important single factor responsible for closure of the bladder neck and proximal urethra for maintaining continence in the female.

## ROLE OF URODYNAMICS

Despite the widespread prevalence of urinary incontinence, the diagnosis and management of urinary incontinence and voiding dysfunction is often challenging. The current role of urodynamic

testing in the evaluation of stress urinary incontinence is controversial. Which women with stress urinary incontinence require urodynamic evaluation? Several studies have demonstrated that subjective symptoms alone are not predictive of stress urinary incontinence. Jensen and colleagues, in a meta-analysis of 19 articles, found the symptom of stress urinary incontinence to be 91% sensitive but only 51% specific in the diagnosis of genuine stress incontinence.<sup>36</sup> This usually means referral for multichannel urodynamic studies, which are expensive, not universally available, and not consistently reproducible. Rapid changes in diagnostic testing technology and further understanding of the pathophysiology of incontinence have resulted in little data and interpretation with varying degrees of consensus on its clinical applicability. This has made it difficult for the practicing clinician to decide which tests are necessary to adequately evaluate lower urinary dysfunction. Most clinicians are overwhelmed by its complexity. The criteria set developed by the American College of Obstetricians and Gynecologists does not mention cystometrography or recommend any specific urodynamic studies in the evaluation of women with stress urinary incontinence due to urethral hypermobility.<sup>37</sup>

The goals of urodynamic testing should include objective observation of urinary leakage, reproduction of the patient's symptoms, correlation of the patient's symptomatology with urodynamic parameters, determination and differentiation of the etiologic factors causing urinary incontinence, and, finally, prediction and evaluation of the response to medical and surgical therapies. Little data is available to support any of these goals. Credibility is lost when the standard urodynamic results do not agree with patients who think they are cured. Nevertheless, urodynamic testing has been considered a standard in the evaluation of the incontinent female. However, studies have also shown that women who were investigated with urodynamics were more likely to receive active treatment with drugs or surgery; thus, the role of urodynamics must be further evaluated before standard use is recommended.

Clinical practice guidelines published by the Agency for Health Care Policy and Research (AHCPR) recommend considering surgery without referral for urodynamic testing for patients with symptoms of pure stress urinary loss as well as a voiding history and results of physical examination suggestive of pure hypermobility stress urinary incontinence that include the following<sup>38</sup>:

- Urine loss only with physical exertion (history and stress test)
- Normal voiding habits ( $\leq 8$  episodes/day and  $\leq 2$  episodes/night)
- No neurologic history and no neurologic findings
- No history of anti-incontinence surgery or radical pelvic surgery
- Hypermobility of the urethra and bladder neck, pliable and compliant vaginal wall, and adequate vaginal capacity documented by physical examination
- Normal postvoid residual values
- Nonpregnant patient

Weidner and colleagues studied the predictive value of the symptom of stress urinary incontinence and the ability of other factors proposed by the AHCPR guidelines for the discrimi-

nation of patients unlikely to require urodynamic testing before surgical management.<sup>39</sup> They concluded that the predictive value of stress incontinence symptoms alone was not high enough to serve as the basis for surgical management. AHCPR guidelines improved the predictive value but are applicable to only a small subset of patients referred with urinary incontinence. They proposed that multichannel urodynamic testing is an imperfect diagnostic method, yet they believed that reliance on clinical assessments to determine which patients should undergo surgery was even more inaccurate and would result in some patients undergoing inappropriate surgical treatment. They concluded that their study supported routine urodynamic evaluation for most women before instigating surgical treatment with incontinence symptoms.

Urodyamists believe the basis of urodynamic testing results from the poor reliability of the patient's symptoms in accurately determining the underlying physiological or pathological state of the bladder. However, I have performed urodynamic testing on patients who give a history of stress urinary incontinence with every episode of straining, sneezing, coughing, and lifting who cannot be made to demonstrate leakage of urine in the urodynamic laboratory. This is a troubling problem. The International Continence Society has recommended that a complete urodynamic evaluation is not necessary in all patients, although some specialists believe urodynamic evaluation of the filling and voiding phases should be performed.<sup>40</sup> The most important aspect of a urodynamic study is that it be accurate and clinically relevant. The interpretation of the urodynamic study should never be independent of the overall clinical picture. If the results do not make sense, they are probably wrong. The generalist and the specialist should have an adequate understanding of the true value and limitations of urodynamic testing. It is beyond our scope to discuss all phases of urodynamic testing, which can be found in most textbooks on urodynamics.

Thus, the evidence to support routine urodynamic testing before any surgical treatment remains unclear. Unfortunately, this is an expensive and imperfect diagnostic test that has limited reproducibility. Physicians who perform urodynamic testing may also be reimbursed for this imperfect test more than the surgeon who performs the anti-incontinence operation. The financial incentive to recommend and perform this as a routine test before operative therapy needs further supportive evidence. Concern has been expressed that too many expensive instruments have been purchased by gynecologists and urologists who do not have the time or expertise to learn basic urodynamics or perform tests in a reproducible manner. Accurate urodynamic assessment requires a combination of appropriate equipment and technique. A retrospective study concluded that the cost and expense of running a urodynamic unit are justified when more than 200 patients are studied per year. Certainly simple office cystometry can be performed in an office setting in a cost-effective manner, providing basic information regarding voiding function and detrusor activity during bladder filling, bladder sensation, and competency of the urethral sphincter mechanism during stress. Some specialists believe that simple office cystometry should be tried first to provide the clinician with a preliminary diagnosis on which to base initial conservative therapy before further urodynamic testing is employed, if indicated.

**Summary**

Many generalists believe that urodynamic studies are a necessary part of the evaluation of lower urinary tract function, but these tests are still evolving and more controlled studies are needed to clarify controversies regarding indications, techniques, and interpretation.

**SURGICAL MANAGEMENT**

Controversy also continues as to the best surgical approach to treat stress urinary incontinence; it is unlikely that the necessary prospective, randomized studies with matched variables will ever be done to help resolve the matter. In the meantime, critical analysis of diagnostic methods, surgical techniques, and long-term results must continue.

Richardson's statement regarding how one chooses the surgical approach to the repair of stress urinary incontinence is enlightening:

To determine the best approach in managing incontinent patients one must wade through a voluminous urogynecological literature inundated with contradiction, unsubstantiated opinions, speculative assertions, and modification upon modification. Adequate comparisons of results, even with ostensibly the same procedure, are generally not available.<sup>41</sup>

More than 200 different surgical procedures for urinary incontinence are performed, using a variety of methods. Wennberg and associates developed a conceptual approach that predicates physician decision making about clinical interventions on the presence of well-defined scientific norms (i.e., professional consensus). When consensus is lacking or ambiguous, as is the case with the management of stress urinary incontinence, physician decision making is driven by subjective factors, referred to as "practice style," which incorporates physician values, attitudes, tastes, and habits.<sup>42</sup> To this list must be added the influence of surgical equipment companies, who actively promote a particular method before long-term studies have been done. This is why the clinical panel of the American Urological Association (AUA) recommended that at least 4 years of data on the outcomes of new technologies must be reported before those technologies are accepted, marketed, and sold to the medical community. This recommendation has gone unheeded by most companies. Eddy has described two main steps in medical decision making: The outcomes of alternative practices must be estimated first, then the desirability of the outcomes of the individual options must be compared.<sup>43</sup> Due to the complexity of urinary incontinence as well as its individual patient expression, the wide variation in surgical procedures offered to correct this problem is perhaps understandable. Success resides in the best understanding of a particular patient's expression, because a complete evaluation prior to surgery may still not identify the most efficacious approach. Even though our present understanding of the continence mechanism and the therapeutic applications available to correct deficiencies in this mechanism is growing, therapy is not always successful.

The key to success is to define the normal anatomy of continence, understand how it becomes defective, then institute a specific surgery to correct the defect directly. Management of stress urinary incontinence has been complicated by a basic

defect in knowledge, namely the anatomic basis of normal continence control. Therefore, empirical attempts to change upper urethral and bladder neck anatomy are commonly in use. Standard empirical procedures can only affect the stability, position, and mobility of the area in relation to the vesicourethral junction. Until the anatomy is understood and used as the basis for corrective surgery, the problem of deciding just what intervention to advise will continue. At present there is no definitive, ideal operation or definitive diagnostic test to separate cases on the basis of what operation to perform. Progress has been made with some very good suggestions, but for some reason surgeons do not always apply what is known.

**Summary**

Among the proposed causes of stress urinary incontinence, the foremost theory is the loss of normal anatomy. Hypermobility of the urethra results in descent of this crucial area during increases in intra-abdominal pressure. The descent results in impaired pressure transmission to the urethra and ineffective compression of the suburethral hammock when discrete breaks in the fascia endopelvina and its attachment to the arcus tendineus fasciae pelvis are present.

**SURGICAL EVIDENCE**

The AUA asked a select panel of seven urologists and one urogynecologist to compare the many surgical procedures for treating stress urinary incontinence on the basis of treatment outcomes.<sup>44</sup> The panel was charged to analyze published outcomes data on surgical procedures to treat female stress urinary incontinence and produce practice recommendations based primarily on outcomes evidence from the literature. Of the 5322 articles from the urologic, gynecologic, and general medical literature relevant to the treatment of stress urinary incontinence, 282 articles had acceptable outcome data. A meta-analysis of the data produced comparative outcome estimates for alternative surgical procedures. The panel discovered that all surgical techniques have similar outcomes for up to 48 months.

This finding is surprising when one considers the various theories and anatomic defects thought to cause incontinence. Have we reached a consensus as to what the continence mechanism is and how it should be repaired? Do we understand how each surgical anti-incontinence operation repairs the continence mechanism?

The AUA panel discovered differences in dry and cure rates that were significant after 48 months. Slings and retropubic suspensions maintained a 82% to 84% success rate after 48 months, compared with needle suspensions, which decreased to 65% to 70% success rates.

Evaluation of anterior repairs was difficult to interpret because a sharp increase in cure/dry status at 24 to 47 months (from 68% to 85%) was followed by a marked decline after 48 months to 61%. It was believed that these results may have occurred because not all studies report outcomes at all time points studied.

Major concerns were encountered as the panel attempted to report on probability estimates for the four major procedure categories of retropubic suspensions, transvaginal suspensions, anterior repairs, and pubovaginal slings. Estimates were derived

from combination cure/dry rates for the Burch procedure, Marshall-Marchetti-Krantz (MMK) procedure, and other individual retropubic suspension procedures and transvaginal suspensions, which derived combined outcomes data for Stamey, Pererya, modified Pereyra, Gittes, and other types of individual transvaginal suspension procedures. Of interest was that no significant differences were found between individual procedures among the four groups.

### **Summary**

Even though the purpose of the panel was to distinguish between alternative surgical procedures and to provide estimates of the outcomes that could be expected with each, the four groups studied surgically manage the continence mechanism in different ways. Long-term outcomes data (>48 months) concluded that the surgical treatment of female stress urinary incontinence is effective despite what means was used and how the anatomic derangement of the continence mechanism was surgically corrected. Pubovaginal slings appear to closely and more directly correlate with the current theories of continence mechanism. Slings have currently evolved into the gold standard for the treatment of stress urinary incontinence caused by intrinsic sphincter deficiency and are more frequently utilized as the first-line surgical therapy for stress urinary incontinence associated with female urethral hypermobility. Slings seem to use the deranged anatomy of the continence mechanism as a basis for treatment in a more direct fashion than do other anti-incontinence procedures.

Retropubic suspensions were considered for many years the gold standard for the treatment of stress urinary incontinence. These procedures have been quite successful, yet the mechanism for their success is poorly understood. One theory is that the procedure stabilizes the proximal urethra. Thus, this assumes that urethral mobility is the cause of stress urinary incontinence. This theory differs from the original concept of retropubic procedures that were thought to be successful in treating stress urinary incontinence by placing the urethra in a high retropubic position. Furthermore, theories such as pressure transmission ratios were developed to explain why continence occurred after suspension procedures. During the 1990s procedures that neither suspend nor support the proximal urethra or bladder neck but rather place a tension-free suburethral sling under the mid-portion of the urethra were discovered to be as efficient as and less invasive than the more traditional procedures.

### **CHOICE OF SURGICAL PROCEDURE**

Many gynecologists seem to prefer the simplest rather than the most effective operation. Throughout the first half of the 20th century anterior colporrhaphy and the Kelly plication became the standard therapy for the treatment of female stress urinary incontinence. The purpose of this operation, described in 1914 by Kelly, was to repair the injured sphincter muscle at the vesicourethral junction. Marked variation in success of the Kelly-Kennedy plication in the literature ranges from 34% to 91%. Failure of this procedure may be the consequence of the imprecise understanding in the early 1900s of the pathophysiology of incontinence and urethral anatomy. Because it is now understood that there is no internal urethral sphincter, as

postulated by Kelly, or torn urethral sphincter, as conceived by Kennedy (see Fig. 26-2), this operation may function by being obstructive. It was also believed that this procedure could elevate the proximal urethra into the abdominal pressure zone, another theory for the cure of stress urinary incontinence, which was dismissed when the urethra was shown not to be an intra-abdominal structure. It is still confusing why this procedure works at all. Yet, Beck and McCormick<sup>45</sup> and Nichols<sup>46</sup> reported on acceptable success rates with their variations of this procedure. Beck attached the periurethral tissue to the pubic bone periosteum in a fashion similar to the abdominally performed MMK procedure. Nichols overlapped these tissues in a vest-over-trouser fashion.

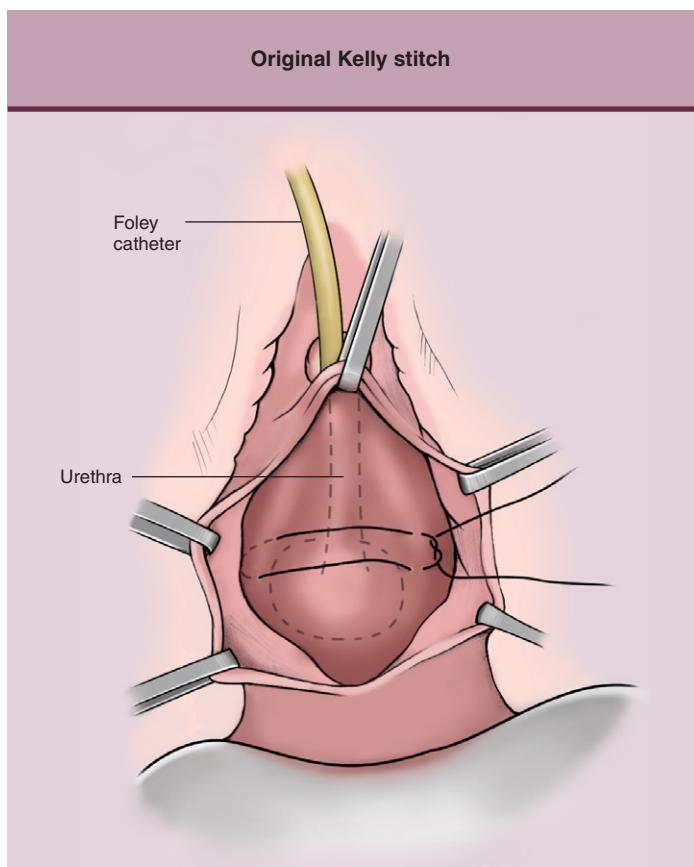

Even though these investigators reported high levels of success, a considerable body of evidence does not support this approach for the treatment of stress urinary incontinence. Unfortunately there were many surgical failures, which were then subsequently treated by the sling operation. This gave rise to the unwise dictum to operate first from below and if this fails then from above. The use of anterior colporrhaphy and the Kelly-Kennedy plication as the sole operation for stress urinary incontinence appear no longer acceptable.

In 1949 Marshall, Marchetti, and Krantz collaborated on a new operation and reported on cure rates of 90% overall in patients complaining of stress urinary incontinence and 76% of patients with previously failed anti-incontinence surgery.<sup>47</sup> Various modifications of the MMK procedure were developed because of the occasional complication of osteitis pubis, presumably from placing sutures into the pubic bone. Further modification lead to the development of the attachment of the periurethral tissue to Cooper's ligament, the Burch procedure (Fig. 26-3). The physiological principle developed by Enhorning in 1961 was that elevation of the vesicourethral junction allows transference of abdominal pressures to the urethra.<sup>48</sup> Thus, many surgeons have oversuspended the urethra based on this theory. Current investigators are in conflict as to whether retropubic suspensions create urethral obstruction or simply return voiding pressures and flow conditions to normal levels. Therefore, this operation does not appear to restore the continence mechanism to normal. Until we know precisely what we are treating, we will not be able to choose the most effective, least noxious treatments for a particular patient, even though effective, non-destructive treatments do exist for particular types of stress urinary incontinence.

We really do not understand how the Burch procedure works, even though the success of the Burch procedure in the hands of many surgeons is well documented. It is a relatively simple procedure to perform, which may explain its high acceptance rate; common disadvantages include postoperative voiding dysfunction (22%) from high elevation of the vesicourethral junction and perivaginal tissues. Postoperative enterocele and vaginal prolapse (20%) are noted in the following patients:

- Women at risk for genital prolapse, including a strong history of prolapse
- Women with a history of heavy lifting or chronic constipation
- Women with coexisting genital prolapse

Burch initially fixed the paravaginal tissue to the arcus tendineus fasciae pelvis but was fearful that not enough elevation

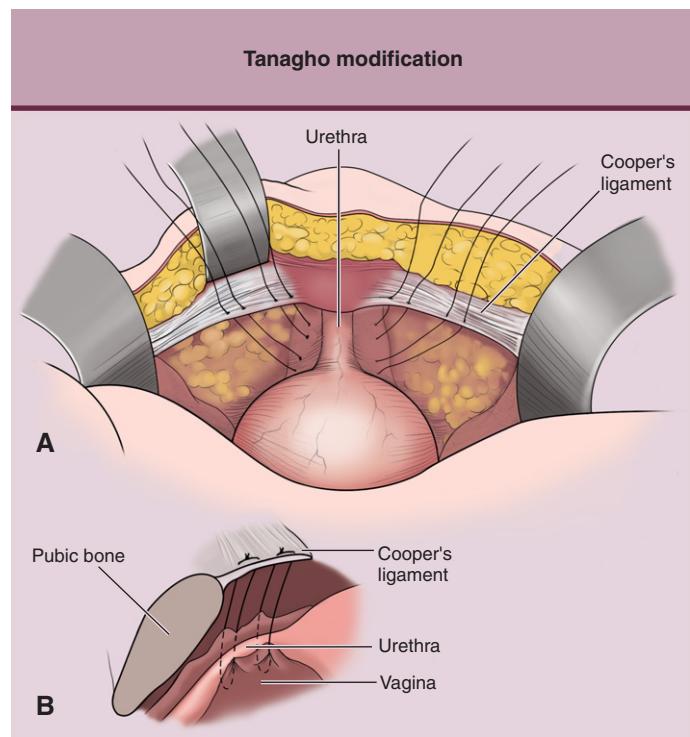

**Figure 26-3** The original Kelly stitch, introduced to plicate a presumed internal urethral sphincter.

would be provided. Stanton modified the Burch procedure by suspending not only the vesicourethral junction, but also the entire length of the vagina to Cooper's ligament to reduce coexisting cystocele. This did cause him to report on a higher risk of enterocele because the vagina is placed in an extreme anterior position. Tanagho's modification recommended no dissection within 2 cm of the urethra as well as removing the fatty tissues from this area to stimulate fibrosis. He also avoided unnecessary tension on the sutures to Cooper's ligament by employing suture bridges to prevent hyperelevation of the urethra (Fig. 26-4).

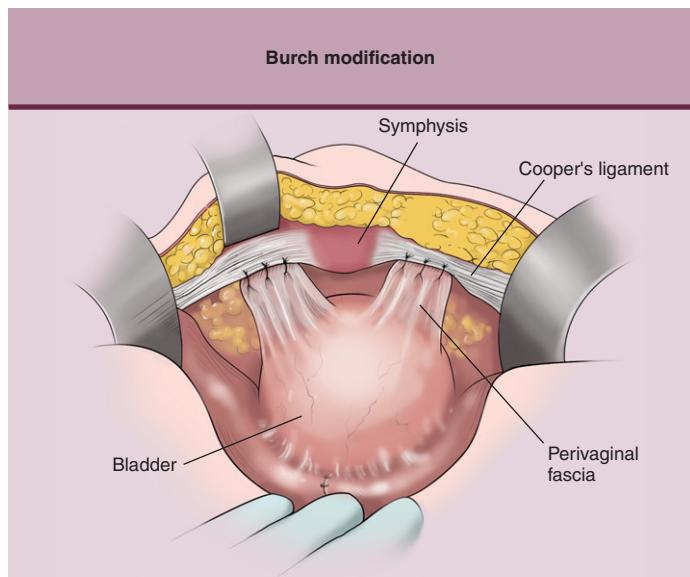

The Burch procedure was adopted in the 20th century as the gold standard for the treatment of stress urinary incontinence by many urogynecologists, but because the Burch procedure is performed using many different techniques, it is difficult to recommend any particular type. The key to successful surgery for stress urinary incontinence is to define the normal anatomy of the continence mechanism, understand how it become defective, then institute surgery to correct the defect directly. There is no doubt that the Burch procedure is a successful operation, but is it an operation that correctly repairs the defective continence mechanism that results in incontinence? The basic goal of this procedure has always been to place the urethra in a high retropubic position, yet it has been shown that the amount of bladder neck elevation and position in relation to the pubic bone after colposuspension does not affect the cure rate. Because that

is not the normal position of the urethra, the Burch procedure must be considered an operation that distorts rather than corrects the normal anatomy of the urethra. Regrettably, surgeons who employ the Burch procedure seem to focus more on the technical merits of this operation than on the underlying pathophysiology and how best to restore the normal urethra anatomy. Yet, who can deny the long-term success rates of this operation? This questions whether it is necessary to restore normal anatomy or correct the presumed continence mechanism in the surgical management of stress urinary incontinence.

As our understanding of the pathophysiology of incontinence progressed over time, the familiar adage to the surgeon to place the urethra in a high retropubic position was questioned (Fig. 26-5). DeLancey's hammock hypothesis suggested that continence is maintained because the urethra is compressed against a hammock support layer rather than lying in a intra-abdominal position. Cadaver dissections have confirmed that the urethra is separated from the extra-abdominal area by a hammock-like supportive layer composed of fascia endopelvina and by the anterior vaginal wall, and by a distal attachment to the pubic bone. Weakening of the fascia endopelvina, anterior vaginal wall, or attachment to the pubic bone alone or in combination was believed to ultimately lead to incontinence.

**Figure 26-4** Tanagho modification. *A*, Diaphragmatic illustration of retropubic space after mobilization of anterior wall of vagina and placement of sutures, two on either side and far lateral from midline. Distal sutures are opposite midurethra, whereas proximal sutures are at end of vesicourethral junction. Sutures are attached to Cooper's ligament. *B*, Side view of suture placement with one side tied. Anterior wall of vagina is acting as a broad sling, supporting and lifting the vesicourethral segment. Yet urethra is free in spacious retropubic space. (From Tanagho EA: Colpocystourethropexy: the way we do it. J Urol 1976;116:752. Copyright 1976, Williams & Wilkins.)

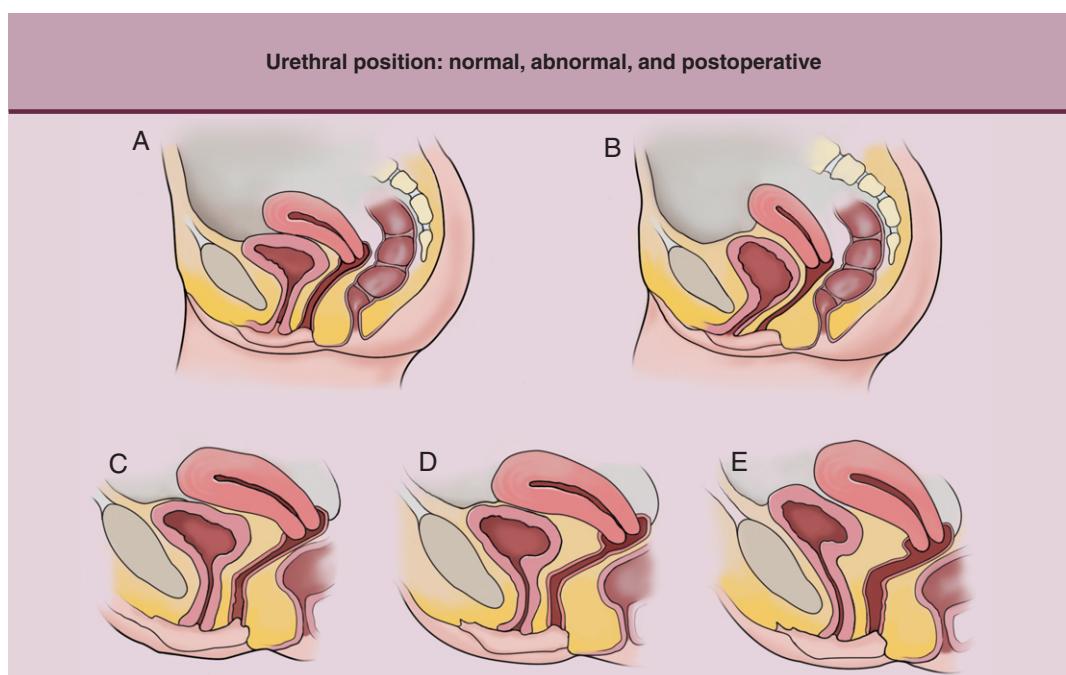

**Figure 26-5 Burch modification.** Lateral edges of vagina have been approximated to Cooper's ligament by using three interrupted sutures. (From Burch JC: Urethrovaginal fixation to Cooper's ligament for correction of stress incontinence, cystocele, and prolapse. Am J Obstet and Gynecol 1961;81:283. Copyright 1961, Mosby-Year Book.)

These findings suggest that successful correction of urinary incontinence would be best served by restoring the normal functional anatomic position of the urethra rather than by elevating the urethra to an unnatural position. Because stress urinary incontinence results when the quality and integrity of

the continence control anatomy cannot resist intra-abdominal pressures, it is logical to assume that treatment must be directed to reducing intra-abdominal pressures, restoring the continence anatomy to a functional state, or a combination of both. Hypothetically, restoring the anatomy to its normal position should produce a better clinical outcome (Fig. 26-6).

Laparoscopic colposuspension was developed to have presumed advantages over the Burch procedure: no major incisions, shorter hospital stay, and quicker return to normal activities. This is an admirable goal but due to the numerous modifications developed by individual authors and the different measures of clinical outcomes it is difficult to understand what modification results in the best outcomes. Sutures have been replaced by staples and synthetic mesh to accomplish bladder neck elevation. The evaluation of these techniques may also be difficult as a result of the difficulty and length of time required to perform this operation, the so-called "for-ever-scopy." Definitive comparative studies have not been produced. The superiority of this technique has not been demonstrated over open procedures, and long-term success of this operation is unknown. Combining these procedures demonstrates a success rate of 80% to 90% over less than 2 years. McDougall reported a success rate of 72% at 2 years, but when he studied the same patients at a mean of 45 months he found that the success rate was reduced to 30%.<sup>49</sup> It can be theorized that the laparoscopic technique may not duplicate the open procedure and may not offer significant fibrosis at the repair site. One of the most difficult measures in the success or failure of incontinence operations may be the judgement and skill of the operating surgeon.

In a large study by Burton in Australia women were randomized to laparoscopic Burch or standard Burch urethropexy. The results for the laparoscopic Burch procedure were initially

**Figure 26-6 Urethral position.** A, Normal urethral position in continent patient. B, Abnormal urethral position in incontinent patient. C-E, Abnormally high retropubic position of urethra with Marshall-Marchetti-Krantz (C), Burch (D), and needle suspension procedures (E; patient in standing position).

## Urogynecology

good at 6 weeks' evaluation, but at 6 and 12 months the laparoscopic Burch procedure had significantly poorer results than the open procedure. It is clear that more long-term data is necessary. Current available evidence suggests that laparoscopic colposuspension leads to a quicker recovery, but takes longer to perform and may be associated with more complications.

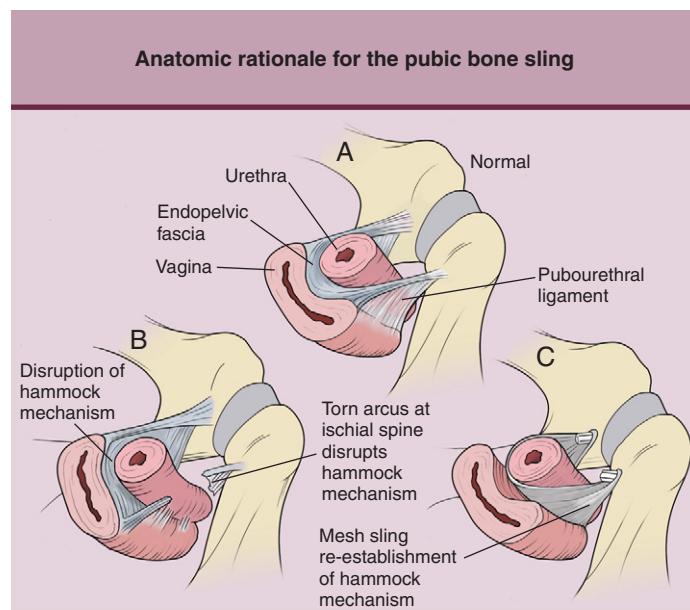

Having observed that the elevation of the vesicourethral junction was an effective means of treating urinary incontinence, Pereyra developed a vaginal approach. The aim of the procedure was to combine a high cure rate with low operative morbidity. In his original description he placed wire sutures into the periurethral tissues on each side of the bladder neck to the rectus fascia. These procedures were rapidly adopted because they were quicker, did not require splitting of the anterior abdominal fascia, and reduced perioperative and postoperative morbidity. The intent of needle procedures was to elevate and support the bladder neck, which achieves continence, it was presumed, like the retropubic suspensions by maintaining the bladder neck inside the sphere of abdominal pressure transmission during increased intra-abdominal pressure. There have been many modifications since the first needle suspension procedure over 40 years ago, including the Stamey, Raz, Gittes, and Muzsan modifications. Despite these modifications the long-term outcome data does not support the efficacy of needle suspension procedures, with only 67% cure/dry rate measured after 48 months. Kondo and colleagues, in a long-term study, found the Stamey procedure had a higher continence rate than Gittes (71% at 14 years vs. 31% at 6 years).<sup>50</sup> Clemens and colleagues found a low continence rate for the Stamey procedure (44%; mean term follow-up, 15.2 years).<sup>51</sup> Therefore, although needle suspension procedures may have historical significance, they currently have a limited role in the management of stress urinary incontinence because of the poor long-term results.

The newer minimally invasive suburethral slings were not studied in the AUA panel report, but their current success rates have been so remarkable that each procedure deserves mention. The first report on suburethral slings was in 1995, when Ulmstem and Petros described the transvaginal slingplasty.<sup>52</sup> This procedure is now known as the TTV (tension-free vaginal tape) procedure (Ethicon, Gynecare, Somerville, N.J.). The introduction of tension-free tape challenged the understanding of the continence mechanism and taught the importance of the midurethra in maintaining continence. Since 1995 the company (Data on file, Gynecare, Johnson & Johnson) believe that 750,000 TTV procedures have been performed. The procedure employs a knitted polypropylene mesh and is performed with conscious sedation with local anesthesia, with regional anesthesia, or with general anesthesia. Long-term follow-up studies ( $\geq 4$  years) are available and indicate cure rates similar to those for retropubic colposuspension procedures. Although few complications were noted in early reports, later reports have shown that this operation is not without risks that were infrequent with traditional procedures. Operative cystotomy has been reported in some series to occur in about 23% of cases. Twenty-eight cases of bowel injury have been reported, some leading to death; 55 cases of vascular injuries, some also leading to death; 20 urethral erosions, 20 hematomas, 60 mesh erosions, and 4 nerve injuries. Because of the number of successful TTV procedures without complications, the occasional adverse

results of this operation must be considered minimal, yet operative mortality is an unusual complication of incontinence procedures.

Another midurethral tension-free sling, the pubic bone stabilization sling involved the use of transvaginally placed bone screws (InFast, American Medical Systems, Minnetonka, Minn.) into the back of the pubic bone to support a tension-free piece of Mersilene over the midurethra. In this tension-free sling, the mesh is attached to the periurethral tissues by four sutures, which does not allow the mesh under the urethra to be placed on tension when the mesh is tied to the bone screws situated at the point where the arcus tendineus fasciae pelvis attaches to the pubic bone (Fig. 26-7). Personal communications with the company reveal that more than 150,000 of these procedures have been performed since 1997. A 4-year report on outcomes was published before the procedure was actively marketed; long-term durable results (8 years) were subsequently published in a cohort study of 105 patients with cure/dry/improved rates greater than 98%.<sup>53</sup> Of interest is that the pubic bone stabilization sling has been successfully used in men who have become incontinent following radical prostatectomy and so is the only incontinence procedure currently used in both men and women.

Variations of this technique using bone anchors, not bone screws, with transvaginal suspension suture techniques were not reported to be as successful. Transabdominal bone anchors with sutures to suspend the urethra also reported less favorable outcomes. When transabdominal bone anchors were used to suspend a suburethral sling made of Protegen, the incidence of osteomyelitis was reported to be 480 of 60,000 cases. Although several anecdotal reports mention osteomyelitis with transvaginal bone screws, most of these have occurred with the

**Figure 26-7 Anatomic rationale for the sling.** A, Normal anatomy. B, Abnormal anatomy. Note the hypermobility of the urethra, caused by torn arcus from pelvis with incompetent pubourethral ligaments, paravaginal defect, and attenuated fascia endopelvina. C, Normal anatomy restored with pubic bone suburethral stabilization sling.

## Surgical Treatment of Urinary Incontinence

transabdominal placement of bone anchors.<sup>54</sup> There is only one documented case in the literature of osteomyelitis with transvaginally placed bone screws. However, the perception of such a complication became a major concern to anyone wanting to place transvaginal bone screws despite the reports of osteomyelitis occurring with other incontinence procedures, such as the retropubic procedures, the Burch procedure,<sup>55</sup> the MMK procedure<sup>56</sup> and needle suspensions.<sup>57</sup> Because osteomyelitis has been reported with other incontinence procedures,<sup>58</sup> the etiology of this condition is still unclear. Because there are no reported cases of operative cystotomy, bowel injuries, significant hemorrhage, reported deaths, or mesh erosions into the urethra with this procedure, the recommendation by some urogynecologists to avoid it because of the fear of osteomyelitis appears to be unjustified. If Eddy's description of the two main steps in medical decision making are followed, both steps would favor the pubic bone stabilization sling over the TTV procedure. The influence of surgical instrument companies must be factored into the reasons the TTV has been the most commonly used procedure performed worldwide. The rapid adoption of these minimally invasive slings may be because they have been found to be effective for both urethral hypermobility and intrinsic sphincter dysfunction; there are some reports that indicate an association with bacterial vaginosis and osteomyelitis.

Because of the reported risks with the TTV, other midurethral slings have been developed. The SPARC (American Medical Systems, Minnetonka, Minn.) passes the sling from an abdominal to vaginal approach. Initial studies appear to be promising, but no long-term studies are available. The latest suburethral sling is the transobturator sling, or TOT (American Medical Systems, Minnetonka, Minn.). This method aims to avoid the incidence of operative cystotomies and the need to use the cystoscope; however, there several cases of operative cystotomies have already been reported with this method. A small prospective randomized study comparing TTV to TOT showed that TOT was equally as efficient as TTV for the surgical management of stress urinary incontinence, with no reduction of bladder outlet obstruction at 1-year follow-up. The etiology of outlet obstruction with these procedures remains unclear. This method is being actively marketed by several companies who have developed other methods for transobturator placement of suburethral mesh; there are no studies longer than 2 years reporting on long-term outcomes.

The decision as to what type of suburethral sling procedure surgeons will use may be made on factors other than an evaluation of the outcomes of each technique. Unfortunately, this is not what patients expect or fellow colleagues expect when a patient is referred for management of stress urinary incontinence.

Pubovaginal suburethral slings (Goebel-Stockel-Frannenheim) have been in clinical use for almost a century, but because of their high complication rate, including urethral obstruction, urethral compression, detrusor instability, high postoperative residuals, and urethral and vaginal erosions, their usage is generally reserved for patients with failed surgery or a dysfunctional low-pressure urethra. The basic problem of this type of pubovaginal sling, which is not a concern with the tension-free slings, is adjusting the proper tension on the sling, which is difficult to assess and teach because the sling is attached to a high fixation point, the

rectus fascia. In a select group of patients with low urethra pressures, the pubovaginal sling may be indicated as a primary procedure.

The artificial urinary sphincter (American Medical Systems, Minnetonka, Minn.) was developed for patients with pure sphincter incompetency and normal detrusor function. It consists of four components: a pump mechanism, a cuff that encircles the bladder neck and /or urethra, a pressure-regulating balloon, and tubing connectors. Cuff placement can be abdominal or vaginal. Results of both the abdominal and transvaginal approach have been excellent, with greater than 90% attaining continence. The best results are obtained with women with total incontinence and no prolapse of the bladder base. However, only a small number (approximately 29,000) artificial urethral sphincters have been implanted worldwide, ostensibly due to the surgeon's concern regarding the technical difficulties during the crucial part of the operation, developing a space between the bladder neck and the vagina.

Glutaraldehyde cross-linked bovine collagen (GAX) is a bulking agent used effectively in patients with a fixed low-pressure urethra (Type III incontinence). GAX is injected periurethrally at the bladder neck under endoscopic control until closure of the urethra is seen through a zero-degree urethroscope. Patients must undergo a subcutaneous injection as a test for allergy before attempting periurethral injections. Small clinical studies have obtained 81% cure rates using up to two treatments. Collagen may prove to be a satisfactory treatment in women who are not surgical candidates, particularly the elderly. Other bulking agents have also been used, including Teflon, cellulose, and autologous fat. Long-term success is not known.

Many surgical procedures have been described for the treatment of genuine stress incontinence in women since the early 20th century, with variable degrees of morbidity and effectiveness. The early operations were believed to share the same goal (i.e., restore the proposed normal anatomic position and mobility of the bladder neck and proximal urethra while providing adequate support). In addition, it was believed the urethra should have limited mobility without compression or obstruction. Normal anatomic position and stability of the bladder neck was thought to control continence if the urethra was placed in a high retropubic intra-abdominal position. In recent years we have learned that the urethra's normal position is not elevated to a high retropubic position, yet we have not been able to define normal urethral mobility and how it influences the continence mechanism.

Midsuburethral slings have stimulated more investigation into the mechanism of incontinence. The success of these new surgical procedures has questioned the actual mechanics of continence because these procedures do not support or suspend the proximal urethra or bladder neck. It is apparent that we really do not know why women develop incontinence and more importantly why the surgeries we perform work when they do.

Is there sufficient evidence that supports a particular surgical management of stress urinary incontinence? The answer to that question is not yet and maybe never. If we could agree on the anatomy of the continence mechanism, the physiology of the continence mechanism, and how the operations we perform relate to the anatomy and physiology of the continence. We might be able to select the appropriate operation for stress

## Urogynecology

urinary incontinence by evaluating the outcomes of alternative practices and the desirability of those outcomes.

Studies that have used urodynamic criteria to assess the cure of stress urinary incontinence have also shown variable results. The evaluation of clinical evidence also presents problems in how decisions are made. For example, it is generally believed from direct comparative studies that retropubic urethropexy is more effective than needle suspensions, but not always. In at least three "same group" studies,<sup>59–61</sup> urethropexy had poorer results than did retropubic urethropexy. In Van Geelen's study, it was superior to retropubic urethropexy. How are these differences explained? In at least one of these studies the authors did not use permanent suture to perform the needle urethropexy that is normally described by almost all authors.<sup>61</sup> Early failures from retropubic surgery have long been associated with the early use of absorbable sutures. Thus, we need to be able to evaluate what role the technique, the skill, and the experience of the surgeon play in the evaluations of various procedures.

### Summary

Knowledge of various types of surgery is also mandatory so that the patient is not tailored to the surgeon's favorite or only procedure. Several other factors hamper the evaluation of any surgery for the correction of urinary incontinence: diagnostic criteria, including urodynamics (controversial); variations in patient populations, including prior incontinence surgery, age, weight, childbearing, and associated medical conditions; variations in surgical technique, operative experience, and skill; and what length of time constitutes a cure or failure.

These retropubic operations were the operation for stress urinary incontinence in the 20th century. Current evidence suggests that minimally invasive tension-free midurethral slings will be the operation for stress urinary incontinence in the 21st century.

## KEY POINTS

- Fecal incontinence is a quality-of-life issue defined as the inability to control the elimination of rectal contents at a socially acceptable time and place.
- In women, this is frequently related to obstetric trauma to the anal sphincters, irritable bowel syndrome causing diarrhea, or neurologic diseases affecting the sphincters.
- Once medical treatment with dietary changes, bulking agents, antidiarrheals, and biofeedback has failed, surgical treatments may be considered.
- Sphincter repair offers the best likelihood for improvement in continence for patients with sphincter defects, but long-term durability of the repairs is often disappointing.
- Complex procedures such as dynamic graciloplasty, artificial neosphincters, the Secca procedure, and sacral nerve stimulation treatment are options that are still under investigation.
- Fecal diversion with ileostomy or colostomy is a final option that can provide significant improvement in quality of life.

A universally accepted definition of fecal incontinence has not been established, but most surgeons consider it to be the inability to control the elimination of rectal contents until a socially acceptable time and place. This can then be categorized into varying degrees of incontinence based on the type of material that is eliminated (gas, liquid stool, or solid stool) and the frequency with which it occurs. Incontinence can also be categorized based on the timing in the defecatory cycle as passive incontinence, urge incontinence, postdefecation leakage, or a combination of the three. A number of scoring systems have been established to try to obtain objective criteria through scoring systems for fecal incontinence,<sup>1,2</sup> but none of these have gained universal acceptance by those who treat the patients afflicted with this condition.<sup>3</sup> An example of such an incontinence scoring system can be found in Table 27-1. These systems appear to be more useful in determining the effectiveness of treatment and establishing the prevalence of incontinence within populations for the purpose of research rather than in determining the best modality of treatment for each individual patient. Some of these scales have been validated and tested for reliability,<sup>2</sup> but results are mixed when comparing their effectiveness head-to-head in assessing fecal incontinence.

## EPIDEMIOLOGY

The epidemiology of fecal incontinence is extremely difficult to determine due to population variability, biases (e.g., referral

bias, selection bias), lack of consistency in definitions, and patient embarrassment to report symptoms or seek treatment (between 33% and less than 50% are believed to mention the condition to their physician).<sup>4,5</sup> Although not a life-threatening condition, fecal incontinence has significant impact on quality of life (QOL) and on the public health system as a whole. The best available data from large population-based studies and surveys shows varying degrees of fecal incontinence affecting 1% to 17% of individuals in the community<sup>6-8</sup> and nearly 50% of all nursing home residents.<sup>5,9</sup> Although fecal incontinence affects both women and men (approximately 8:1),<sup>10</sup> this chapter focuses on fecal incontinence in women, who have a greater incidence, likely due to increased risks from obstetric trauma. The incidence is also higher in older age groups because they more commonly suffer from associated risk factors of urinary incontinence, fecal impaction, immobility, diminished mental status, and dementia.<sup>4,8</sup> The economic impact of this condition has been difficult to estimate (one estimate being approximately \$10,000 per year per nursing home patient), but it is believed that it is even greater than the cost of urinary incontinence, which has been shown to be \$16.3 billion per year in direct health care costs alone.<sup>4</sup> In addition, the social and psychological impact is immense and difficult to quantify.

## Risk Factors

No controlled trials looking at the risk factors related to fecal incontinence are available. The greatest risk factors for fecal incontinence in women under age 65 are believed to be injury to the anal sphincter or pudendal nerves from obstetric trauma, irritable bowel syndrome (IBS), and neurologic diseases. Overall, however, the greatest risk factor in all women, regardless of age, is general health and physical status.<sup>4,7,11</sup> These risks were supported in a prospective observational survey by Chassagne and colleagues of 2602 institutionalized elderly over age 60 where the greatest independent risk factors for prolonged fecal incontinence were urinary incontinence, immobility, diminished mental status, and dementia.<sup>7</sup> Diseases associated with incontinence also include the following: diabetes, cerebrovascular accidents, multiple sclerosis, Parkinson's disease, spinal cord injury, and congenital abnormalities. Diarrhea, regardless of etiology, also has a strong association with incontinence, associated with 51% to 71% of cases of fecal incontinence.<sup>7,8</sup> Anal surgery increases the risk of fecal incontinence as well (up to 45% incidence with lateral internal sphincterotomy for anal fissure).<sup>6,11,12</sup>

## Obstetric Injury

The risk of developing fecal incontinence in women is highly linked with obstetric trauma. The incidence of fecal incontinence

**Table 27-1**  
**Cleveland Clinic Incontinence Score**

Frequency	Gas	Liquid Stool	Solid Stool	Pad
Occasionally	1	4	7	1
>1 per week	2	5	8	2
Daily	3	6	9	3

0, perfect continence; 1–7, good continence; 8–14, moderate incontinence; 15–20, severe incontinence; 21, completely incontinent.  
From Agachan F, Chen T, Pfeifer J, et al: A constipation scoring system to simplify evaluation and management of constipated patients. *Dis Colon Rectum* 1996;39:681–685.

to solid or liquid stool in primiparous women is 3% to 13% after vaginal delivery.<sup>11,13</sup> The confounding aspect of sphincter injuries at the time of vaginal delivery is that they are often occult and symptoms may not arise until long after delivery.<sup>11,14</sup> Therefore, the relationship between birth trauma and incontinence is not always clear. The incidence of sphincter defect based on early postpartum endoanal ultrasound has been as high as 35% in some series,<sup>13,14</sup> with defects being recognized by ultrasound often 7 times more frequently than by postpartum physical examination.<sup>13</sup> The risk of developing early fecal incontinence once an injury occurs, even if repaired, is approximately 40%.<sup>13</sup>

## PATHOGENESIS AND CLINICAL FEATURES

An appreciation for the pathophysiology leading to fecal incontinence can only be gained through an understanding of the normal anatomy and physiology necessary for defecation. For normal continence to occur, the rectal vault must be able to distend, an ability to sense that distention must be present, the stool must be of sufficient consistency to be held in the vault, and the complex anal sphincter mechanism must be able to hold the contents until a time when those contents can appropriately be released. Any abnormalities in these synchronized physiologic steps can lead to varying degrees of fecal incontinence.

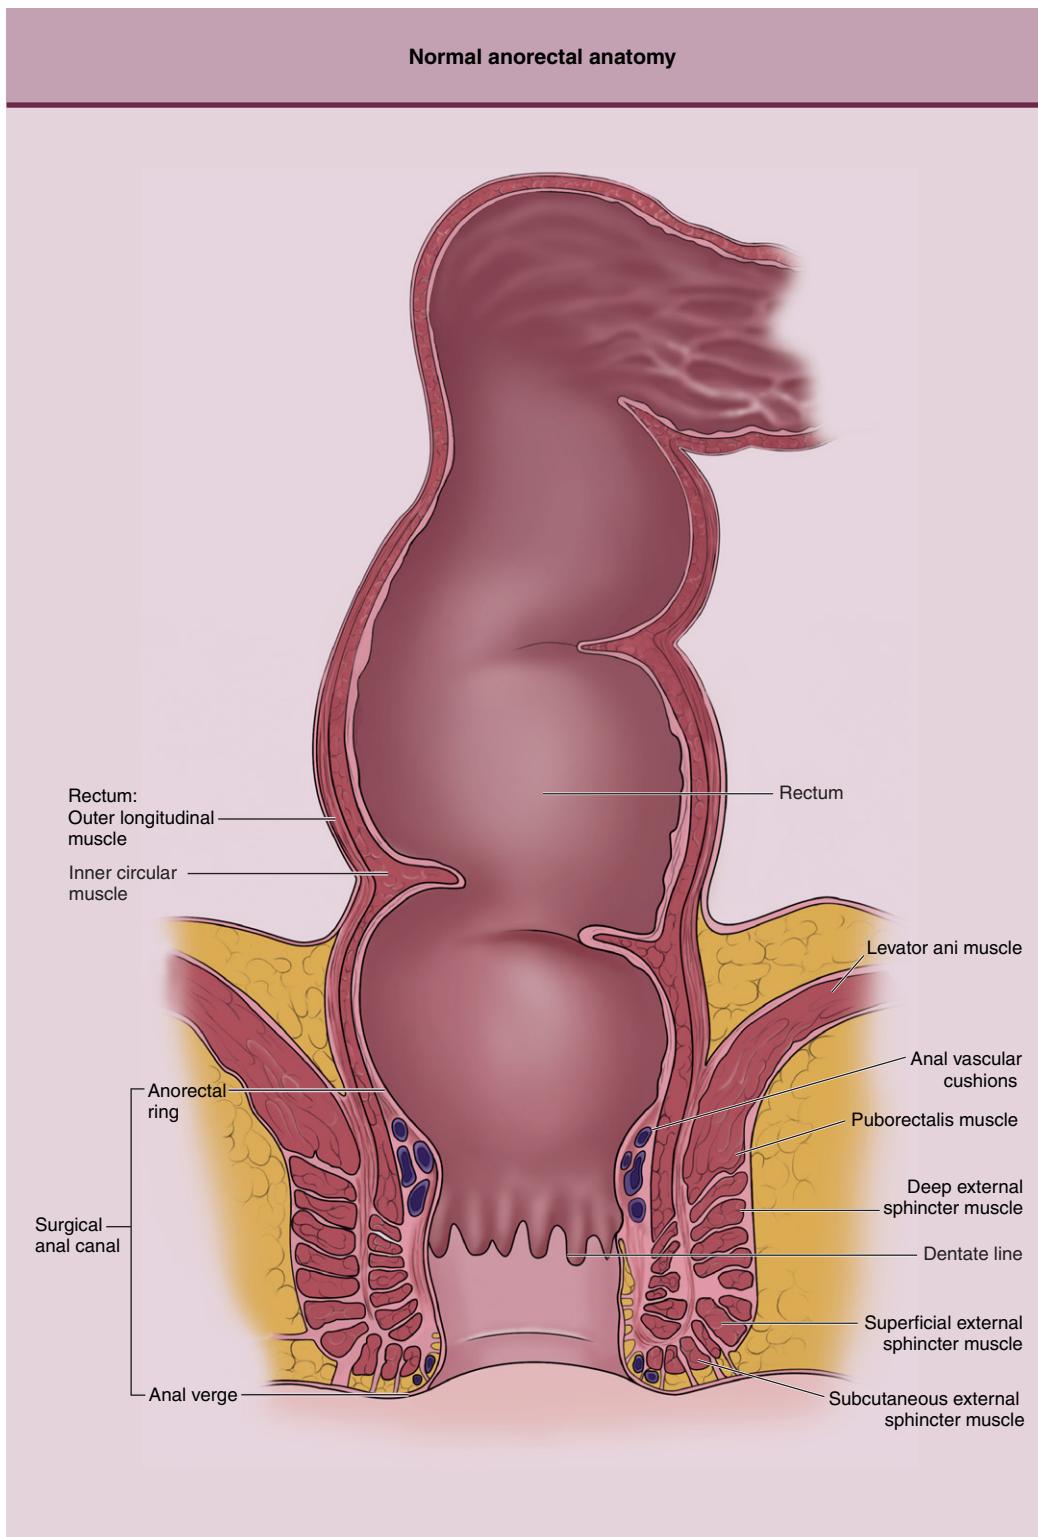

Anatomically, the 12 to 15 cm long rectum and 2 to 5 cm long anal canal are crucial to defecatory function (Fig. 27-1). The rectum is a muscular tube with inner circular and outer longitudinal muscle that acts as a pelvic continuation of the colon and a reservoir for stool. The cephalad extent of the surgical anal canal begins at the top of the anorectal ring of musculature that includes the internal and external anal sphincters and the puborectalis muscle (the U-shaped distalmost aspect of the levator ani muscle complex). The internal sphincter is a continuation and expansion of the rectal inner circular muscle. It is the involuntary, autonomically innervated muscle responsible for 80% of the resting basal pressure of the sphincter complex.<sup>15</sup> The internal sphincter is responsible for maintaining continence at rest only, due to the fact that it relaxes with rectal distention (rectoanal inhibitory reflex), making the external sphincter crucial during that phase of defecation.<sup>14</sup> The external sphincter and puborectalis muscle are the voluntary muscles responsible for 20% of the basal resting pressure and all of the squeeze pressure of the anal canal. The external sphincter is the primary voluntary muscle bulk in women anteriorly (Fig. 27-2), and thus

can have significant sequelae in terms of continence if damaged or torn. The puborectalis muscle forms a sling around the anus that creates an anorectal angle, forming a valve while contracted at rest, thus maintaining continence (Fig. 27-3A).<sup>14</sup> Voluntary relaxation of this muscle straightens this angle, thus allowing stool to pass (Fig. 27-3B). Therefore, the puborectalis muscle is thought to play the key function of maintaining continence to solid stool; the internal and external anal sphincters are believed to be integral to gas and liquid stool continence. As the anal canal continues caudally, there is a transitional zone from the columnar epithelium of the rectum to cuboidal and eventually squamous epithelium of the skin at the dentate line. In addition, at this level of the canal the redundant anal mucosal folds and vascular cushions (hemorrhoids) improve the distal seal,<sup>14</sup> and the highly innervated anoderm (primarily from the pudendal nerve from S2-S4) provides crucial sensory input for maintaining continence. Finally, the anal canal ends as it extends from the dentate line to the anal verge, where the perianal skin becomes the nonhair-bearing anoderm, which contains many somatic sensory nerve endings.

Defecation is initiated by the peristaltic movement of feces from the sigmoid colon into the rectal vault, a capacitance organ that can hold over 500 mL of liquid in normal subjects before leaking.<sup>15</sup> This leads to accommodation by the internal sphincter as part of the rectoanal inhibitory reflex—also occurring intermittently during the day as part of the sampling reflex—that allows for sensation of the rectal contents to occur in the transition zone of the anal canal. Voluntary relaxation of the external sphincter and puborectalis allow for expulsion of the rectal contents when associated with an increase in abdominal pressure (Valsalva maneuver). An aberration in any of these components can lead to continence difficulties, both incontinence and constipation. This is especially true in the aged, demented, or disabled population, who have altered physiology and decreased physiologic reserve.

Alteration in stool consistency is one of the most common pathophysiologic entities leading to incontinence. This is most frequently seen in IBS with diarrhea, infectious enteritis/colitis, inflammatory bowel disease (Crohn's disease or ulcerative colitis), bile salt malabsorption, or medication abuse/misuse where the consistency of stool is so thin that it overrides the compensatory mechanisms of the external sphincter and anal cushions to seal the anal canal. This alteration in stool consistency may also be associated with a decrease in rectal compliance, especially in conditions such as inflammatory bowel disease, radiation proctitis, or malignancy, where the rectum becomes more like a nondistensible tube than a compliance vessel. Stool consistency can also lead to incontinence when severe constipation or a nonrelaxing puborectalis muscle leads to overdistention of the rectal vault and overflow incontinence.

Altered neurophysiology can also lead to incontinence, primarily due to decreased anal sensation or decreased motor function of the sphincter complex. This is frequently associated with systemic diseases such as diabetes, collagen vascular diseases, multiple sclerosis, acquired immune deficiency syndrome (AIDS), or congenital disorders such as spina bifida.<sup>14</sup> Altered neurophysiology is also thought to be the etiology of fecal incontinence after childbirth when no structural abnormality of the sphincter is identified. This incontinence is usually due to direct

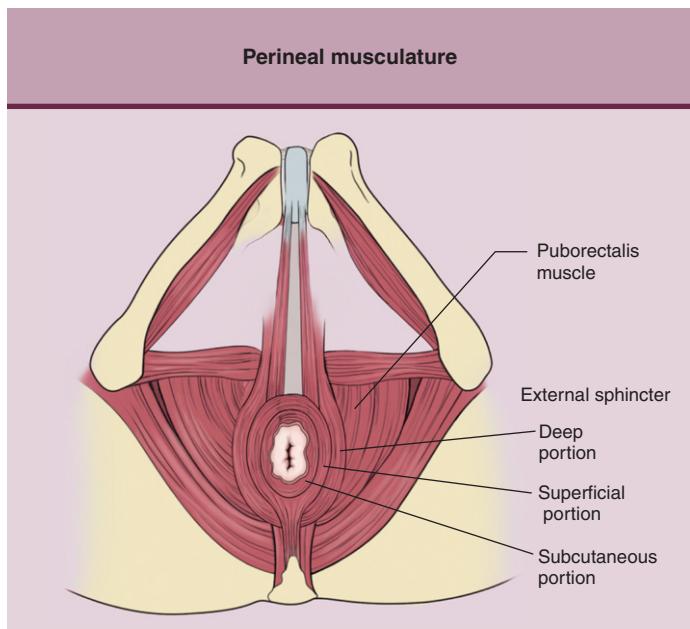

**Figure 27-1** Normal anatomy of the anal canal and rectum.

damage to the pudendal nerves from fetal compression, forceps trauma, or stretching of the nerves during elongation of the birth canal or with prolonged labor.<sup>14</sup> This damage is usually an asymmetric injury that partially recovers with time, but it can be bilateral with permanent sequelae. Similar neurologic trauma can occur over time from extensive straining at stool from

constipation leading to stretching of the pudendal nerves over the ischial spines as the perineum descends. This may be part of the etiology of the association of fecal incontinence with rectal prolapse, but this has not been clearly established.

Alteration in the structure of the anal sphincter is the most common cause of fecal incontinence in women. Trauma is

**Figure 27-2 Perineal musculature in the normal female.** The anal sphincter mechanism is the only substantial musculature of the perineal body in women.

usually the etiology of the change in the muscle complex; this is most frequently associated in women with childbirth, but can also occur due to anal injury or sexual trauma.<sup>16</sup> Muscular trauma can also occur from iatrogenic causes at the time of fistulotomy for anal fistula, sphincterotomy for anal fissure, or hemorrhoidectomy.<sup>11</sup> For these procedures for benign anorectal disease, the incontinence rate is believed to be up to as high as 45% (depending on the definition and follow-up period),<sup>6,11,12</sup> although a recent prospective study by Hyman of patients after lateral internal sphincterotomy for anal fissure showed only 1 of 35 patients postoperatively to have QOL deterioration due to fecal incontinence.<sup>12</sup> Other structural alterations in the sphincter complex may be due to systemic diseases such as scleroderma, inflammatory bowel disease, or AIDS.

### Obstetric Injury

The pathophysiology of birth trauma leading to fecal incontinence through sphincter or neurologic injury seems fairly intuitive, but the risk factors leading to these injuries are not always clear. Therefore, trying to identify the risk factors leading to sphincter injury is crucial to reducing the incidence of fecal incontinence in women. One survey of 475 incontinent females by Lunniss and colleagues, trying to assess potential risk factors in incontinent patients, showed that 78% of women reported a complicated delivery (episiotomy or perineal tear, forceps delivery, or vacuum extraction), with 86% of those deliveries being their first.<sup>11</sup> This same study also identified most of the incontinent women as having undergone pelvic surgery (58%) or anal surgery (19%) at some time in their lives before having incontinence, thus clouding the picture as to the true etiology of their incontinence. Only 40% of the women in this study could ascribe their onset of symptoms to a single event.<sup>11</sup> Therefore, large retrospective and some prospective case series and a few

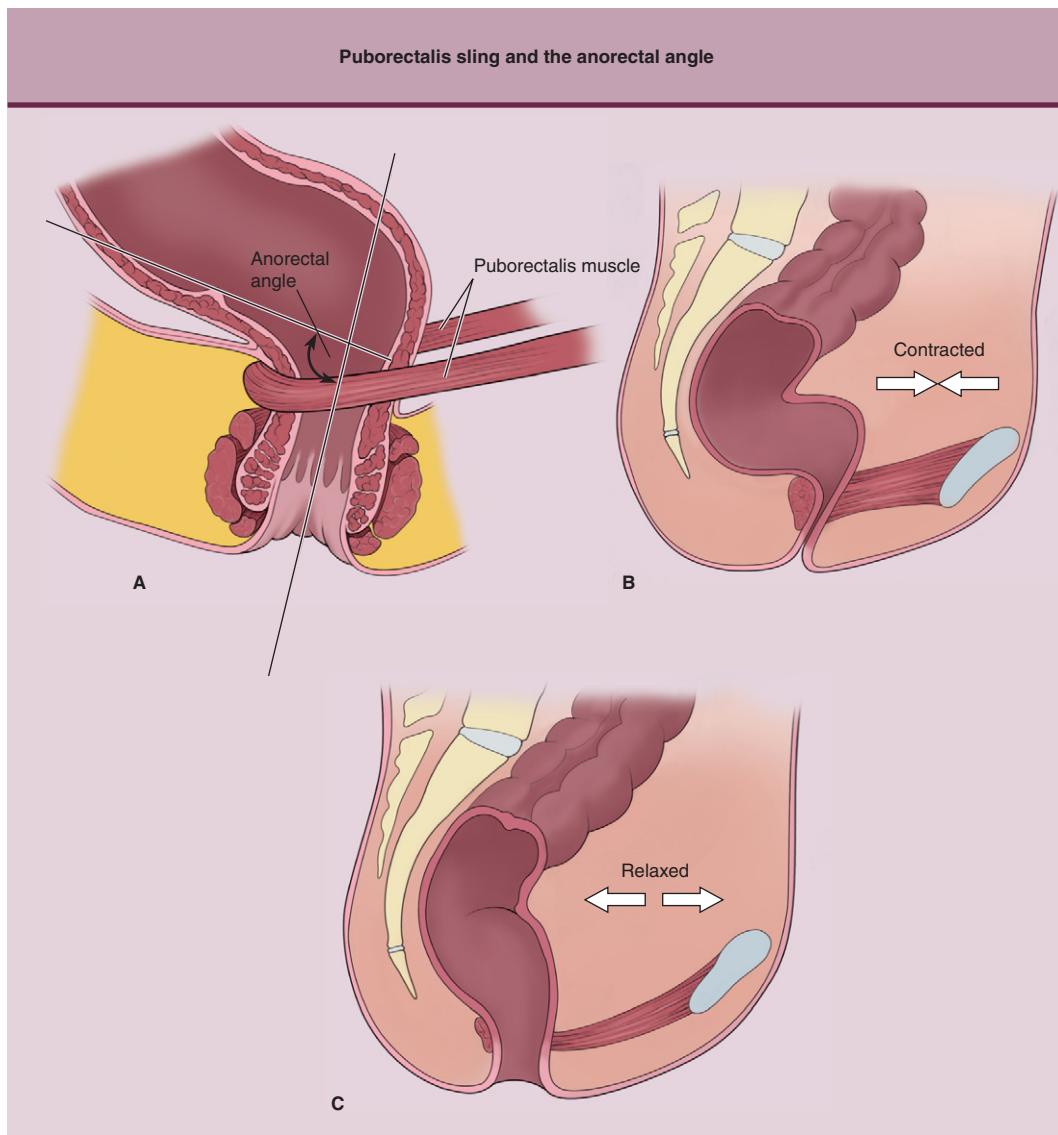

randomized, controlled trials have looked at risk factors for fecal incontinence in relation to birth trauma.

Multiple aspects of vaginal deliveries have been noted to increase the risk of fecal incontinence. The risk seems to be greatest at the time of first delivery and decreases with subsequent deliveries in most but not all studies.<sup>13</sup> The foremost of the seemingly modifiable risk factors, though, is midline episiotomy or significant perineal laceration (third- or fourth-degree tears). These are usually associated with primiparity, large infant birth weight, macrosomia, prolonged labor, and forceps or vacuum extraction. Midline episiotomy has been shown to increase the sphincter injury rate by up to 9 times that of a vaginal delivery without episiotomy.<sup>13,14</sup> The use of mediolateral episiotomy, however, while more painful, has shown a substantially decreased risk for sphincter injury versus the midline approach in most studies.<sup>13</sup> Forceps deliveries have also been linked in prospective studies to an anal sphincter injury in 63% to 83% of deliveries, although a more recent analysis by de Parades and colleagues of 93 women after forceps delivery showed only 13% to have sphincter defects and 22% to be incontinent to flatus or liquid stool with limited follow-up.<sup>17</sup> Perineal laceration (presumably from the forceps) was the only factor in this latter study that could be linked to sphincter injury, although all episiotomies in this study were performed in the posterolateral position rather than in the midline or mediolateral. Overall, vacuum extraction and forceps deliveries have a 3 times and 7 times greater likelihood of sphincter injury, respectively. Other risks, such as prolonged active second stage of labor and the use of epidurals, have also been borne out in some studies to increase sphincter injury rates.<sup>13</sup>

## DIAGNOSIS

### History and Physical Examination

As with most medical conditions, the history and physical examination are the mainstays of diagnosis and can frequently divulge the etiology of fecal incontinence before any confirmatory investigations. The history should focus on the pathophysiological entities leading to incontinence and rule out any potentially confounding diseases. A detailed past medical and surgical history as well as medication review can frequently provide a source for an underlying disease or treatment/medication side effect leading to the incontinence. Queries about changes in stool consistency (diarrhea or constipation related to medications or other conditions), associated abdominal bloating or cramps (IBS or inflammatory bowel disease), perineal pain, hematochezia or purulent drainage (tumors, inflammatory bowel disease, radiation proctitis, or benign anorectal conditions such as hemorrhoids or fistula-causing disease) can elucidate other diagnoses. Consistency of the stool being leaked (gas, liquid, solid), timing of that leak (day and/or night, after bowel movements), and degree of effect on lifestyle and QOL (use of incontinence scoring systems can help standardize these questions) will help to clarify the degree of incontinence and perhaps the extent of underlying pathology. Identifying previous obstetric history, including number of children, difficult deliveries (episiotomy, perineal tear, use of forceps or vacuum, and prolonged labor) and mode of delivery, and complications of those deliveries will guide the management and anticipated need for further evaluation and possible sphincter

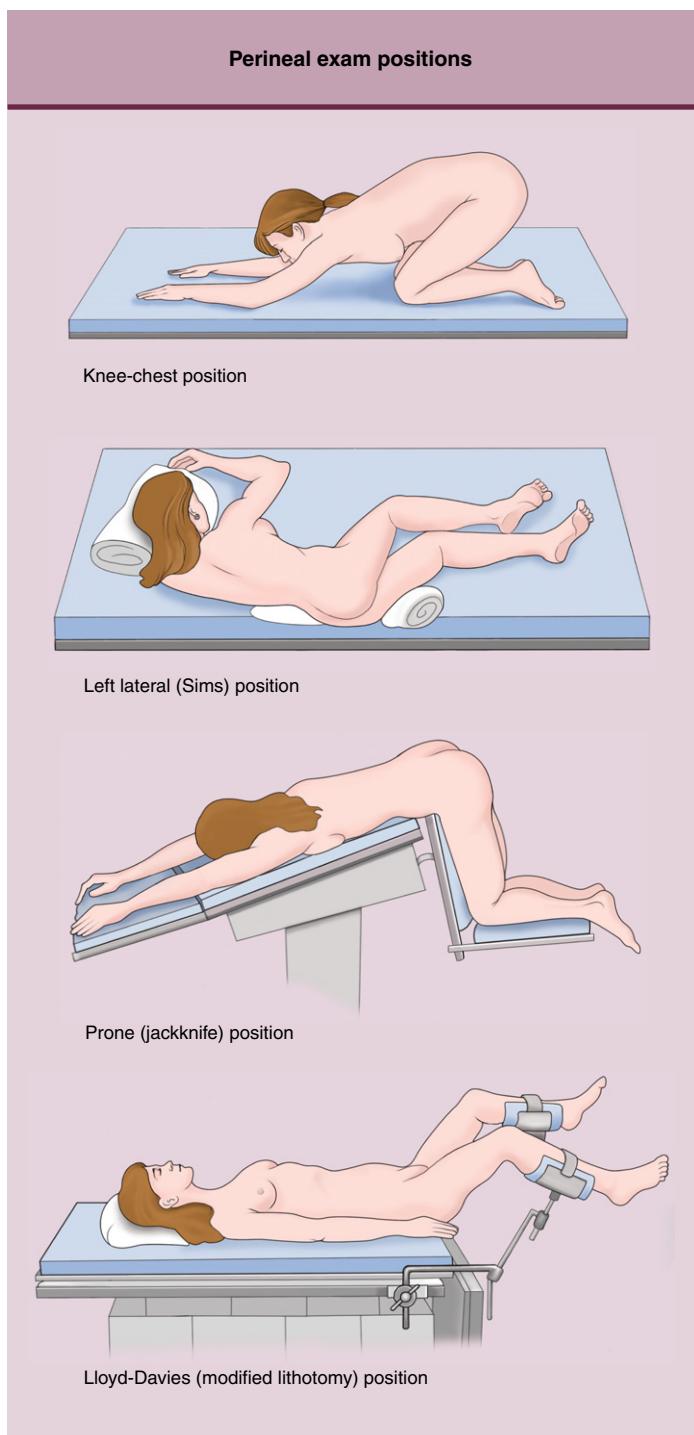

**Figure 27-3 Puborectalis sling and the anorectal angle.** A, Anatomy and function of the puborectalis sling. B, When contracted, the muscle creates the anorectal angle, which assists in maintaining continence. C, When relaxed, the angle changes and defecation is facilitated.

reconstruction. This should be in addition to obtaining a history about perineal or anal trauma from injury or rough sex as well as a history of past perineal operations.

After a complete physical examination looking for manifestations of diseases that can impact continence or masquerade as symptoms of incontinence, a detailed anal and perineal examination should be performed. The perineum can best be examined in the prone jackknife (Kraske), knee–chest, left lateral decubitus or, in some cases, modified lithotomy position (Fig. 27-4). Visual and digital examination should focus on the presence of mass lesions, scars, fistulae, fecal impaction, or inflammatory changes. Digital examination (including bimanual examination of the perineum) can clarify the resting sphincter tone, mobility and strength of the sphincter on voluntary squeeze, thickness of the perineum and rectovaginal septum, and presence of other pathology (e.g., rectocele). Having the patient perform a Valsalva maneuver while observing the perineum and

perianal area may show evidence of inappropriate perineal descent, rectocele, cystocele, or rectal or vaginal prolapse. The utility of these subjective examination findings has been questioned when compared to more objective studies such as ultrasound or manometry, but they are still necessary in the evaluation.<sup>16,18</sup>

Anoscopy, rigid or flexible sigmoidoscopy, and/or full colonoscopy with or without abdominal radiographs should be added to the investigative armamentarium when deemed appropriate. Additionally, defecography (fluoroscopic evaluation of the defecation process through voiding of barium paste) and dynamic pelvic magnetic resonance imaging are useful in select situations to confirm or identify other pathology, such as mucosal intussusception, rectal prolapse, or rectocele, that may affect continence.<sup>18</sup> Finally, a number of physiological tests have been shown to provide adjunctive information to the history and physical examination and may even alter the treatment plan in

**Figure 27-4** Patient positioning for examination of the anorectum and perineum.

10% to 84% of patients with fecal incontinence.<sup>19</sup> These include endoanal ultrasound, anal manometry, and neurophysiology testing.

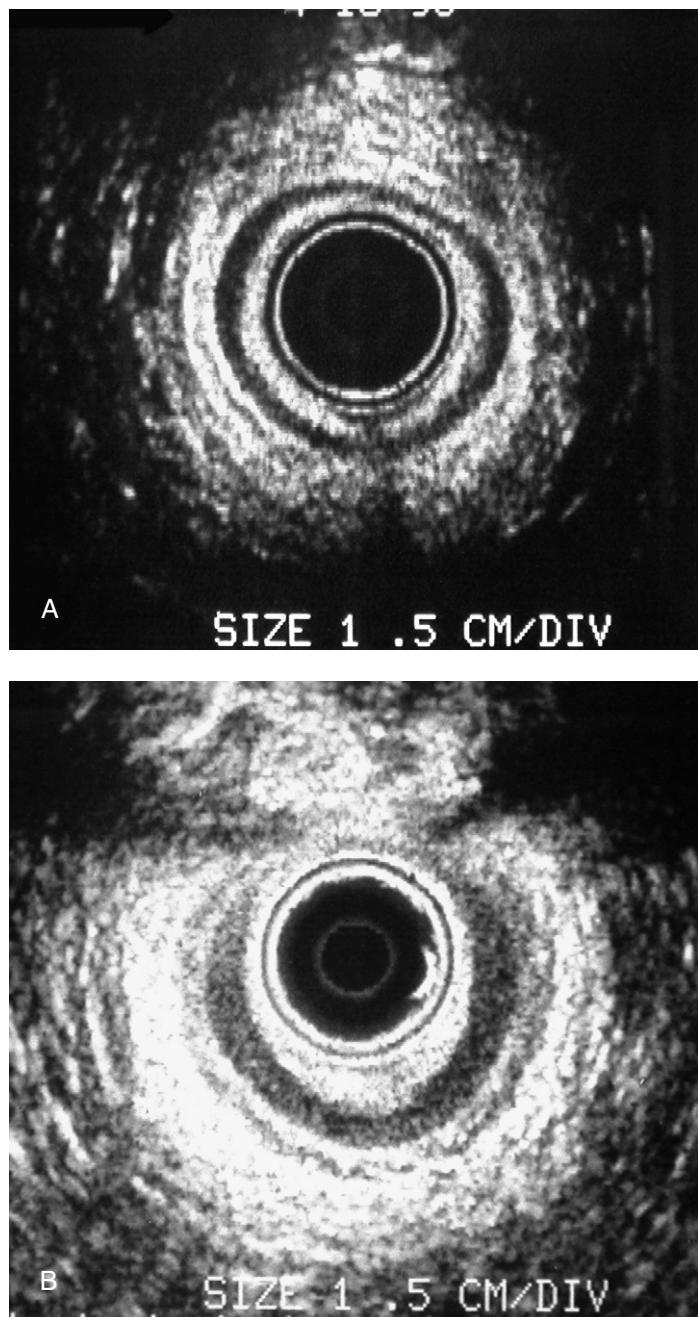

### Ultrasonography

Endoanal ultrasound has become the mainstay of fecal incontinence investigations, primarily because it is one of the few tests

that can reliably, accurately, and in a minimally invasive fashion identify one of the few causes of incontinence that has shown benefit from surgical correction: the anal sphincter defect.<sup>19</sup> The study is performed with a rotating 360-degree 7.5- to 10-MHz ultrasound transducer with an anal cap, allowing for structural visualization and, with some instruments, three-dimensional reconstruction of the anal canal. The higher the frequency, the better the structural resolution; therefore a 10-MHz transducer is ideal for mapping the anal sphincter.<sup>16,18</sup> The test is best performed with the patient in prone jackknife or left lateral decubitus position, and is often facilitated by a preprocedure enema, although this is not mandatory. Normal appearance of the internal sphincter is a hypoechoic circumferential ring around the middle anal canal; the external sphincter (more difficult to interpret and identify in comparison to the internal sphincter) first appears in the upper anal canal in continuity with the horseshoe appearance of the puborectalis muscle as a hyperechoic ring that extends to the lower anal canal (Fig. 27-5A).<sup>18</sup> Defects are noted as unanticipated changes in the echogenicity or thickness of the sphincters (Fig. 27-5B), suggesting separation or scarring of the muscles.

Although sphincter defects may be due to injuries and may therefore be the etiology of incontinence, they may also be normal anatomic variants, which lead to false-positive results in 5% to 25% of individuals.<sup>20</sup> Ultrasound studies by Bolland and colleagues of 57 normal primiparous women in the first trimester showed some degree of sphincter gap in 44 (77%) of them, most in the upper anal canal.<sup>21</sup> These findings were substantiated in a small group of normal male and female controls, with none of the men and all of the women having some degree of anterior defect despite no previous history of trauma, surgery, or pregnancy. By limiting the definition of sphincter injury to those that had irregular borders and occurred in the lower anal canal, the authors were able to eliminate a 10% false-positive rate if an ultrasound was originally considered positive simply for showing any sphincter defect.<sup>21</sup> The results of this study underscore the fact that experienced technicians are necessary to provide accurate data about the anatomy of the sphincter complex. This is further underscored by studies showing variability in interobserver agreement, although significant defects are usually identified with good to very good correlation between experienced observers.<sup>22</sup>

The results of mapping the sphincter with ultrasound have been shown to be compatible with defects found at the time of operation,<sup>18</sup> and even occult defects or injuries are well-delineated with this methodology (up to 100% sensitivity with experienced technicians).<sup>16,20</sup> Ultrasound has also been shown to be more effective than manometry and is clearly better tolerated and at least as effective as needle electromyography (EMG) in mapping the anal sphincters.<sup>16</sup> It is therefore believed that ultrasound is necessary when surgical correction of a sphincter defect is planned to obtain a "road map" of the abnormal sphincter anatomy. In addition, ultrasound may provide useful information as to other pathology (such as fistula or abscess)<sup>22</sup> and the thickness of the perineal body, which has been found to be predictive of the presence of a pathologic sphincter defect (97% when perineal body thickness < 10 mm) but not correlated with the degree of fecal incontinence.<sup>20</sup> Finally, ultrasound is essential when evaluating patients with

**Figure 27-5 Examples of endorectal ultrasounds.** A, Appearance of normal concentric ring anatomy of the internal (central hypoechoic ring) and external (outer hyperechoic ring) anal sphincters. B, Appearance of an abnormal endorectal ultrasound, showing an anterior defect in both internal and external anal sphincters replaced with hyperechoic scar (from obstetric trauma).

recurrent incontinence after previous sphincter repair to determine the integrity of the repair and whether other etiologies of the recurrence should be sought.

### Manometry

Anal manometry is the study of pressures within the anal canal at rest and with contraction (squeeze) as well as the determination of muscle responses to distention within the rectum

(rectoanal inhibitory reflex). At rest the pressure is indicative of the baseline tonicity of the internal and external anal sphincters, whereas squeeze pressures are indicative of external sphincter function (Fig. 27-6). The data can be used to suggest the approximate length of the anal canal (ranging from 2 to 5 cm in women)<sup>16</sup> and, with some instruments, the portion of the anal canal with abnormal function. It cannot, however, differentiate between muscular and neural sources of pathology in the anal canal.

The procedure is performed with any number of water-perfused catheters, solid-state transducers, or balloon-tipped catheters (Fig. 27-7). The balloon-tipped catheters are useful in determining the presence of the rectoanal inhibitory reflex as well as obtaining information about the first detected sensation of volume in the rectum (indicating ability to sense rectal filling), volume when a defecatory urge occurs (indicating normal stool volume for that patient), and the maximum tolerable volume (indicating full rectal compliance or irritability). These catheters are also used to guide biofeedback training.

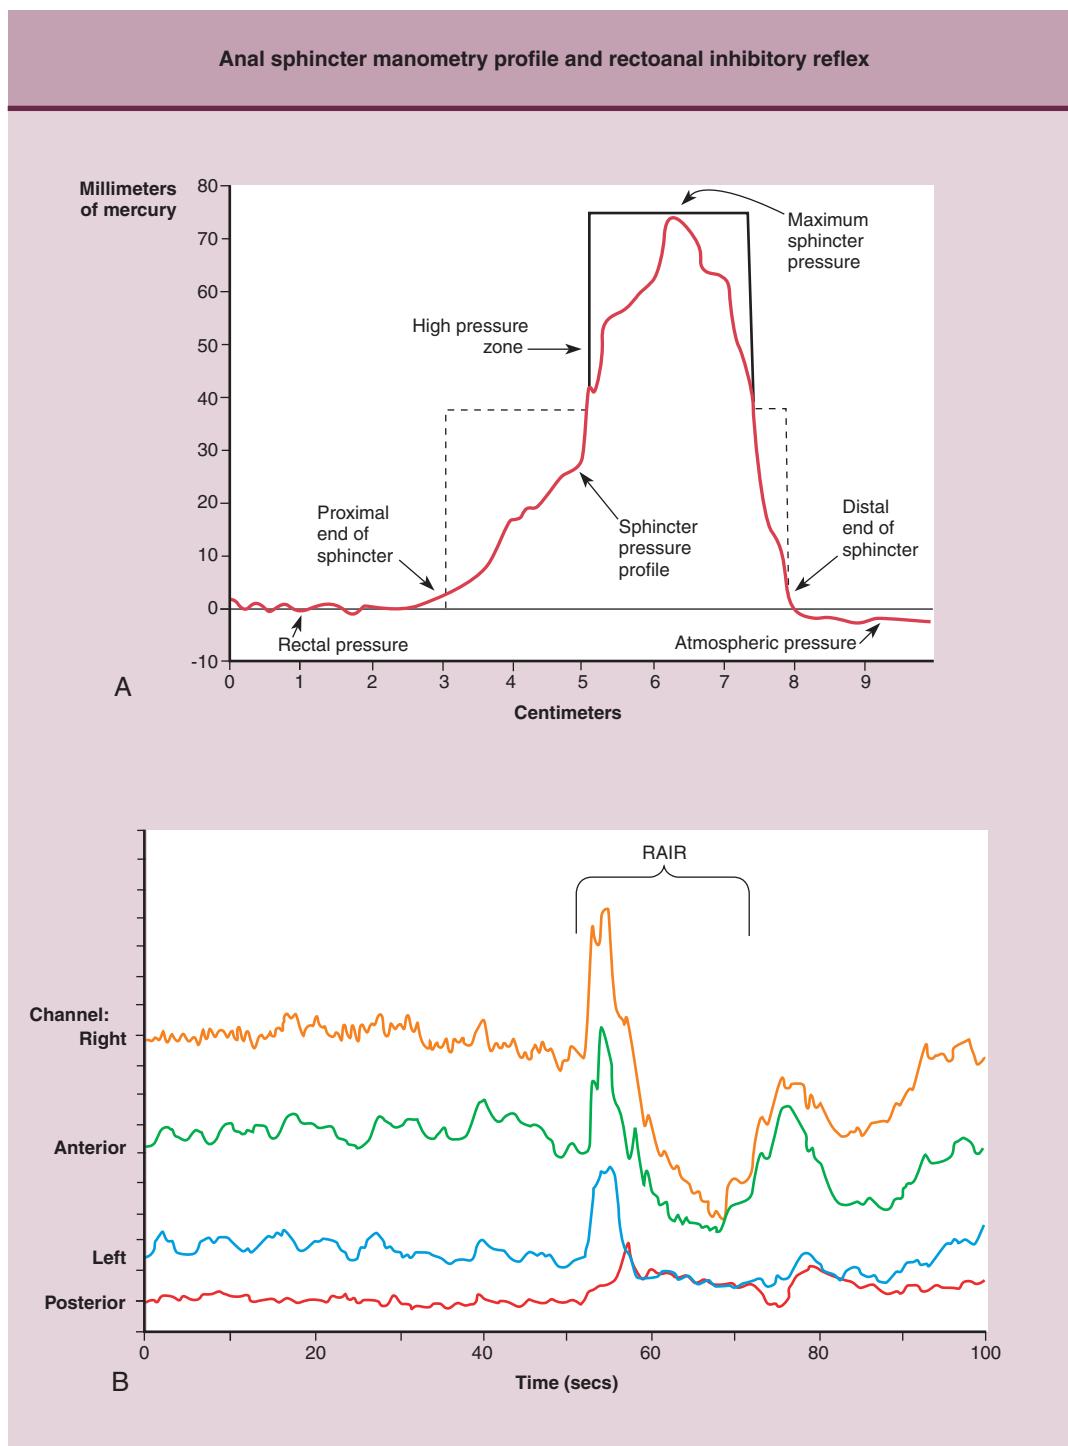

The most important aspect of this testing is that it is dependent on the examiner and instrument as well as the compliance of the patient (especially for the squeeze portion of the examination and the reporting of sensory changes); therefore, the results must always be viewed in context with the clinical situation. Studies have both confirmed and refuted the reproducibility of these tests between different examiners on the same patient.<sup>16</sup> In addition, some studies show variability in correlating manometric results with degrees of incontinence (sensitivity, 32% to 92%; specificity, 67% to 97%, depending on the cutoffs used),<sup>16</sup> which is likely due to the significant variability in "normal" values detected in controls as well as the differences in "normal" values between gender and age groups.<sup>16,18</sup> Therefore, it is recommended that manometric techniques within laboratories be standardized and normal ranges for each laboratory be established to avoid blaming technique as the source of variability. The American Gastroenterological Association (AGA) reports that fecal incontinence is one of the indications for manometric study, despite the lack of controlled clinical trials.<sup>16</sup>

### Neurophysiology

The two primary means by which the integrity of the neuromuscular function of the pelvic musculature can be tested are EMG and pudendal nerve terminal motor latencies (PNTML). Both of these tests have distinct advantages and disadvantages that make them variably useful in the assessment of fecal incontinence, and both have been used as adjuncts to the other physiological studies described in this chapter.

### Electromyography

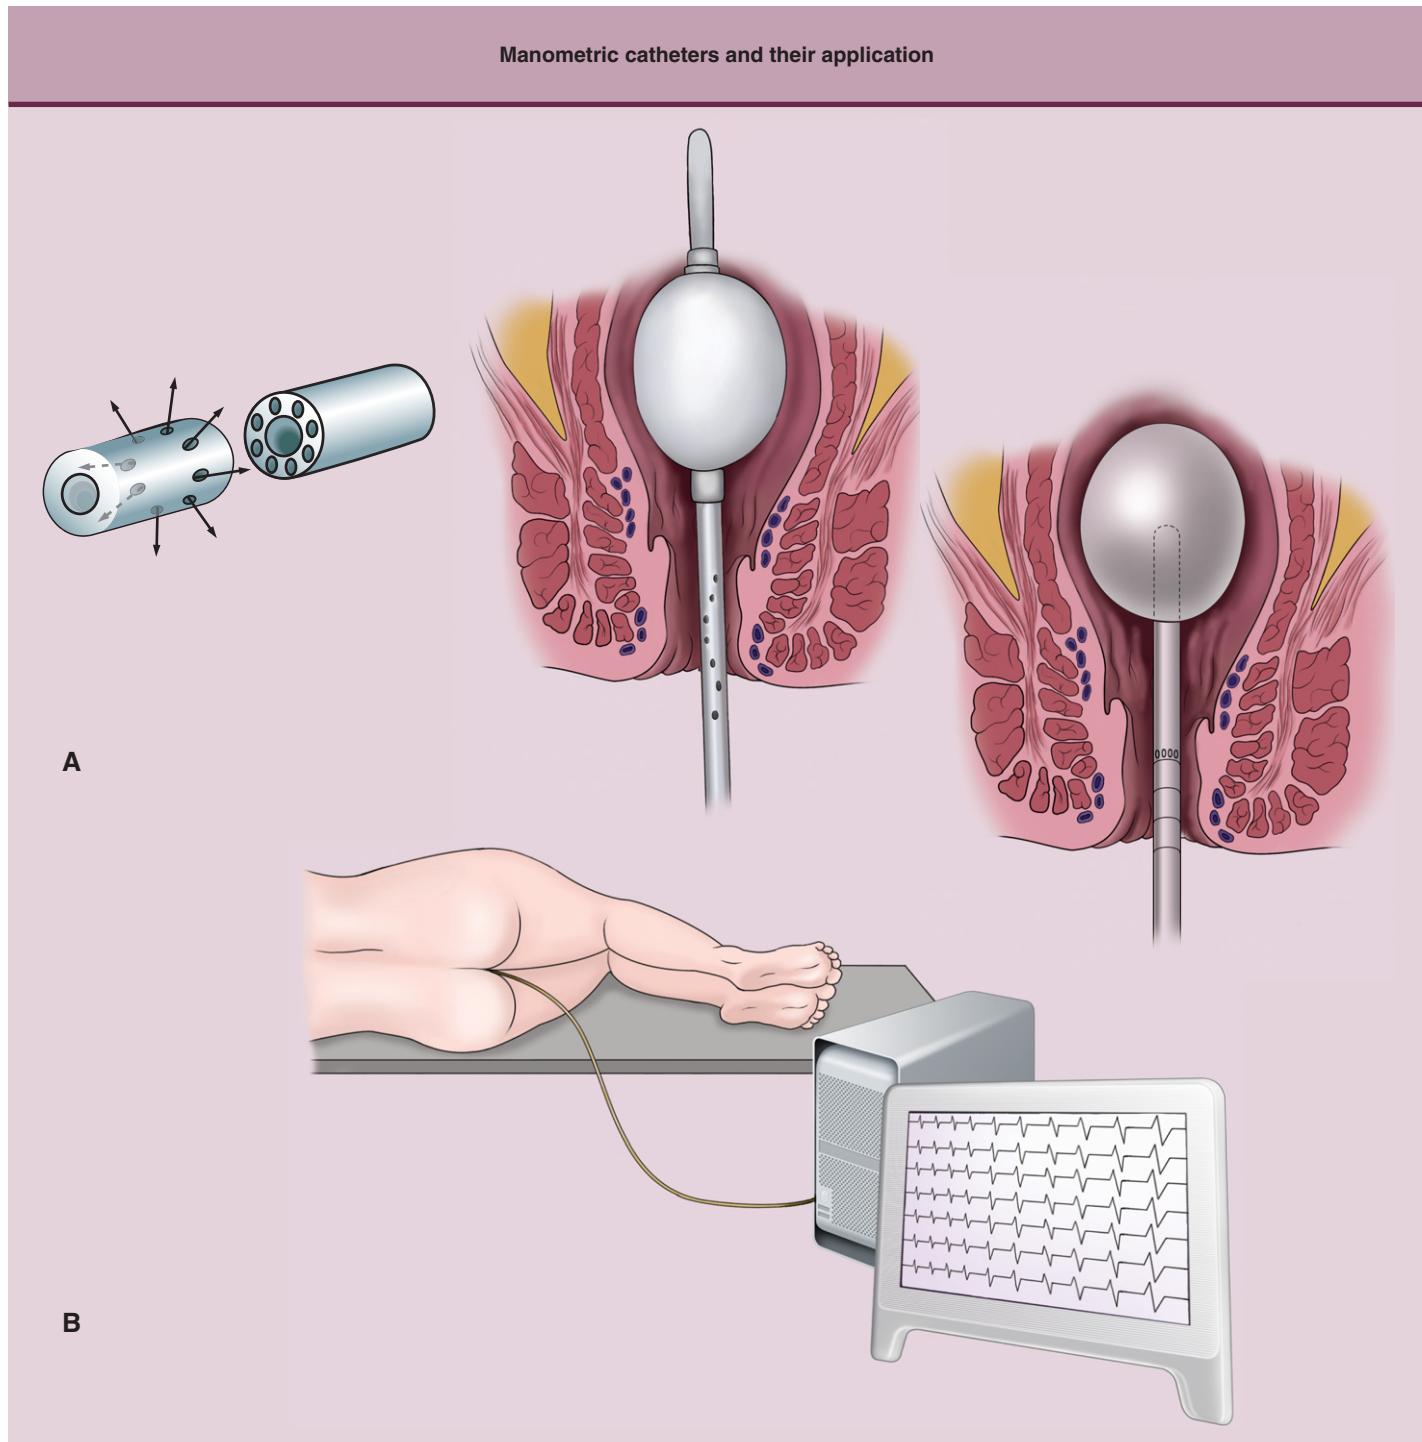

Electromyography is used to assess external anal sphincter and puborectal muscle function, map the anal sphincter complex, and provide information on the presence of neuropathic and/or myopathic injury by measuring the electrical activity of the muscular motor units. The study requires specialized training to perform and interpret the findings.<sup>16</sup> It can be performed by either needle electrodes (insertion of concentric or single fibers) or anal plug (sponge or hard plug), which can indicate nerve injury and reinnervation of the muscle units by adjacent nerve

**Figure 27-6 Normal manometric studies.** A, Normal manometric squeeze pressure profile of the anal canal (from an eight-channel water perfusion pressure catheter). B, Normal rectoanal inhibitory reflex (RAIR; from a four-channel water perfusion balloon-tipped pressure catheter).

fibers. Surface EMG electrodes are also available, but they are more useful in evaluating gross motor activity over larger areas than the needle EMG. Surface electrodes are best used for evaluating paradoxical sphincter spasm during defecation in constipated patients as well as for biofeedback training.<sup>16,18</sup> Of the other methods, needle EMG is more uncomfortable for the

patient<sup>18</sup> and carries a higher risk of infection than the anal plug, but it offers the most reproducible intraobserver and interobserver results. Both needle and plug techniques are well-correlated with manometric squeeze pressures. Overall, however, EMG has not been validated by histologic evidence of nerve injury, is less sensitive than ultrasound in mapping the anal sphincter, is

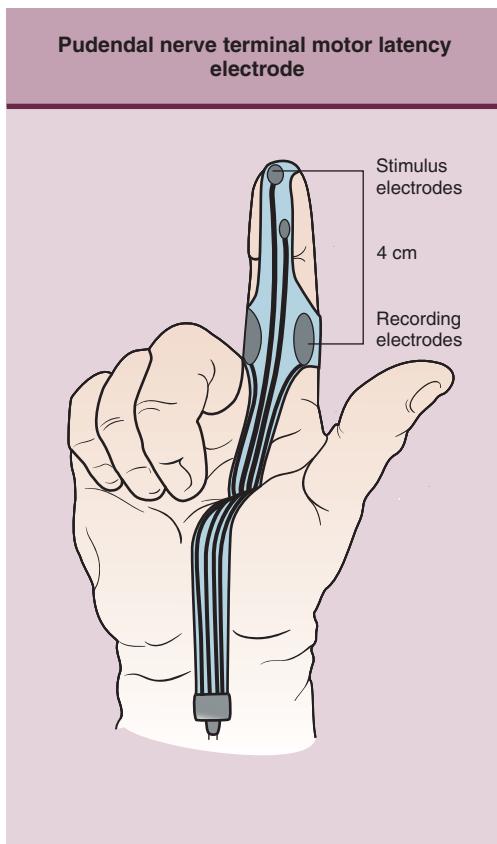

**Figure 27-7 Examples of manometric catheters (A) and their application (B).**

subject to potential sampling error, and is limited to primarily distal portions of the anal canal (although the puborectalis muscle can be examined).<sup>16</sup> Because of the better results and tolerability of endoanal ultrasound, the AGA has stated that “(n)eedle EMG cannot be recommended for fecally incontinent patients” while surface EMG is of “possible value” in the assessment of sphincter function in incontinence.<sup>16</sup>

#### **Pudendal Nerve Terminal Motor Latencies**

The external anal sphincter is innervated by the pudendal nerve. PNTML evaluates pudendal neuropathy by measuring the time (or “latency”) between stimulation of the pudendal nerve at the ischial spine and contraction of the external anal sphincter. A stimulating and recording electrode that fits on a gloved index finger was designed for this purpose (Fig. 27-8). A digital

**Figure 27-8 Pudendal nerve terminal motor latencies measurement electrode.**

examination is performed with the apparatus in place, and the tip of the finger electrode is placed to stimulate the nerve as it courses through Alcock's canal beneath the ischial spine (a difficult maneuver in some patients). The recording electrode is at the base of the examining finger and therefore records the motor unit potential of the external sphincter at the lower anal canal. This is tested on both sides of the pelvis to ensure that there is not a bilateral neuropathy. Because the energy used to stimulate the nerve is low (50 volts with 8 to 10 mA of current), discomfort involved in performing the test is usually minimal. Nerve conduction delay above the norm of  $2.0 \pm 0.2$  msec is caused by demyelination of the fast-conducting fibers of the distal pudendal nerve due to aging, systemic disease (e.g., diabetes, scleroderma), and/or nerve injury or stretch (e.g., from vaginal delivery, rectal prolapse). This data is believed to best help differentiate between fecal incontinence due to nerve injury, muscle injury, or both, especially when combined with endoanal ultrasound results. Initial studies showed that patients with bilateral even more than unilateral neuropathy fared poorly after anal sphincter repair, and it was therefore believed to be a crucial preoperative test.<sup>23</sup> Other studies, however, have not shown PNTML results to impact surgical outcomes<sup>24,25</sup> or affect clinical decision making.<sup>19</sup> Other issues with PNTML relate to overall poor sensitivity and specificity for etiologies of incontinence, the lack of normal values for various age and gender groups, lack of data on intraobserver or interobserver reproducibility, and the fact that a normal study through a few

remaining normal distal pudendal nerve fibers could potentially camouflage a more global or proximal pudendal nerve injury.<sup>16</sup> It is therefore believed by some authors that this test should be abandoned in the evaluation of fecal incontinence, and the AGA has stated that "(t)he PNTML cannot be recommended for evaluation of patients with fecal incontinence," although it may be "interesting from a research point of view."<sup>16</sup>

## TREATMENT AND CLINICAL COURSE

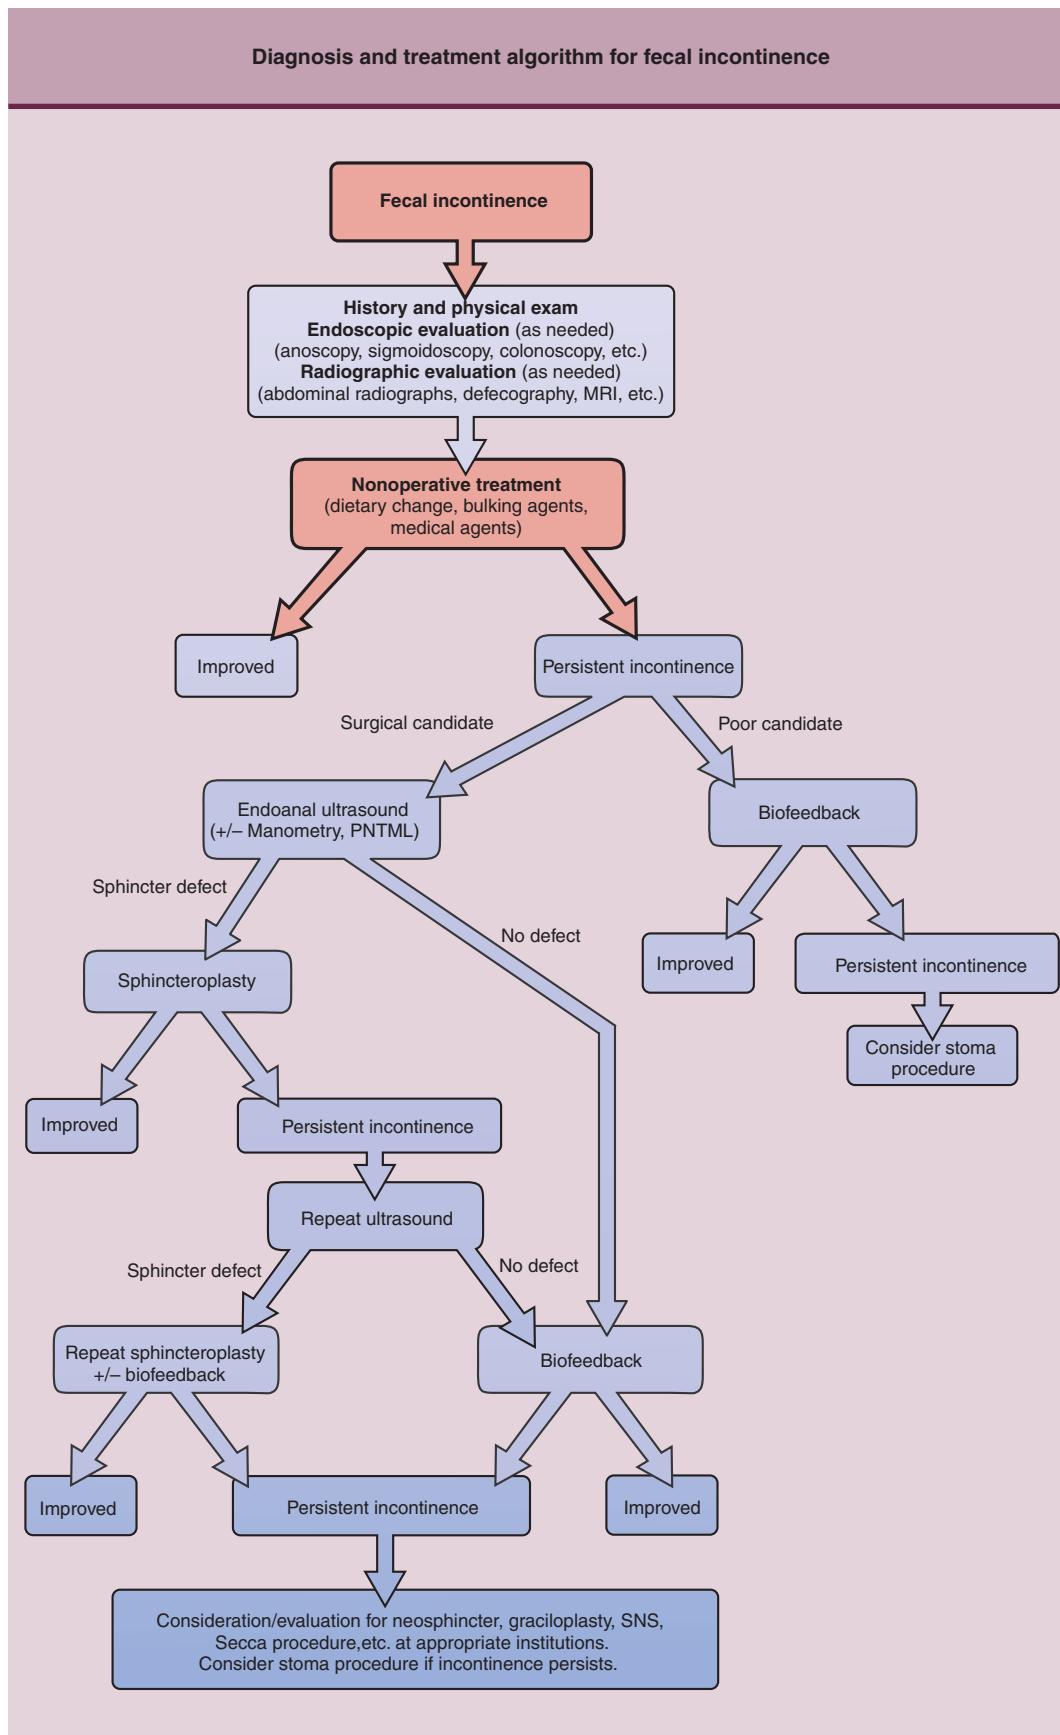

Usually a complete cure for fecal incontinence cannot be attained; therefore, treatments are aimed at improving symptoms and QOL as much as possible. The treatments range from medical management through the use of bulk-forming agents and antidiarrheals to behavioral management and retraining through the use of biofeedback to multiple surgical options, including sphincter repairs, artificial and autologous neosphincters, and even fecal diversion through the creation of a stoma. Often a treatment algorithm is best followed to standardize the incontinence evaluation and avoid the pitfalls of missed diagnoses. An example of one such treatment algorithm is presented in Figure 27-9.

### Nonsurgical Treatment

The majority of patients suffering from fecal incontinence will not need surgical intervention. They often will benefit enough from nonoperative management of their disease that surgical therapies are not necessary or justified. As long as the dietary, medical, or behavioral therapies are complied with, they are effective long-term. In addition, these therapies have few side effects, avoid the potential complications associated with operative intervention, and do not preclude the potential for operative correction in the future. Therefore, most physicians will explore the use of nonsurgical treatments before more invasive means of fecal incontinence treatment.

Because incontinence is frequently related to systemic disease or medication side effects, treatment of these underlying diseases or use of alternative medications often "cures" the incontinence. Diarrhea from IBS or inflammatory bowel disease can usually be improved with pharmacologic therapies targeted to these conditions. Tumors, radiation proctitis, and benign anorectal conditions leading to incontinence will benefit from surgical therapies aimed at these conditions for those who are candidates. Medications leading to diarrhea are best discontinued, if possible, but when the medication is necessary, agents to slow motility or add bulk to the stool may be helpful. If the etiology of fecal incontinence cannot be attributed to a medication or underlying medical condition, the history, examination, and adjunctive tests can help clarify the etiology. If the incontinence symptoms are mild to moderate and are not having a substantial impact on QOL, or if the patient is not a surgical candidate, medical therapies often offer satisfactory results.

Alteration in diet is the first line of nonsurgical treatment for fecal incontinence related to alterations in stool consistency or colonic transit. This is based on increasing the dietary fiber to 25 to 30 g/day of insoluble fiber, primarily in the form of raw fruits and vegetables and whole grains. If this is not achievable through dietary means alone, bulking agents in the form of psyllium or other raw fiber can be added. This is often sufficient

**Figure 27-9 Diagnostic and treatment algorithm for fecal incontinence.** PNTML, pudendal nerve terminal motor latencies; SNS, sacral nerve stimulation.

## Urogynecology

to increase the formed stools and thus decrease the incontinence episodes to liquid stool. A common side effect of this fiber regimen may be increased gas that requires further alteration in the diet or raw fiber until a nongas-forming regimen can be achieved. Additionally, a strict bowel movement regimen should be sought to have complete evacuation of the rectal contents each morning and thus avoid difficulty with overflow incontinence and stool leakage during the day. This may be facilitated through the use of stool softeners, laxatives (avoiding senna and cascara, which can lead to dependency), and a glycerin suppository or small enema each morning to further stimulate complete evacuation. Adherence to this regimen can lead to fewer episodes of incontinence and can be especially beneficial in the bed-bound or physically limited nursing home patient.<sup>5</sup>

### Medical Agents

If dietary adjustments or bulking agents are insufficient or not tenable due to patient comorbidities or limitations, pharmacotherapy may be a viable option for some patients. These agents can be especially useful when trying to alter stool consistency and thus improve bowel control and decrease stool frequency. Care must be taken to avoid constipation when using these agents, however. Loperamide (a synthetic opioid) has been shown to inhibit peristalsis, increase bowel transit time, increase anal sphincter tone, and decrease fecal urgency and stool volume. Its utility in improving incontinence episodes has been supported in a number of placebo-controlled trials. Its side effects can include paralytic ileus and central nervous system (CNS) effects on overdose. Diphenoxylate, also an opioid derivative, which is often given in combination with atropine to limit the CNS effects of the drug, has been shown to be less potent than loperamide but with a similar safety and side effect profile. This drug has also been shown to decrease stool volume and frequency in placebo-controlled trials on incontinent patients. Amitriptyline, a tricyclic antidepressant with the side effect of reducing rectal motor complexes, has been tested in incontinent patients in low doses and been shown to lead to firmer stool formation and decreased incontinence scores. This and other agents such as phenylephrine gel (applied directly to the anus to increase sphincter tone) or bile-acid binders must be examined in randomized, prospective trials before their use can be advocated in all patients with fecal incontinence.<sup>26</sup>

### Biofeedback

Biofeedback is a behavioral retraining technique best used in patients with pudendal neuropathy causing external anal sphincter weakness (e.g., from diabetes, pudendal stretch injury), in patients with diminished rectal sensation (from diabetes, scleroderma) leading to incontinence, or in patients with small sphincter defects who wish to avoid surgery as the initial treatment.<sup>9</sup> Biofeedback has also shown significant benefit when used by patients after sphincter repair.<sup>27</sup> Types of biofeedback include use of a balloon-tipped catheter and pressure sensors in the anal canal, use of EMG surface or anal canal electrodes, use of endoanal ultrasound, or simply use of digital self-examination. Each of the techniques focuses on training the patient to contract the anal sphincter muscles. Some of the techniques also attempt to improve the detection of rectal distention (balloon technique) and avoid inappropriate timing of the Valsalva maneuver during

the defecation process (EMG surface technique). They all use either visual, auditory, or sensory responses through the pressure sensors, EMG, ultrasound screen, or digital examination to provide feedback to the patient as to their progress. Given that some amount of rectal sensation and sphincter contraction must be feasible for these methods to be successful, these techniques have not been effective in patients with severe limitations such as those with spinal cord injuries. In addition, these techniques require dedication on the part of the patient as well as dedicated and well-trained therapists,<sup>5</sup> who are not always available in all communities and whose availability may be limited by insurance coverage.

Biofeedback techniques have been shown to be effective in 50% to 92% of selected patients, and the results are usually sustained and have been effective even when compared to sham training.<sup>10</sup> Primarily, there seems to be improved continence with biofeedback more often in patients with sensory deficits as compared to patients with neurologic (i.e., functional) and structural deficits, but this is based on a nonsystematic review of multiple uncontrolled studies.<sup>28</sup> Interestingly, the symptom improvement in these studies did not necessarily correlate to improvement in objective physiological studies or improved QOL, so the reason for the effectiveness of biofeedback remains elusive.<sup>28</sup> A Cochrane review of five randomized, controlled trials on biofeedback also failed to make definitive conclusions because of the variety of techniques and endpoints used in the trials.<sup>10,28</sup> One other well-designed randomized, controlled trial looking at various counseling and biofeedback techniques in 171 patients with and without structural sphincter defects concluded that patient–therapist interactions and patient coping strategies had a greater impact than treatment methodology or etiology of incontinence.<sup>28</sup> Although the reason for the effectiveness of these techniques remains unclear, they are painless, safe, and well-tolerated; and they are a useful means by which to potentially avoid the need for operative intervention.<sup>10</sup>

### Surgical Treatment

When dietary, medical, or biofeedback treatments are not efficacious, surgical treatments for fecal incontinence may be effective options. They include the universally accepted and performed treatment of anal sphincter repair (sphincteroplasty) in addition to more controversial procedures performed at specialized centers to create a neosphincter (graciloplasty or artificial sphincter), improve function through sacral nerve stimulation, or increase resting sphincter pressure with radiofrequency treatments (Secca). A final surgical option is stoma formation to try to improve QOL in patients with fecal incontinence.

### *Anal Sphincteroplasty*

The most successful and commonly performed surgical procedure for fecal incontinence is primary repair of the anal sphincter, or anal sphincteroplasty. This procedure is for those patients with incontinence who have not responded to non-operative measures and who have an identifiable anatomic sphincter defect on examination, ultrasound, or EMG. The majority of these patients have sphincter defects from obstetric or surgical trauma, some of which may have been identified and repaired at the time of the initial injury. The evaluation prior to sphincteroplasty, beyond a detailed history and physical

## Surgical Treatment of Fecal Incontinence

examination, needs to establish the presence of a sphincter defect. Absolute contraindications to the procedure are intuitive and relate to the medical and mental fitness of the patient, active perineal or perianal infection, and the patient's eligibility for spinal or general anesthesia. Relative contraindications include radiation proctitis, malignancy, inflammatory bowel disease, or plans for subsequent vaginal deliveries. If the injury has occurred recently (<6 weeks), it is usually recommended to wait for the inflammation to decrease for at least 6 weeks, although early reoperations have shown good results in terms of postrepair continence in small case series.<sup>13</sup>

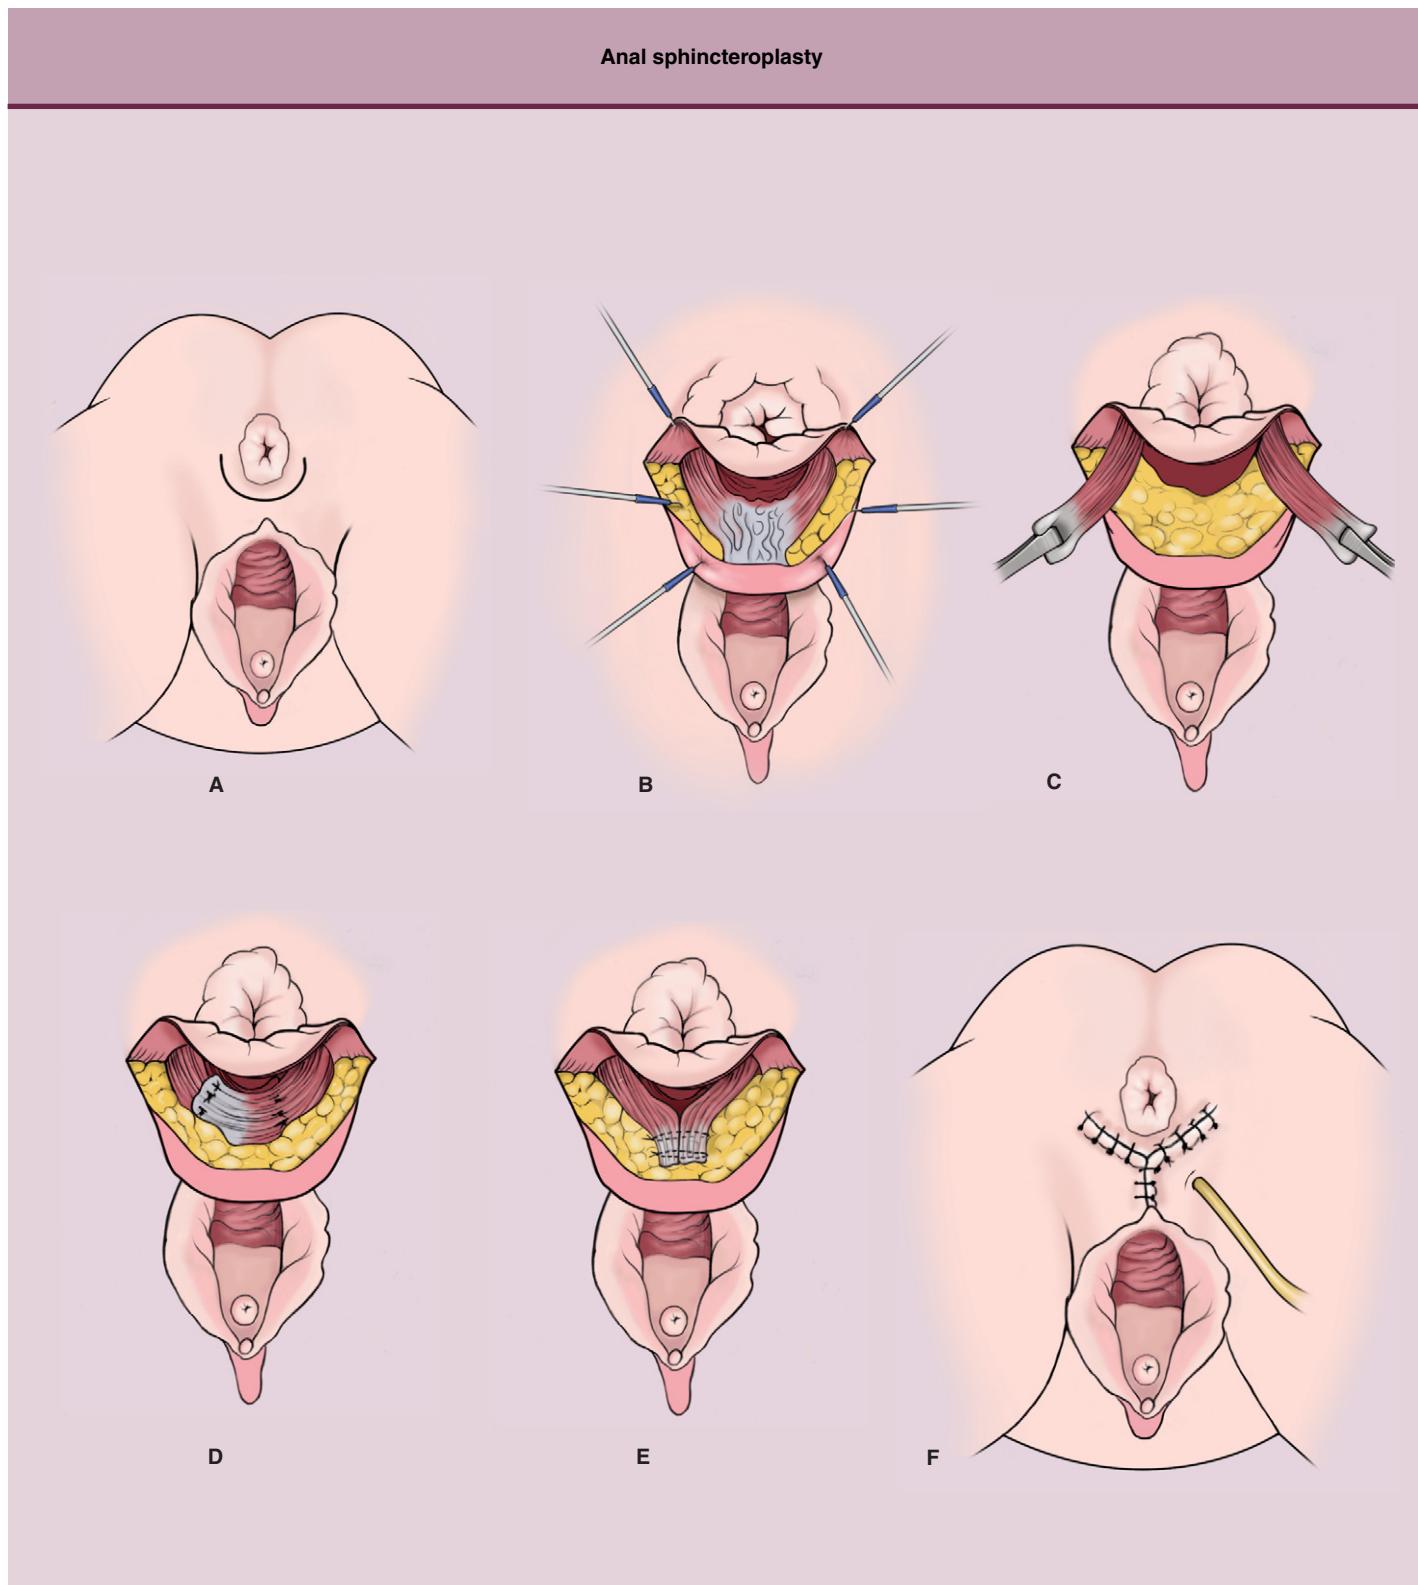

Sphincteroplasty at the time of acute obstetric sphincter injury (third- and fourth-degree tears) is routinely performed by most obstetricians in a direct end-to-end fashion with absorbable interrupted sutures. Fecal incontinence rates 6 to 12 months after this type of acute repair have been shown to be approximately 40% (range, 20% to 50%), depending on the definitions used.<sup>13</sup> This high rate of incontinence has been established by endoanal ultrasounds performed up to 12 months' postpartum, showing a persistent sphincter defect in 54% to 85% of women despite the performed repair.<sup>18</sup> It is unclear whether these later defects were unrecognized or whether the repairs were disrupted. Performing an overlapping repair at the time of acute injury has shown an improvement in sphincter integrity postpartum in some studies but not in others.<sup>13</sup> Ultimately, though, it is unclear what impact these acute repairs truly have on later continence; therefore, well-designed long-term trials need to be done before conclusions about the effectiveness of acute repair techniques can be made.

Anal sphincteroplasty for more chronic injuries is preferentially performed in the prone jackknife position via a transperineal approach, modified from that described by Parks and McPartlin in 1971.<sup>5</sup> Preoperative preparation for sphincteroplasty includes a full mechanical bowel preparation and appropriate broad-spectrum perioperative intravenous antibiotics (usually cefoxitin or cefotetan). Once the patient has been positioned and before preparation of the perineum, rigid proctoscopy should be performed both to evacuate any remaining stool and to reveal any previously unidentified rectal pathology. After preparation, an anterior 180-degree circumanal incision is created in the perineal body (if one still exists) approximately 1 cm distal to the dentate line (Fig. 27-10A). A flap of skin and rectal wall is elevated in the cephalad direction for 4 to 5 cm to expose the midline scar and adjacent edges of the sphincter complex (Fig. 27-10B). Lateral dissection into the ischiorectal fat provides for further identification and mobilization of the sphincters, but care must be taken to avoid injury to the pudendal nerve as it enters the sphincter complex from the posterolateral direction. Separation of the internal and external aspects of the sphincter is optional because this does not affect repair outcomes. The posterior aspect of the vagina and its adjacent perineal skin is dissected off the midline scar, and the scar is divided but not excised as it plays a crucial role in the repair (Fig. 27-10C). Once mobilization is complete, judgment is made as to whether an overlapping or abutting end-to-end repair is performed to avoid undo tension on the repair and allow the tip of the small finger or 15-mm dilator into the anus (Figs. 27-10D, 27-10E). Slow-dissolving (e.g., polydioxanone) or permanent (polypropylene) monofilament sutures are used to create a layered

horizontal mattress closure (routinely two layers three sutures deep) using the scar as suture support wherever possible. The perineal body is then closed with or without the presence of a closed suction drain. The closure frequently must be in a vertical direction, creating a T or Y configuration (Fig. 27-10F), which helps to recreate the perineal body. Postoperative care in terms of early versus late feeding, iatrogenic constipation versus early stool softeners and bulk-forming laxatives have not shown a difference in outcomes from the repair.<sup>29</sup> Complications are usually minor in most series and include urine retention and superficial wound infections (approximately 15%) leading to delayed healing.<sup>30</sup> Sitz baths and meticulous perianal hygiene is recommended to decrease wound complications, and the drain, if left in, should remain until drainage is less than 5 mL in 24 hours. The anal sphincteroplasty has also been combined with anterior levator plication or, through a posterior circumanal incision, a Parks' postanal levatorplasty with only fair long-term results.<sup>9</sup>

The effectiveness of sphincteroplasty alone for chronic injuries, both with overlapping and end-to-end technique, has been reported in a number of retrospective and prospective case series with a variety of clinical outcomes, incontinence scores, QOL, and physiological measures used. Most reports show 71% to 98% early improvement after anal sphincteroplasty<sup>30</sup> with approximately 66% of patients (52% to 83%) having excellent to good overall outcomes.<sup>3</sup> Factors that may lead to early poor outcomes have not been completely delineated. Diversion with a stoma at the time of initial repair has not been shown to improve outcomes,<sup>31</sup> although it may improve outcomes after subsequent repairs.<sup>5</sup> It is unclear whether the status of the pudendal nerve (specifically, PNTML duration) at the time of initial repair has an impact on the final sphincteroplasty outcomes as there are mixed results in the literature about the effect of both unilateral and bilateral PNTML delay.<sup>3,5,19,23–25</sup> Age has similarly shown a mixed impact on results while obesity and longer duration of incontinence before repair has been shown to have a negative impact on outcomes.<sup>5</sup> Reoperations for recurrent sphincter defects after prior reconstruction have not precluded good outcomes.<sup>25,30</sup> Finally, adjunctive measures such as the use of postsphincteroplasty biofeedback have shown improved outcomes versus sphincteroplasty alone.<sup>3,27</sup>

The most concerning aspect of anal sphincteroplasty is the long-term efficacy of the repair. It was originally believed that the repair had exceptional longevity. Unfortunately, recent studies have brought this into doubt. Halverson and Hull did a telephone survey at a median of 69 months postrepair of 49 of 71 patients, of whom 54% were incontinent to liquid stool and only 14% had complete continence.<sup>32</sup> This was in comparison to early results of the study showing 19% incontinence to liquid stool and 49% having total continence. A similar follow-up questionnaire study in 74 of 86 patients at 40 months postrepair showed a 28% complete continence rate, down from 49% at 3 months postoperatively.<sup>31</sup> Other studies with follow-up at 5 to 10 years showed rates of total continence of 0% to 42%, having decreased from initial total continence rates of 49% to 64%.<sup>3</sup> The reason for this time-dependent diminution is unclear, but it is likely related to gradual repair separation, pudendal nerve deterioration, or age effects on the pelvic floor musculature.<sup>3</sup> Women must be counseled before the initial sphincter repair

**Figure 27-10 Sphincteroplasty technique.** *A*, Anterior curvilinear incision. *B*, Flap dissection and identification of the underlying musculature and scar (facilitated by a self-retaining retractor such as the Lone Star [Lone Star Medical Systems, Stafford, Tex.]). *C*, Mobilization and central division of the anal sphincter. *D*, Creation of overlapping muscle repair. *E*, Creation of end-to-end muscle repair. *F*, Closure of the incision in a Y- or T-shape to facilitate re-creation of the perineal body.

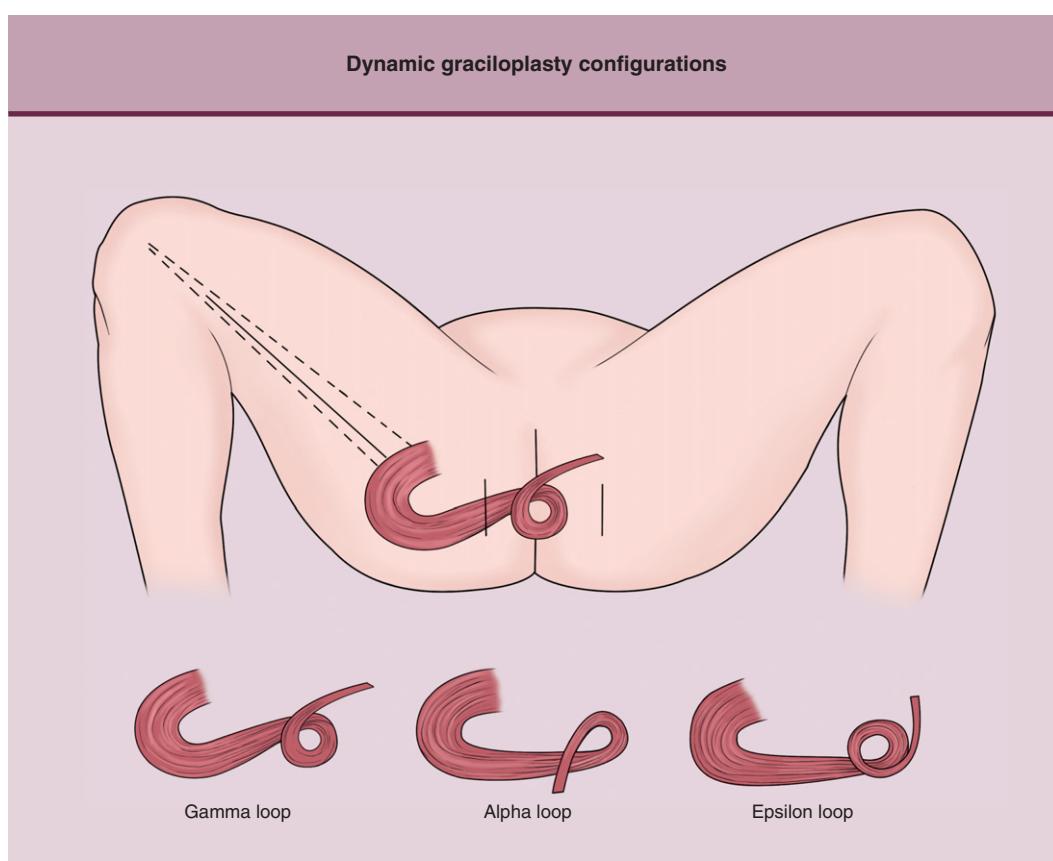

that reoperation or further treatments may be necessary in the future even if initial procedures are successful.

### **Dynamic Graciloplasty**

For patients who have failed anal sphincteroplasty, have nerve injury-related incontinence not responsive to nonoperative management, or congenital anomalies leading to fecal incontinence, attempts at creation of a new sphincter have been undertaken. Often inspired by similar attempts in the treatment of urinary incontinence, neosphincters for fecal incontinence have been created through the use of both autologous and artificial tissue. The first attempts with autologous tissue were undertaken through the use of muscles in proximity to the anal canal that could be allowed to maintain a neurovascular supply and provide some tonicity or resistance to improve continence. Initial trials were with sartorius, gluteus maximus (gluteoplasty), or gracilis (graciloplasty) muscle wraps.<sup>33</sup> These each involve wrapping at least a portion of the respective muscle through subcutaneous tunnels around the anal canal. Sartorius wrap results were poor due to the segmental neurovasculature, making effective wraps difficult. The initial gluteoplasties were done as early as 1902.<sup>33</sup> Case series for gluteoplasties developed again in the 1980s when favorable results were found in approximately 60% of patients, but because of the gluteus muscle's function in routine activities, patients had to limit those activities for almost a month after the operation, and it potentially led to long-term disability.<sup>33</sup> The graciloplasty also showed favorable results in initial series in the early 1950s, but these "passive" wraps had

inconsistent results because of fatiguing of the voluntary, type II, fast-twitch muscle fibers of the gracilis.<sup>33</sup> This prompted the addition of an implantable stimulating generator to convert these fibers into type I, slow-twitch, fatigue-resistant, involuntary muscle fibers.<sup>3,33</sup> This then led to the development of the stimulated or "dynamic" graciloplasty in the late 1980s.

Dynamic graciloplasty usually involves two steps. The first is the creation of the wrap by freeing the insertion of the gracilis muscle from the medial thigh through one long or two or three smaller incisions on the thigh and ligating the vessels to the distal two thirds of the muscle. The proximal neurovascular bundle from the obturator nerve and deep femoral vessels is preserved as the muscle is mobilized enough to be tunneled around the anal canal guided by one or two perianal/perineal incisions. A 360-degree wrap is then performed in any of three configurations (Fig. 27-11) to allow the new insertion to be created to the ischial tuberosity or adjacent skin.<sup>33,34</sup> Creation of a diverting stoma at that time is optional but does not appear to limit infectious complications and has been shown to prolong time to continence by 6 months.<sup>34</sup> The second step, which some surgeons perform at the time of the first operation, is placement of the pulse generator (in a lower abdominal subcutaneous pocket); this may be performed 6 to 8 weeks after the initial procedure (the generator is turned on in 6 weeks if placed at the first operation). The leads from the generator are implanted in the gracilis muscle near the main nerve trunk to facilitate conversion to slow-twitch muscle fibers. The generator is started 3 days later and is slowly increased in intensity over the course

**Figure 27-11 Options for graciloplasty configurations.**

## Urogynecology

of 8 weeks, eventually being left on continuously except when the patient turns it off to allow defecation. Because of the difficulty of the operation and risk for infection, it is contraindicated in patients with inflammatory bowel disease, neuromuscular disease, perianal infections, cancer, poor functional or mental status, pregnancy, or presence of a cardiac pacemaker or defibrillator.<sup>33,34</sup>

As with most of the technically demanding and experimental techniques for fecal incontinence, there are no randomized, controlled trials studying the use of dynamic graciloplasty.<sup>3</sup> Therefore, most of the outcome data come from more recent large, prospective, multicenter case series. Overall, despite varying definitions and outcomes measured, most reports show a success rate of approximately 60% (42% to 85%) and show that centers with greater experience have better outcomes with fewer complications.<sup>3,33,34</sup> Physiologic studies post-transposition consistently show improved sphincter tone with graciloplasty, but QOL studies have not always correlated with this improvement.<sup>34</sup> Mortality rates for most series have been 0, but other studies have had death rates of up to 13% (when cancer deaths are excluded), usually related to cardiopulmonary complications in small series.<sup>33</sup> Overall, the mortality rate is considered to be approximately 2%.<sup>33</sup> Morbidity rates range extensively, and many studies show substantially more complications than patients, showing that many patients have multiple complications and approximately 40% need reoperation.<sup>33,34</sup> In the larger series, these morbidities include major and minor infections (13% to 30%), apparatus failure (12% to 18%), chronic pain (13% to 28%), and constipation (19% to 23%).<sup>34</sup> Fortunately, despite the high complication rate, even patients with complications can have good outcomes after treatment.<sup>30</sup> Still, dynamic graciloplasty continues to be an experimental treatment best performed on highly selected, well-informed patients at high-volume centers.

### **Artificial Neosphincter**

Whereas the dynamic graciloplasty creates an autologous neosphincter, an artificial implantable neosphincter has also been developed to attempt to recreate the effect of an intact sphincter mechanism. The device was initially developed in the 1970s for use in the treatment of urinary incontinence but was successfully used in the late 1980s for fecal incontinence.<sup>35</sup> The device was then modified to a three-component mechanism (Fig. 27-12) for the treatment of fecal incontinence that includes an inflatable “sphincter” cuff implanted around the anal canal, a pressure-regulating reservoir in the retroperitoneum, and a control pump placed in the labia (or scrotum), all connected by kink-proof tubing. It functions by maintaining tonic filling of the cuff and thus closure of the anal canal until the pump is used to deflate the cuff into the reservoir and allow defecation to occur. The device is implanted after antibiotic prophylaxis through at least two perianal/perineal incisions and one lower abdominal incision (for the reservoir pocket) and then allowed to heal for 6 to 8 weeks before actually activating the system.

The indications for placement of the device have been limited due to the high cost and high complication rate associated with the device. It has primarily been reserved for patients who have congenital abnormalities, traumatic sphincter injuries or failed surgical repairs not amenable to further correction, or severe

neurologic dysfunction.<sup>35</sup> As expected with the placement of a foreign body around the anal canal, the most common and devastating complications are infection and/or device erosion requiring explantation.<sup>3</sup> Other complications have included device malfunctions, chronic pain, persistent incontinence, and fecal impaction, all potentially necessitating removal or revision of the device.<sup>3,35,36</sup> In a review of 13 case series (there are no available randomized, controlled trials evaluating the use of the artificial neosphincter), including a multicenter trial with 112 patients, approximately 33% required explantation and 13% to 50% required surgical revision.<sup>36</sup> This was primarily due to an infection rate of approximately 25% (range, 4% to 38%) and an erosion rate of approximately 18% (range, 6% to 25%). Rates of postoperative fecal impaction ranged from 6% to 83% and chronic pain from 4% to 17%.<sup>36</sup>

Despite these potentially devastating complications, those patients that retain their devices in a functioning state have shown a statistically and clinically significant improvement in incontinence scores and QOL based on a variety of assessment tools.<sup>35,36</sup> Unfortunately, only one of the studies presents results on an intention-to-treat basis (showing an overall success rate in 53% of 97 patients<sup>35</sup>); therefore, no firm conclusions can be made as to the overall impact on continence and QOL of the artificial sphincter. Because firm conclusions cannot be drawn, it is as yet unclear whether there is a subset of incontinence patients who would more substantially benefit from the artificial neosphincter. However, as the multicenter trial by Wong and colleagues concluded:

... there were no life-threatening complications with its use..., and it can be concluded that this procedure is a safe alternative for patients with end-stage fecal incontinence when no other medical or surgical treatment options exist.<sup>35</sup>

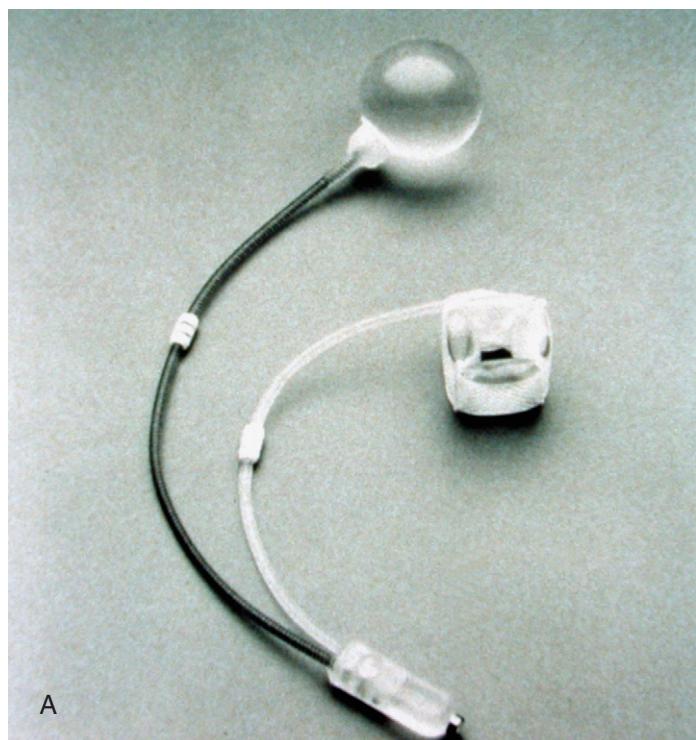

### **Sacral Spinal Nerve Stimulation**

Sacral nerve stimulation, or the use of an implantable device to stimulate the sacral nerves to contract the pelvic musculature, was first explored and approved by the U.S. Food and Drug Administration (FDA) in the late 1990s for use with urinary incontinence. It was noted that some of these early patients had improved fecal continence concordant with improved urinary continence; therefore trials for fecal incontinence were started in 1995.<sup>37</sup> The technique is still not widely available because it has not yet been approved by the FDA, but has been used in more than 1300 patients in trials for fecal incontinence.<sup>38</sup>

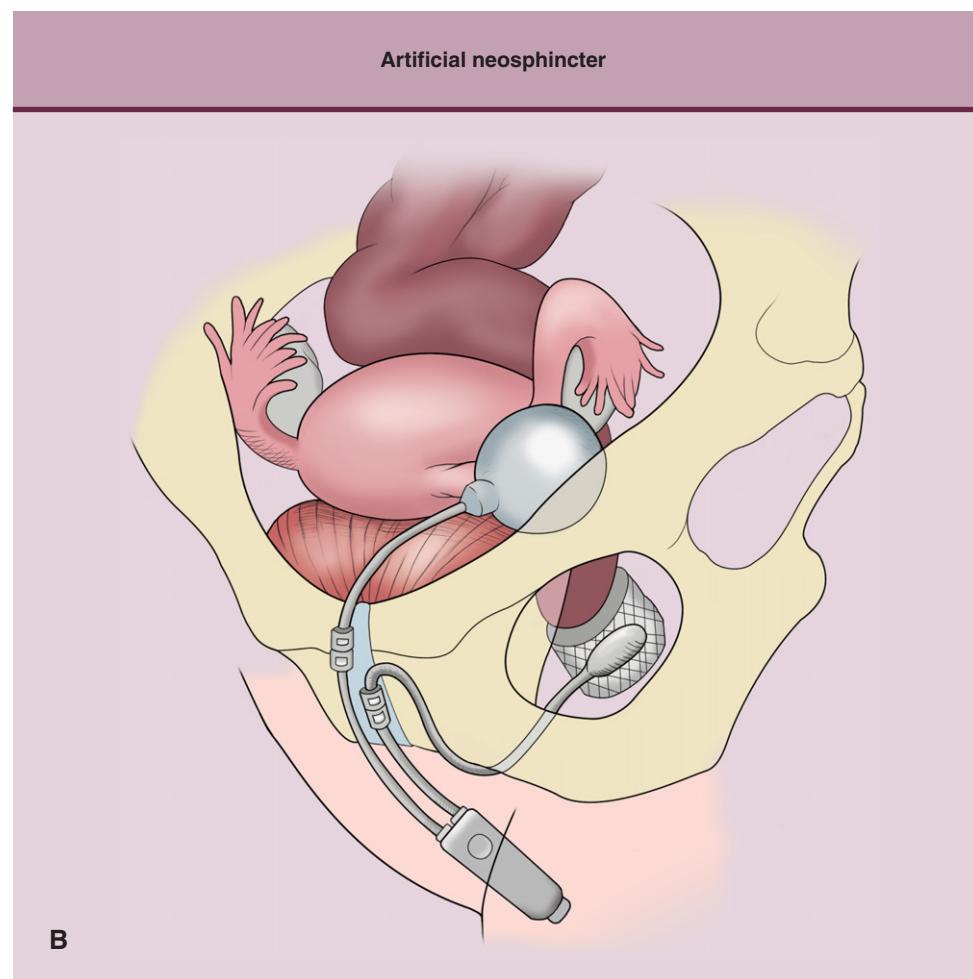

The procedure involves three steps (two diagnostic, one therapeutic) focusing on appropriate placement of electrodes into the dorsal foramina of S2–S4 that elicits the best anal sphincter contraction. The first step is performed in the operating room and involves a temporary stimulation of each of the bilateral sacral nerves to identify whether there is in fact a response from the pelvic musculature and thus confirm that the nerves are intact and adequate muscle is present. If there is an appropriate response, the second step is undertaken with continuous stimulation of the nerves (discontinued only to allow for voiding or defecation) for 2 to 3 weeks depending on the degree of incontinence. This step is initiated by attaching an external pulse generator to newly placed permanent electrodes

or longer-lasting temporary percutaneous electrodes. Various settings on the pulse generator are then tested to identify which are the most effective prior to permanent implantation of the generator in the third step (with permanent electrode placement if needed). The greatest benefit of this device, therefore, is that its efficacy is confirmed prior to permanent implantation, unlike other implantable devices for incontinence.<sup>30</sup>

The indications for the device have broadened as more patients with varying etiologies of their incontinence have been tested. It is now felt to be indicated in any incontinent patient with an anal sphincter and any residual muscular and reflex function, and it is contraindicated in those with severe psychological or mental deficiencies or those without sphincters, with large sphincter defects, with sacral injuries/abnormalities preventing electrode placement, or with implanted cardiac pacemakers or defibrillators.<sup>37,38</sup> Because the indications have broadened, there has been a heterogeneous population of patients tested for a variety of endpoints. Although further controlled testing is clearly indicated to make firm conclusions about these devices, the conglomeration of preliminary studies have shown that a majority of patients have improved continence scores and QOL (most showing 75% to 100% improvement, with 41% to 75% reaching “complete” continence).<sup>37,38</sup> Possible complications

A

**Figure 27-12 Artificial neosphincter apparatus (A) and appearance after implantation (B).**

(occurring in up to 50% of patients) include pain, generator or lead malfunction, or infection (no neurologic infections have been reported), lead dislocation requiring replacement, and deterioration or complete loss of effect.<sup>37</sup> The longevity of the results in most of these trials, however, has been excellent as long as generator and lead function has been maintained. Physiologic testing results, on the other hand, have been more inconsistent despite the subjective continence and QOL improvements.<sup>37,38</sup> This lack of clear change in physiology underscores the lack of understanding as to how this technique actually improves continence. Theories have included increasing the presence of

type I, fatigue-resistant muscle fibers in the anal sphincter and increasing blood flow from autonomic nervous system effects.<sup>38</sup> Regardless of the mechanism, the use of sacral nerve stimulation will likely play a prominent role in the care of fecal incontinence in the future.

#### **Secca Procedure**

Similar to the Stretta procedure for esophageal reflux disease, the Secca procedure (Curon Medical, Fremont, Calif.) uses temperature-controlled radiofrequency energy applied to the anal canal to attempt to create scarring in the internal sphincter, theoretically leading to improved anal canal apposition and resting pressures and thereby improving control.<sup>39</sup> The procedure is usually performed on an outpatient basis with local anesthesia, and the energy is applied through the use of a custom anoscope with needle electrodes (Fig. 27-13A) that apply the energy deep to the anal mucosa on varying levels (Fig. 27-13B). Initial data was encouraging based primarily on QOL improvement and few complications.<sup>39</sup> A subsequent multicenter trial by Efron and colleagues for a variety of etiologies of incontinence showed good subjective results without objective improvement in physiological measurements, thus bringing into question the true mechanism of the technique's effectiveness.<sup>40</sup> There were 3 complications out of 50 patients: two mucosal ulcerations and one postoperative bleed.<sup>40</sup> Despite the initially promising results, however, the procedure has yet to be tested on a larger scale so as to gain FDA approval or wider acceptance, likely due to the lack of data on any long-term sequelae of the procedure.

#### **Fecal Diversion**

Creation of a colostomy or ileostomy when all other methods at improving continence have failed or are not practical is a viable means by which to relieve the social stigma of fecal incontinence and improve quality of life. Although they are not without the potential for complication and may present anesthetic and post-operative care dilemmas in the weak and frail, diverting stomas can be considered a "cure" for unremitting fecal incontinence. Performing these laparoscopically is a viable option for some patients to improve initial postoperative recovery.

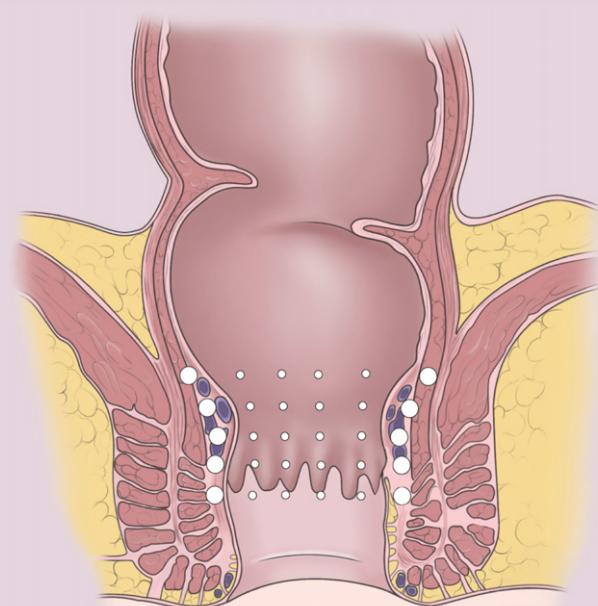

#### **PITFALLS AND CONTROVERSIES**

The first controversy in the realm of fecal incontinence is identifying a universally accepted definition and QOL indices. Other issues include developing protective strategies for preventing injury to the anal sphincters at the time of childbirth, effective methods for sphincter repair at the time of injury, and trying to identify the risk factors for fecal incontinence in women that can be altered to prevent injury. In addition, the diagnostic evaluation for fecal incontinence is far from standardized—both from a symptom/QOL standpoint as well as a physiologic and anatomic testing standpoint. Although endoanal ultrasound has provided an improved diagnostic modality, the use of manometry, EMG, and PNTML is still common despite data suggesting that the latter two are outdated and ineffectual at best. Finally, none of the listed treatment modalities have been tested in well-constructed, controlled trials with long-term follow-up to confirm their efficacy and longevity; therefore, the best treatments are left up to the surgeon and their experience with the various techniques.

## KEY POINTS

- Urinary incontinence is a common condition of epidemic proportions.
- History and physical examination, although a must, is not an accurate way to diagnose different types of urinary incontinence.
- Urodynamic testing is not a single test but rather a collection of various different tests that are done individually or more commonly in conjunction.
- The purpose of urodynamic testing is to objectively reproduce the patient's symptoms in a laboratory environment.

## HISTORY

History taking is at the center of all medical evaluations because it yields an appropriate diagnosis for most symptoms. Unfortunately the overlapping, nonspecific, and nonpathognomonic nature of most urologic symptoms results in failure of the history to establish a correct diagnosis in a significant number of patients. It has been suggested that urologic history is only 60% accurate in establishing the correct diagnosis.<sup>1</sup> For example, urinary frequency and urgency are symptoms common to several different conditions, such as overactive bladder, interstitial cystitis, and urinary tract infections. Despite this shortcoming, every patient presenting with urogynecologic complaints must go through a complete history because it will guide the clinician in obtaining appropriate tests as well as help in diagnosing comorbid conditions such as diabetes insipidus. The history should include obstetric, gynecologic, medical (including review of systems and medications), surgical, and family histories (Table 28-1). It is helpful to have the patient fill out a complete medical and urogynecologic questionnaire before her consultation. This allows the patient to write down her chief complaint in her own words as well as giving her a chance to be more complete about her history. This approach allows clinicians to be more efficient and gather a larger amount of data.

Urinary incontinence is a prevalent condition, which may or may not affect a patient medically, socially, or psychologically. It is important to elucidate the most bothersome symptom during the interview process. It is important to note daytime and nighttime urinary frequency, urgency, the frequency and quantity of leakage, provoking factors, and factors that improve or worsen urine loss. It is imperative to understand which if any of these symptoms affect the patient's quality of life. This will be the guiding principle behind further investigations and treat-

ment. Table 28-2 gives examples of direct questions that might be helpful in assessing an incontinent patient.

## Voiding Diary

The voiding diary is an important part of the evaluation of urinary incontinence and could be considered the first urodynamic screening test (Fig. 28-1). The length of time a voiding diary is kept can vary significantly. A 1-week diary has been shown to be reliable in assessing urinary frequency, nocturia, and the number of incontinence episodes.<sup>2</sup> Ideally a patient fills out a complete diary for 1 to 2 typical days before her consultation, and the physician reviews this with her.

Urinary incontinence is often episodic and situational. It is most useful when the patient keeps the voiding diary on her most typical days (i.e., a work day, a day spent at home, and a day spent running errands). When a patient fails to complete the diary she should be given another opportunity to do so. The voiding diary can also be used to evaluate responses to treatment. During the initial visit, when the physician reviews the diary, he or she should obtain a subjective history on various voiding parameters. This is helpful in pointing out some of the subjective perceptions that are not confirmed with the diary. The voiding diary is not only a useful evaluation tool, but it can also be a very powerful treatment tool.

The voiding diary should include the following (Table 28-3):

- Type, amount, and times of fluid intake
- Time and amount of voids
- Leakage episodes
- Amount of leakage (e.g., mild, moderate, or severe)
- Events such as urgency or whether activities such as coughing or sneezing immediately precede the leakage episode

The following information should be gathered or calculated from the voiding diary:

- Average daily fluid intake and urine output
- Pattern of fluid intake (e.g., more during daytime or right before going to bed)
- Maximum and average functional bladder capacity
- Urinary frequency during daytime and after falling asleep (This should be compared with the information obtained during subjective history taking.)
- Number of leakage episodes per day and type of leakage (stress vs. urge)

The voiding diary may help the clinician to come up with a working diagnosis such as stress or urge incontinence. It may also provide more objective evidence for information obtained during history taking or may contradict the subjective history and indicate that the patient may have overestimated her

## Urogynecology

**Table 28-1**  
**Components of the Urogynecology-related History**

Obstetrical history	Number of deliveries, vaginal deliveries, birth weights, complications, including lacerations and episiotomies
Gynecologic history	Menstrual history, birth control, hormone replacement therapy, sexual history and sexually transmitted infections, results of previous Pap smears and mammograms, history of urinary tract infections
Surgical history	History of all surgical procedures and associated complications, including anesthetic complications; particular attention to pelvic surgeries and urologic surgeries and associated complications
Medical history	General medical history, with special attention to conditions that may affect urogynecologic disorder, including diabetes, neurologic conditions such as multiple sclerosis and Parkinson's disease, mental status, mobility status All current medications with doses, medications that can affect urinary incontinence or lower urinary tract function, including: diuretics, beta agonists and antagonists, alpha agonists and antagonists, psychotropic medications such as antidepressants and antipsychotics Current allergies
Social history	Alcohol, tobacco, and caffeine abuse

**Table 28-2**  
**Assessment of an Incontinent Patient**

Condition and/or Symptom	Helpful Questions
Stress incontinence	Do you leak urine with strenuous activity such as coughing, sneezing, laughing, lifting, bending, pushing, pulling? Do you leak with an empty or full bladder? Do you leak with straining in the lying-down position?
Urinary urgency and urge incontinence	How frequently do you void during the daytime? How frequently do you wake up to void after falling asleep? Do you have a strong urge to void? Can you make it to the bathroom with the strong urge to void? Do you leak urine on your way to the bathroom?
Voiding difficulties and/or urine retention	After you empty your bladder, do you feel you emptied well? Do you have any difficulty starting the stream? Do you have any difficulty maintaining the stream? Do you feel your stream is strong? Do you have to push to void? Do you have frequent bladder infections?
Severity of leakage	How often do you leak? How much do you leak? Do you use pads? How many pads do you go through in a typical day? How wet are these pads when you change them?
Painful bladder conditions and/or interstitial cystitis	Do you have any pain with a full bladder? Does the pain get better after voiding? Do you have any suprapubic pain or pressure? Do you have any urethral, vaginal, or perineal pain? Do you have any pain with intercourse? Do you feel a strong urge to void at once? Do you void frequently during the day? After falling asleep? Is there any pain or burning with urination? Is there any blood in the urine?
Prolapse	Do you have any bulge or lump protruding from your vagina? Do you have any pelvic pressure? Do you have any difficulty voiding? Do you have any difficulty starting or maintaining the stream? Do you have postvoid fullness? Do you have any difficulty emptying your bowels? Do you have to push vaginally to evacuate your bowels?
Urinary tract infections and other urologic conditions	Do you have recurrent bladder infections? Do you see blood in the urine? Do you have a history of kidney or bladder stones?
Quality of life	Are bladder symptoms bothersome? Do they interfere with the quality of your life (e.g., not able to exercise or attend social functions)? Do you have to know where all restrooms are when you go out? Do you plan your day around your bladder? Do you decline invitations to social functions due to concerns related to bladder control? Have you declined certain jobs due to your bladder condition(s)?

symptoms. The voiding diary may show that significant consumption of certain types of fluid, such as caffeinated drinks, carbonated beverages, and alcohol, coincides with the episode of urinary incontinence and/or frequency. It may establish a pattern of urine loss during certain times of the day, suggesting an associated factor, such as use of diuretics. The diary may suggest excessive fluid intake as a cofactor in urinary frequency and incontinence. Output greatly in excess of input, as indicated by the diary, is suggestive of diabetes insipidus.

The voiding diary can help guide treatment; that is, timed voiding, commonly used for the treatment of overactive bladder, requires the patient to void more frequently at the onset of treatment than her usual frequency. Usual frequency can be established based on her typical voiding pattern as recorded in her diary.

**Pad Test**

The pad test is used for an objective quantification of urinary incontinence. Although its use is generally limited to research protocols, it can be used in a clinical setting in those patients in whom urinary incontinence cannot be demonstrated objectively during clinical examination or urodynamic testing. Various versions of pad tests, ranging from 20 minutes to 48 hours, have been described in the literature. The original 1-hour pad test was described by Sutherst and colleagues.<sup>3</sup> In this study the author demonstrated that a post-test pad weight increase of 1 g/hr or greater is considered abnormal. The International Continence Society has standardized the pad test (Fig. 28-2).<sup>4</sup> The pad test cannot help diagnose the type of urinary incontinence, but it may provide some estimation of the severity of urinary incontinence. Interested readers should read the review by Ryhammer and colleagues.<sup>5</sup>

## PHYSICAL EXAMINATION

Physical examination, like the clinical history of the patient, is not always helpful in patients with urinary incontinence, but it may further guide the investigation and treatment. Hence, a focused physical examination is an integral part of any evaluation for urinary incontinence. The goals of physical examination should include evaluating patients for (1) future surgical candidacy, (2) physical changes due to previous pelvic and/or urinary tract surgeries, (3) the state of urethral and other pelvic organ

Rights were not granted to include this figure in electronic media.  
Please refer to the printed publication.

support structures, and (4) exclusion of neurologic and/or other pelvic pathologies as the cause for her urinary incontinence.

### Abdominal Examination

A general abdominal examination should be performed with attention to obesity and peritoneal signs. Special attention should be devoted to previous surgical scars because they may provide important details that might not have surfaced during the

## Urogynecology

interview process. The abdomen should also be inspected for incisional and inguinal hernias. The abdomen should be palpated in an attempt to reproduce any pain that the patient may have reported. Specific attention should be paid in palpation of the suprapubic area for pain, distended bladder, and midline masses. Percussion of the suprapubic area may aid in recognizing the distended bladder.

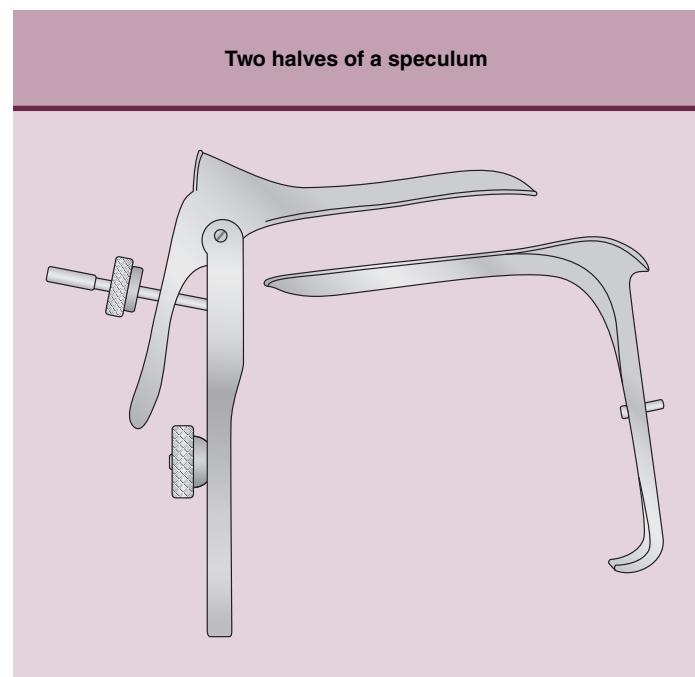

### Pelvic Examination

A complete gynecologic examination, including speculum examination, bimanual examination, and rectovaginal examination, should be performed on all incontinent patients. Gynecologic examination should begin with inspection of the external genitalia. The pelvic structures should be evaluated for any abnormality. Vaginal discharge, estrogen status, and excoriation of skin should be noted. On occasion vaginal discharge may mimic urinary incontinence. If no objective evidence for urinary incontinence is found in this patient, she should be treated for vaginal discharge. Signs suggestive of atrophic vaginitis, such as thin and friable vaginal mucosa and vulvar skin, loss of vaginal rugae, and urethral caruncle, indicate a hypoestrogenic state in the lower urinary tract. Although controversial, estrogen may have some role in the treatment of certain lower urinary tract symptoms. (This discussion is beyond the scope of this chapter, but the interested reader can review two meta-analyses by Cardozo et al<sup>6</sup> and Al-Badr.<sup>7</sup>) After a thorough examination of the vulva, the vagina should be inspected and examined. Vaginal atrophy should be noted. The anterior vaginal wall should be palpated for pain and masses. Painful urethra and bladder may suggest conditions such as urinary tract infection or interstitial cystitis. A suburethral mass with expression of pus from the urethra may suggest urethral or bladder diverticulum. The presence of a mass on the anterior vaginal wall necessitate ruling out carcinomas, Gartner's duct cyst, and other inflammatory conditions of the urethra.

Defects in pelvic organ support commonly coexist with urinary incontinence. Clinicians are expected to treat these two conditions concomitantly. Therefore, a complete examination evaluating all defects is mandatory. The choice of treatment for one condition will often guide the treatment for a coexisting condition. For example, a patient who seeks correction of prolapse via vaginal route may want to consider a vaginal procedure such as a suburethral sling to correct coexisting urodynamic stress urinary incontinence rather than an abdominal procedure such as the Burch procedure. The two halves of the vaginal speculum (Fig. 28-3) can be used sequentially to detect defects in the anterior compartment (cystocele, urethrocele), central compartment (uterine prolapse, enterocele, posthysterectomy vaginal vault prolapse), and posterior compartment (rectocele, enterocele). Prolapse is graded using a system as per personal preference. A complete speculum examination and a bimanual examination are also performed at this time, noting any vaginal scarring and/or reduction in vaginal length and/or calibration from previous surgical interventions. Any pelvic masses should be evaluated further.

### Neurologic Examination

Many neurologic conditions have a significant urologic manifestation. Neurologic conditions with significant urologic

**Figure 28-3** The two halves of the speculum can be used to assess pelvic organ prolapses. (Courtesy of Medtronic Corporation, Minneapolis, Minn.)

symptoms include multiple sclerosis, Parkinson's disease, stroke, dementia, brain tumors, and spinal cord injury of various types. The urologic manifestations of these various neurologic diseases vary depending on the location of the lesion but include urinary urgency, frequency due to detrusor hyperreflexia, and/or urinary retention due to detrusor hypoactivity. In general, lesions involving upper motor neurons cause detrusor hyperactivity (hyperreflexia) and lesions involving lower motor neurons cause hypoactive detrusor (acontractile detrusor).

Although most patients presenting with bladder symptomatology such as urinary urge incontinence and urine retention have no demonstrable nerve lesions (idiopathic), a small percentage of patients will present with urologic symptoms as their first sign of the neurologic disease. For example, 5%–10% of patients with multiple sclerosis present with urologic symptoms as their first signs of disease and up to 90% of MS patients will have urologic symptoms.<sup>8,9</sup> For this reason the clinician must be attuned to this possibility at all times. This requires the clinician evaluating incontinence to perform a focused neurologic examination, including evaluation of mental status and ensuring the integrity of motor, sensory, and reflex functions.

A mini-mental status examination can be performed (Table 28-4).<sup>10</sup> Alternatively, simple observation of the patient's orientation, speech, memory, level of consciousness, and comprehension may suffice to ensure adequate mental status.

Parasympathetic neurons originating from cord segments S2–S4 are the most important neurons involved in micturition (Fig. 28-4). There is also a significant contribution from sympathetic neurons originating from cord segments T10–L2. The rest of the neurologic examination is devoted to ensuring the integrity of these neurons. Sensory function can be evaluated with pinprick at the umbilicus (T10), labia majora (L1), labia minora (L1–L2), and all around the knee (L3–S2). Motor function can

be evaluated with extension and flexion of the knee (L3–S1), hip (L2–L5), and ankle (L4–S1). Abduction and adduction of the ankle will also evaluate L4–S1 motor function.

Finally, testing several reflexes ensures reflex function integrity. Gently stroking the labia majora with a cotton-tipped swab and observing for contraction of the anal sphincter or pelvic floor tests for the bulbocavernosus reflex. Gently stroking the clitoris with a cotton-tipped swab and observing for the contraction of the anal sphincter or pelvic floor tests for the clitoral

reflex. Presence of these two reflexes ensures the integrity of S2–S4. It should be noted that in some patients, especially in obese patients, these reflexes might be difficult to elicit; they might even be absent in some otherwise neurologically intact patients. Anal tone should also be evaluated at the time of pelvic examination. Deep tendon reflexes such as quadriceps (L3–L4), and Achilles (L5–S2) should also be evaluated. Presence of Babinski's sign will reflect an upper motor neuron lesion.

### Stress Test

As a part of a complete pelvic examination the patient is asked to perform a Valsalva maneuver or cough repetitively while leakage from the urethra is observed. Leakage that coincides with the straining is usually related to genuine stress incontinence, whereas the leakage that occurs a few seconds after the stress or persists after the stress event may be indicative of detrusor contraction. This test should be repeated after the patient has emptied her bladder, the so-called *empty supine stress test*. A positive empty supine stress test is a sensitive test for genuine stress incontinence.

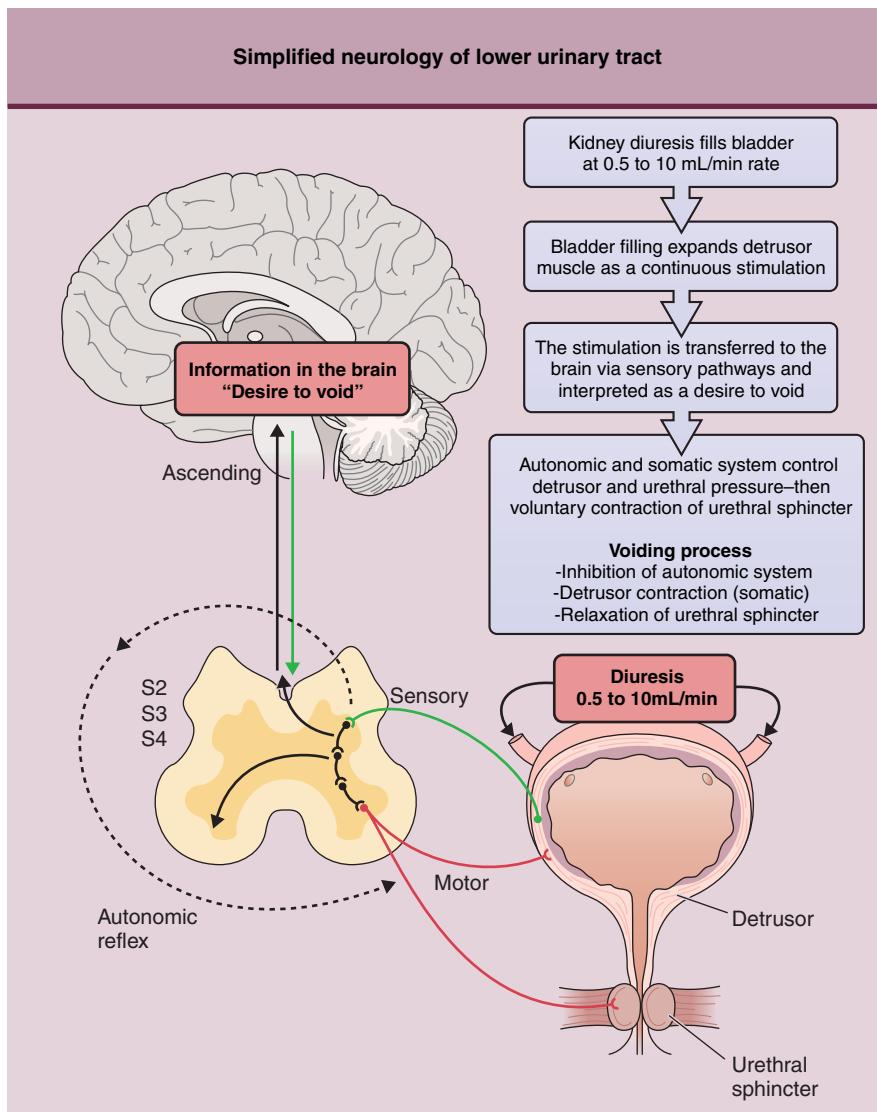

### Marshall-Marchetti Test

Also known as a Bonney test, the Marshall-Marchetti test is frequently used to identify urinary leakage due to urethral hypermobility and to assess whether supporting the vesicourethral junction will prevent stress incontinence. The patient with a full bladder is asked to perform a Valsalva maneuver or cough repetitively and leakage from the urethra is observed. At this point the vesicourethral junction is supported in a high retropubic position with the examiner's index finger. The patient is asked to repeat the test and absence of leakage is considered evidence for the presence of urethral hypermobility. False-positive results may occur as a result of urethral occlusion from the examiner's fingers and render this test less sensitive and of limited use.<sup>11</sup>

### Q-tip Test

The Q-tip test is a very sensitive test, although nonspecific for the diagnosis of genuine stress incontinence. It is a simple, inexpensive test that may shed more light on possible pathophysiology of the patient's incontinence. While the patient is in a supine position, the urethra is prepared with povidone-iodine solution and a well-lubricated cotton-tipped swab, preferably lubricated with lidocaine jelly, is inserted into the urethra. Once the swab is felt to be in the bladder, it is pulled back slowly until resistance is met at the vesicourethral junction. The resting angle is measured in relation to the horizontal axis (floor) using a goniometer (Fig. 28-5A). The patient is then asked to perform a Valsalva maneuver and/or cough repeatedly until maximum deflection of the swab is observed. The straining angle is then measured against the horizontal axis (Fig. 28-5B). Deflection greater than +30 degrees to the horizontal axis is considered abnormal and is called *urethral hypermobility*.

The normal resting angle is not well defined but is generally considered to be between –5 degrees and –30 degrees. Generally speaking the resting angle has little clinical significance except at the time of surgery, when it may be used to judge adequate fixation of the vesicourethral junction. During a retropubic operation such as a Burch urethropexy or bladder neck sling,

**Figure 28-4 Simplified neurology of lower urinary tract.** Please note parasympathetic neurons originating from sacral cord segments S2–S4 are the most important neurons involved in the micturition process. (Courtesy of Medtronic Corporation, Minneapolis, Minn.)

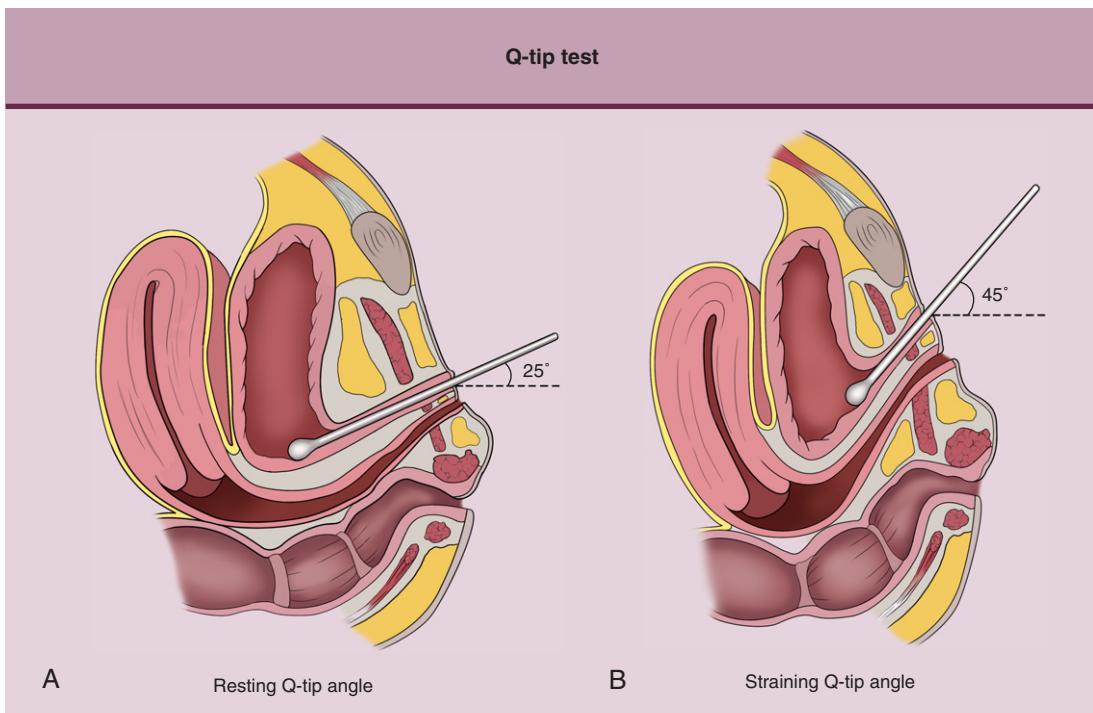

this author routinely uses the Q-tip to fix the resting angle at 0 to -5 degrees.

As stated earlier, urethral hypermobility is not diagnostic of genuine stress incontinence but is suggestive of it.<sup>12</sup> Although most patients with genuine stress incontinence will have urethral hypermobility, not all with urethral hypermobility have genuine stress incontinence. Patients who demonstrate a negative Q-tip test (i.e., no urethral hypermobility) and have symptoms of stress incontinence will need a further workup to define the pathology responsible for their incontinence.<sup>12</sup> Many of these patients may have intrinsic urethral sphincter dysfunction and procedures such as the Burch urethropexy will have a high failure rate.

#### Postvoid Residual Check

Postvoid residual check is an important part of all pelvic examinations performed in an incontinent patient. There is no universally accepted value that is considered abnormal.<sup>13</sup> Values ranging from 50 mL to more than 300 mL have been suggested as a clinically significant postvoid residual.<sup>13</sup> Postvoid residual,

including measurement, should be performed on multiple occasions. If a high value is obtained on a consistent basis, it should be viewed in context of voided volume and the potential symptomatology that the patient may have as a result of a high residual volume. For example, if two patients who voided 200 mL and 600 mL, respectively, both had residual urine measuring 150 mL, it might be considered more abnormal for the patient who only voided 200 mL. This concept is similar to the concept of ejection fraction for the heart and is based on the contractile efficiency of the bladder. We can further consider that the patient who voided 200 mL with 150 mL of residual may have symptoms such as urinary frequency and/or recurrent bladder infections. These symptoms may arise from the abnormal residual urine; their presence or absence may guide us further in deciding whether the high residual urine is clinically significant. Symptoms can guide the clinician to be more aggressive with treatment or be conservative with observation only. It is important to note that in some patients high residual urine volume could be the sole reason for incontinence in the form of overflow incontinence.

**Figure 28-5 Q-tip test.** A, Measurement of the resting urethral angle. Angle of measurement is made in relation to the horizontal axis (floor) using a goniometer. B, Measurement of the straining urethral angle. Angle greater than or equal to +30 degrees to the horizontal axis is considered abnormal and is termed urethral hypermobility. (Courtesy of Medtronic Corporation, Minneapolis, Minn.)

Many methods can be utilized to measure the postvoid residual volume. It can be estimated crudely with bimanual examination. Although it carries a small risk of urinary tract infection, transurethral catheterization is the most common method employed clinically for the accurate measurement of residual urine. Ultrasound scanning is becoming a more popular, noninvasive way to accurately and quickly measure the residual urine.<sup>14</sup> Residual urine can also be measured radiographically using contrast media.

### Other Laboratory Tests

#### *Urinalysis and Urine Culture*

Urinary tract infection can mimic many bladder symptoms, particularly urinary incontinence. For this reason any patient with urinary incontinence or worsening of previously stable urinary incontinence should first have a urinalysis with or without urine culture before any extensive workup or invasive treatments. This should be viewed just as critical as getting an electrocardiogram (EKG) in a patient with complaints of chest pain. Patients with microscopic hematuria may need further workup, including urine cytology, intravenous pyelogram, and urethrocystoscopy.

### URODYNAMIC TESTING

Urodynamic testing is not a single test but rather a group of various tests that can be performed individually or in various combinations. In its simplest form it can involve insertion of a simple catheter with a measuring device; in its complex form it

may involve sophisticated computerized electronics with special catheters. The purpose of urodynamic testing is to help clinicians objectively understand the function of the lower urinary tract. It objectively confirms the suspected diagnosis based on historical information about the patient in a laboratory setting. The test must be performed by, or in the presence of, the interpreter so that an accurate interpretation of data can be made as it is being collected, unlike an EKG.

The use of urodynamic testing is controversial, with more areas of disagreement than agreement. With the introduction of midurethral slings for genuine stress incontinence, the controversy surrounding urodynamic testing seems to be heating up once again. Rationalization regarding urodynamic testing remains of interest.<sup>15</sup> Traditional reasons for not doing urodynamic testing include complex equipment, special training, cost, patient discomfort, and a chance of lower urinary tract infection. However, most importantly, as stated by Dr. Blaivas, there will be little argument on the conclusion of many studies that suggests “neither symptoms nor response to treatment correlate very well with the specific urodynamic diagnosis.”<sup>15</sup> Supporters of urodynamic testing have stated many benefits, including more precise diagnosis, more objective information on an otherwise very subjective clinical history of a urinary incontinent patient, and possible medicolegal issues. Despite the controversy there is little disagreement that certain groups of patients would clearly benefit from urodynamic testing. These groups of patients are listed in Table 28-5.

A closer look with specific examples gives the real flavor of this important controversy. One group of patients with lower

**Table 28-5**  
**Patients who Require Urodynamic Testing**

- Mixed symptoms
- Failed conservative therapy after simple evaluation
- Patients with voiding difficulties
- Urine retention
- Surgical candidates

urinary tract symptomatology who are not uncommonly treated empirically without urodynamic testing is patients with symptoms of overactive bladder. Overactive bladder is a collection of symptoms, including urinary frequency, urinary urgency, and/or urinary urge incontinence.<sup>16,17</sup> A study at a large tertiary care urogynecology center involving 4500 patients with lower urinary tract symptoms who underwent urodynamic testing showed that almost 50% of the patients with overactive bladder symptoms have no urodynamic evidence of detrusor instability. These findings suggest that it would be medically inappropriate to treat these women's symptoms if there are no objective urodynamic abnormalities. However, further evaluation of these patients results in the detection of detrusor instability by other means.<sup>18</sup> A second example is that of a group of patients who have cough-induced detrusor instability. One of the important reasons for performing urodynamic testing in patients with symptoms of stress urinary incontinence is to rule out cough-induced detrusor instability, which may mimic genuine stress incontinence. Treating these patients surgically can significantly worsen their condition. Less than 5% of women with symptoms of stress urinary incontinence will have cough-induced detrusor instability.

### Urodynamic Terminology

The following are commonly used terms in urodynamic testing.

#### Urodynamic Setup

##### Position

The patient is generally sitting or standing (Fig. 28-6). Simple office cystometry can more easily be accomplished in a supine or lithotomy position. Changing to a more upright position is considered to be a provocative measure for the bladder and should be performed if the patient's symptoms are not reproduced.

##### Catheters

The catheters used during the test will be based on investigator's preference, experience, other equipment being used, and cost. Catheters can vary from a simple Foley catheter used for simple office cystometry to a more complex catheter containing an electronic transducer, which could be water filled or air filled (Fig. 28-7).

##### Filling Media

Various filling media can be utilized for the test. Most commonly water or physiologic saline are used. Carbon dioxide has been used as well (Fig. 28-8). The filling media is generally at room

**Urodynamic chair**

**Figure 28-6** Urodynamic chair adjusted for sitting position. (Courtesy of Medtronic Corporation, Minneapolis, Minn.)

temperature or body temperature. Cold solution can be utilized as a provocative measure.

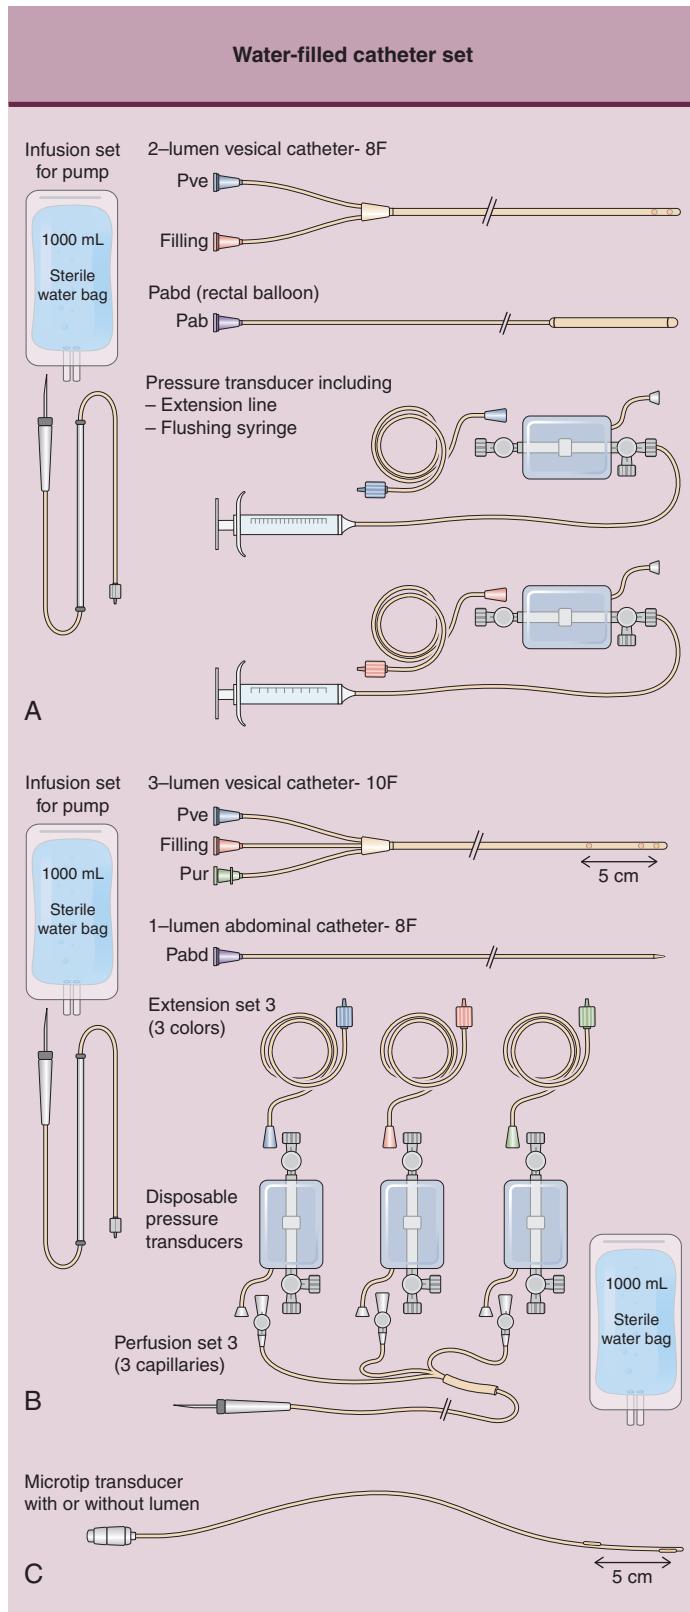

##### Filling Rate

The rate can vary. The International Continence Society has attempted to standardize this by defining a slow filling rate to be less than 10 mL/min, a medium filling rate to be between 10 mL and 100 mL/min, and a fast filling rate to be greater than 100 mL/min.<sup>19</sup>

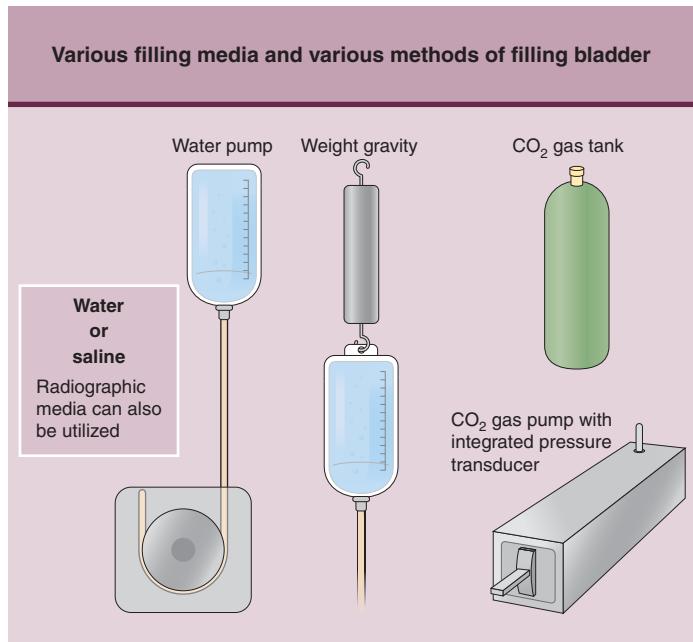

#### Urodynamic Measurements

Three principle pressures are simultaneously measured during the multichannel urodynamic testing: bladder, urethral, and abdominal. Single-channel urodynamic testing measures either the bladder or the urethral pressure at a time. They are depicted in the following fashion:

- **P<sub>Ves</sub>**—Vesical pressure (Fig. 28-9), directly measured by a catheter in the bladder, it is a summation of pressures produced by the detrusor muscle and external pressures (i.e., abdominal) on the detrusor.
- **P<sub>abd</sub>**—Abdominal pressure, measured by a catheter in the vagina or rectum, approximates the value of external pressures on the detrusor at rest before bladder filling. Its value should be approximately equal to P<sub>Ves</sub>.
- **P<sub>ura</sub>**—Urethral pressure, directly measured by a catheter in the urethra, it is a summation of pressures produced by the urethral sphincter muscle and bladder pressures.

**Figure 28-7 Catheter sets.** A, Water-filled catheter set; note the vesicle catheter depicted has only one port for pressure measurement. B, Water-filled catheter set; note the vesicle catheter depicted has two ports for pressure measurement. C, Microtip catheter; note that a double-tip catheter is depicted. (Courtesy of Medtronic Corporation, Minneapolis, Minn.)

**Figure 28-8 Various filling media and various methods of filling.** The bladder can be filled utilizing gravity and a mechanical pump as shown. (Courtesy of Medtronic Corporation, Minneapolis, Minn.)

Because the sphincteric activity along the length of the urethra is not equal, the pressure measurement made along the length will vary based on the location of measurement. The urethral pressure profile (UPP) is the graph or curve created by passing the catheter and measuring pressures along the length of the urethra (Fig. 28-10).

- **Pdet**—Detrusor pressure is a measurement calculated by the following formula:

$$\text{Detrusor pressure} = \text{bladder pressure} - \text{abdominal pressure}$$

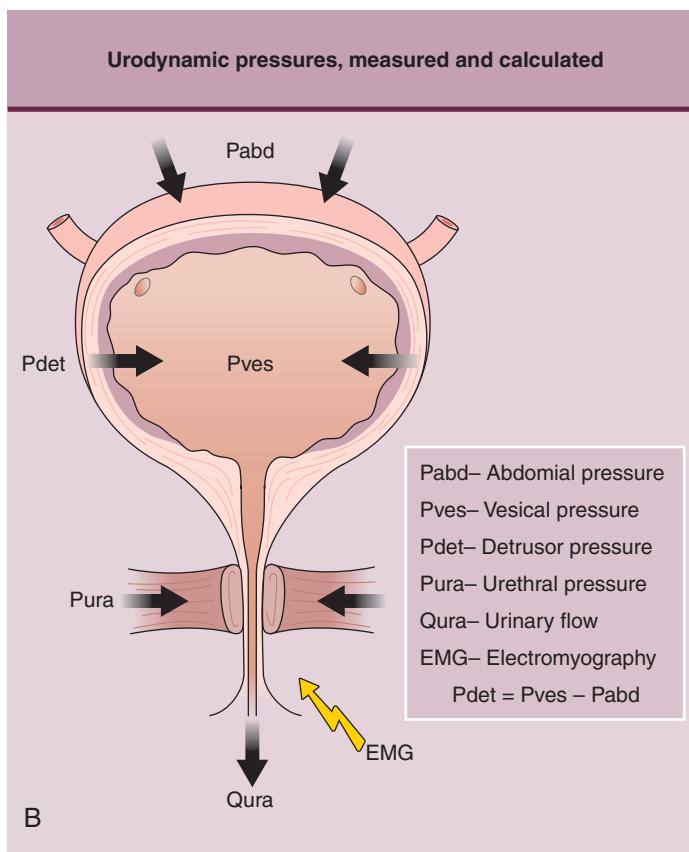

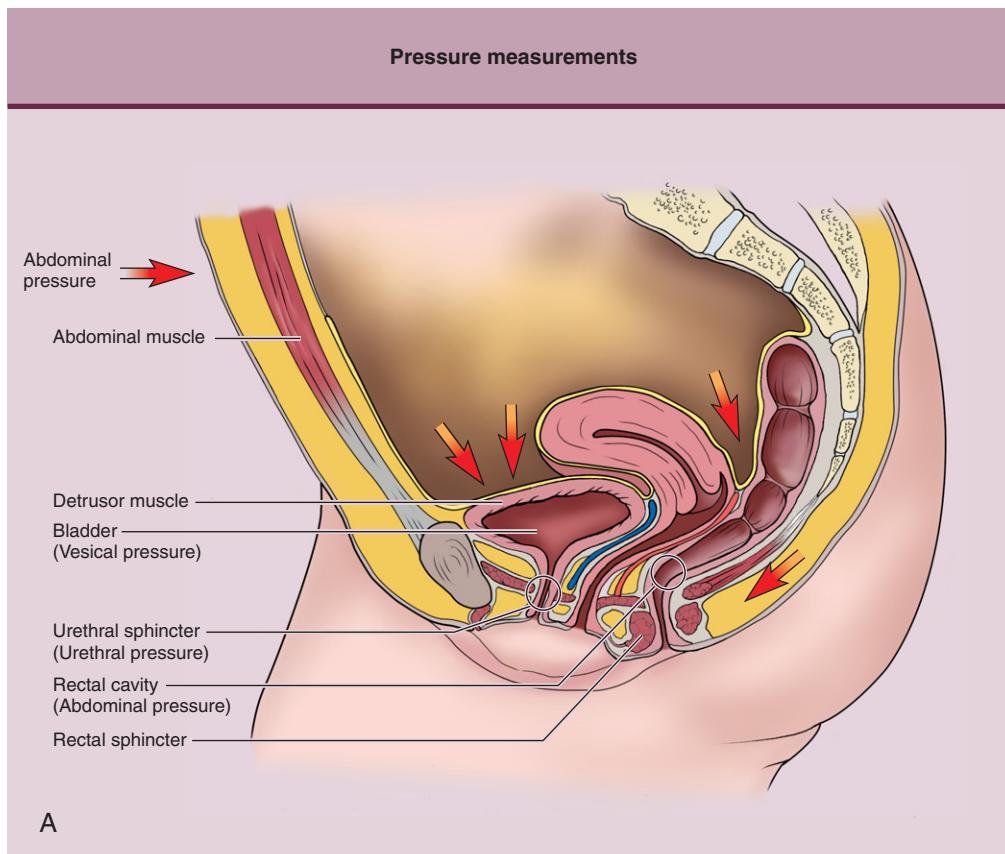

$$\text{Pdet} = \text{Pves} - \text{Pabd}$$

- **Pucp**—Urethral closure pressure is a measurement calculated by the following formula:

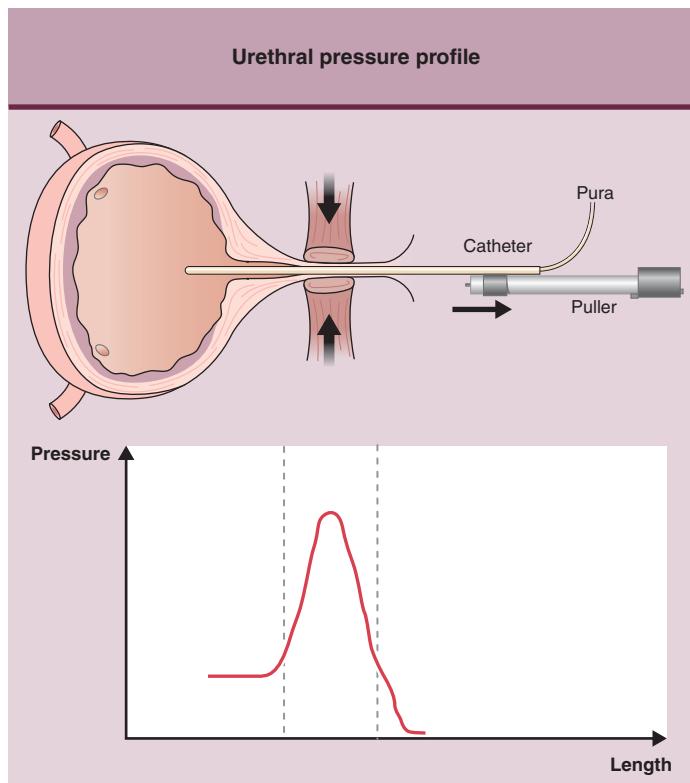

$$\text{Urethral closure pressure} = \text{urethral pressure} - \text{bladder pressure}$$

$$\text{Pucp} = \text{Pura} - \text{Pves}$$

Urodynamic testing evaluates the function of the bladder and urethra during two phases: storage (filling phase) and voiding. The maximum cystometric capacity is when a patient can no longer delay micturition. Functional bladder capacity is assessed from the voiding diary. VLPP (Valsalva leak point pressure) is the minimal Pves observed to cause leakage during the Valsalva maneuver in the absence of detrusor contraction. VLPP of less than 60 cm indicates severe stress incontinence and is defined as ISD (intrinsic urethral sphincter dysfunction). VLPP of 60 to 90 cm is considered to indicate moderate stress incontinence; 90 cm or greater is considered mild stress incontinence. DLPP (detrusor leak point pressure) is the true detrusor pressure that causes leakage in the absence of provocative maneuvers.

**Figure 28-9** Various pressure measurements that could be made or calculated during multichannel urodynamic testing. A, Measured. B, Measured and calculated. (Courtesy of Medtronic Corporation, Minneapolis, Minn.)

**Figure 28-10** The urethral pressure profile (UPP) is the graph or curve created by passing the catheter and measuring the pressures along the length of urethra. (Courtesy of Medtronic Corporation, Minneapolis, Minn.)

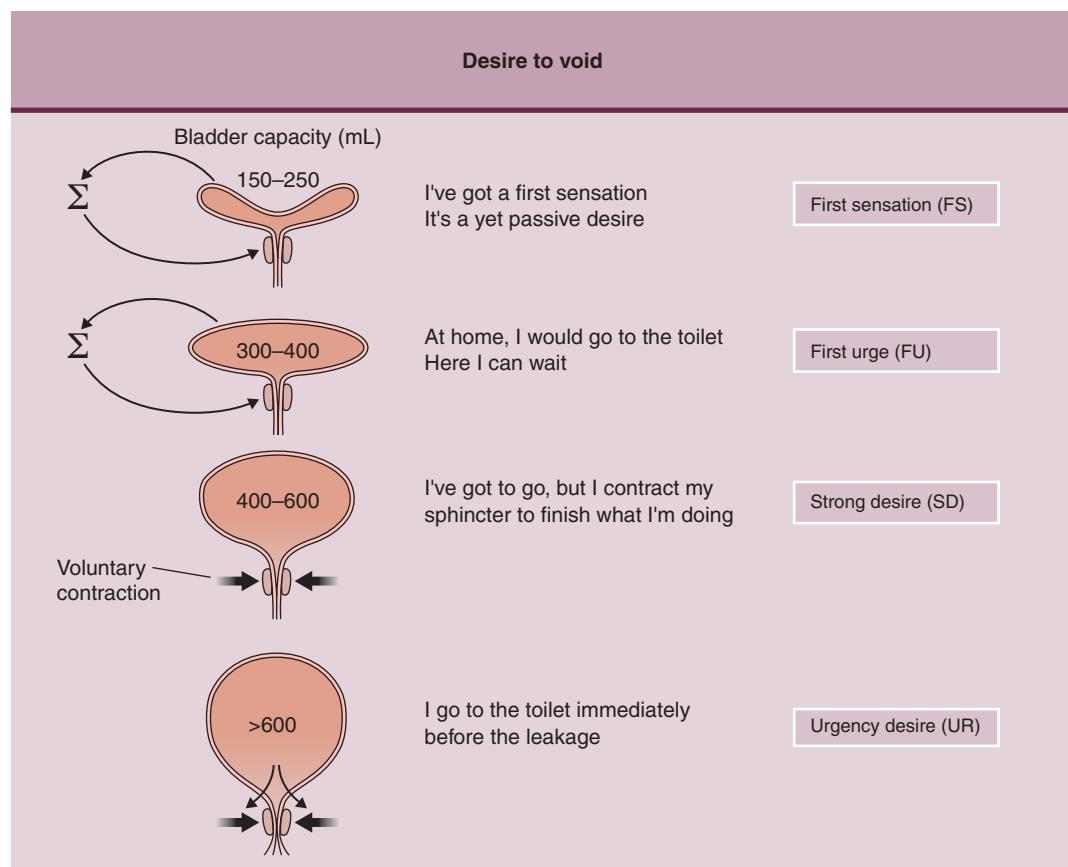

### Urodynamic Sensations

The following observations could be made during the filling phase by asking patients about their sensation. The *first sensation* or first desire to void is when the patient is aware that the bladder is filling and she could void. Volume is usually equal to 150 to 250 mL (Fig. 28-11). *First urge* or normal desire to void is when patient will pass urine at the next convenient moment and could delay if she needed to. Volume is usually equal to 300 to 400 mL. *Strong desire to void* is a persistent desire to void without the fear of leakage. Volume is usually equal to 400 to 600 mL. *Urgency* is a strong desire to void with fear of leakage. Volume is usually greater than 600 mL. *Ambulatory cystometry* involves measurement of abdominal and bladder pressure during natural filling of the bladder over the course of several hours in an ambulatory format.

### Urodynamic Diagnosis

*Compliance* is the bladder volume change per detrusor pressure change ( $\text{mL}/\text{cm H}_2\text{O}$ ). In a normal bladder capacity of 400 to 500 mL, a rise in detrusor pressure of 15  $\text{cm H}_2\text{O}$  or less is considered to be normal. Decreased bladder compliance is

**Figure 28-11** First sensation, first urge, strong desire, and urgency are the observations made during the filling phase by asking patients about their sensation. (Courtesy of Medtronic Corporation, Minneapolis, Minn.)

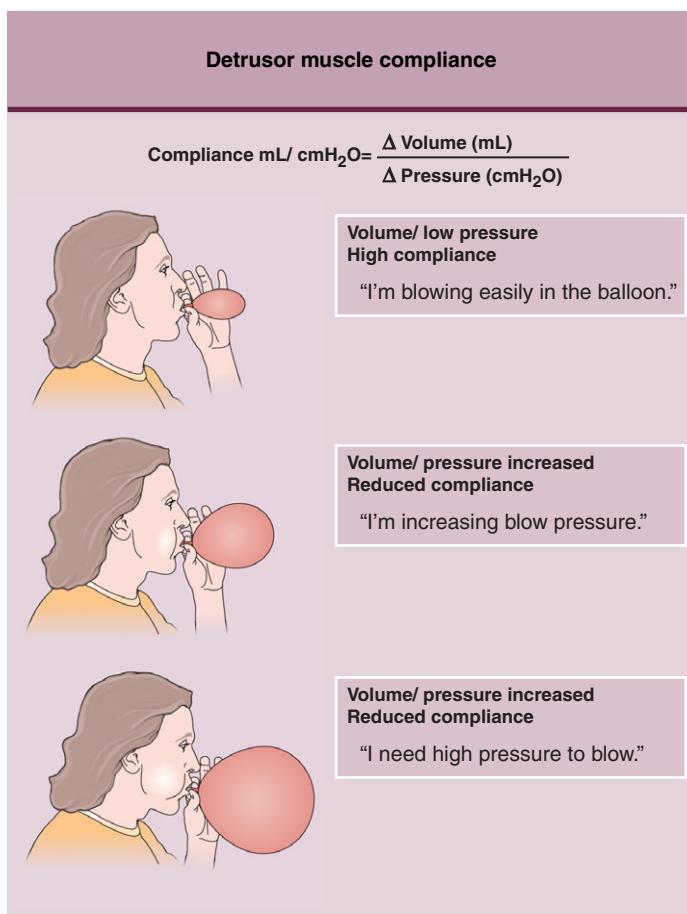

## Urogynecology

diagnosed when pressure rise at normal capacity exceeds 15 cm H<sub>2</sub>O (Figs. 28-12 through 28-14).

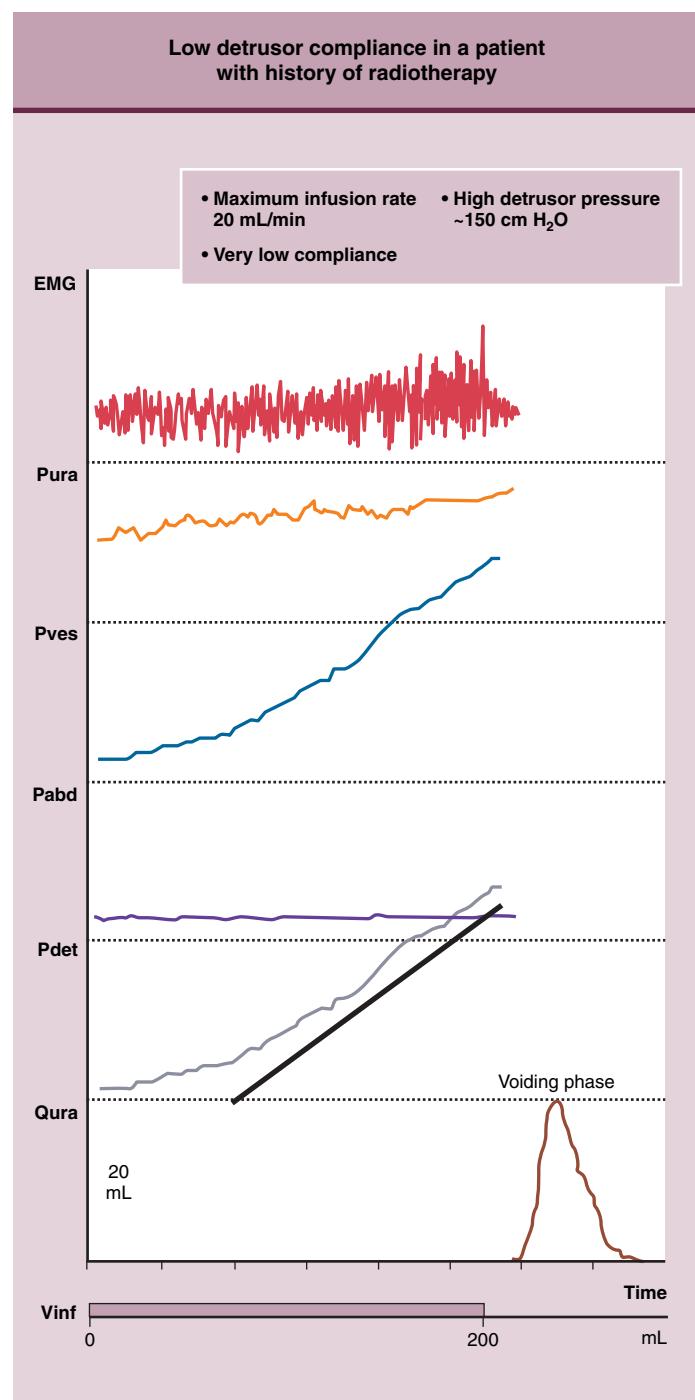

*Detrusor instability* is a urodynamic diagnosis. It is defined as the presence of spontaneous or provoked involuntary contraction during bladder filling in a patient with appropriate signs and symptoms. It is considered to be idiopathic in etiology (Fig. 28-15).

*Detrusor hyperreflexia* is the term used when there is a neurologic condition, such as multiple sclerosis, in a patient with spontaneous or provoked involuntary contraction during bladder filling, as well as appropriate signs and symptoms of the condition. Its etiology is considered to be an upper motor neuron disease (Fig. 28-16).

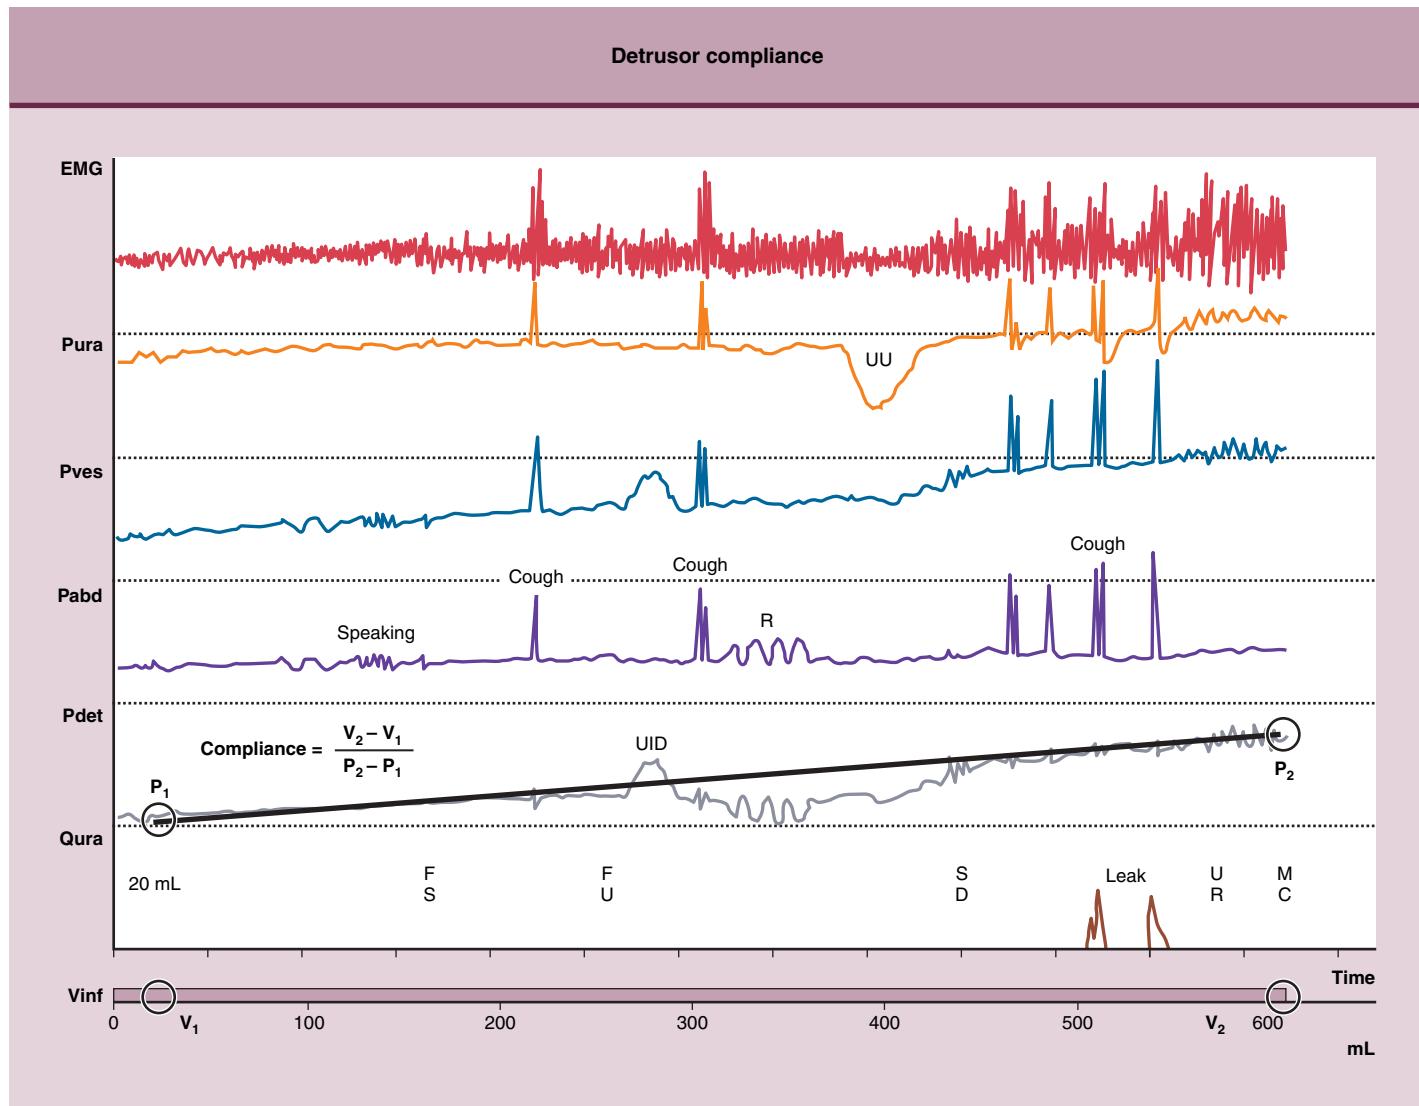

*Detrusor sphincter dyssynergia* is defined as lack of urethral relaxation with the bladder contraction. This could be a learned or conditioned response or may reflect upper motor neuron disease (Fig. 28-17).

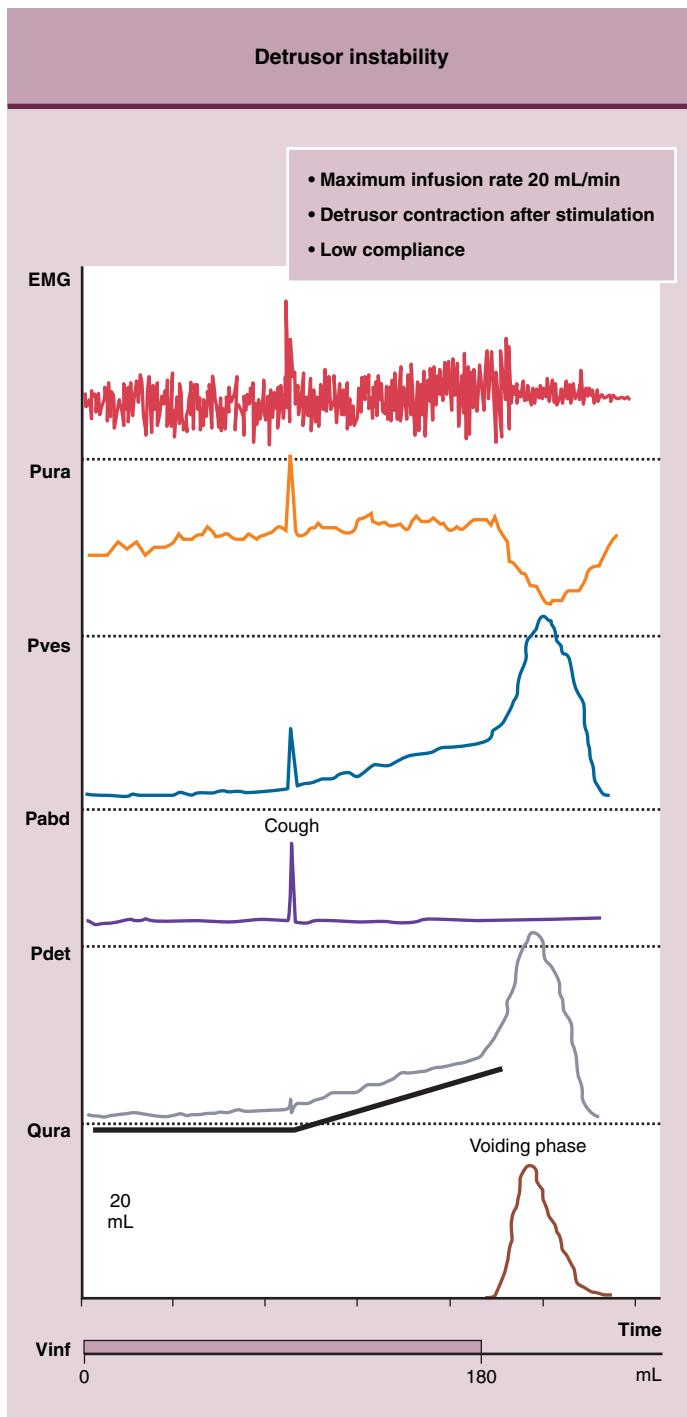

**Figure 28-12 Detrusor muscle compliance.** Under normal condition, the bladder is a very compliant organ. A large volume change in the bladder results in a minimal rise in detrusor pressure. (Courtesy of Medtronic Corporation, Minneapolis, Minn.)

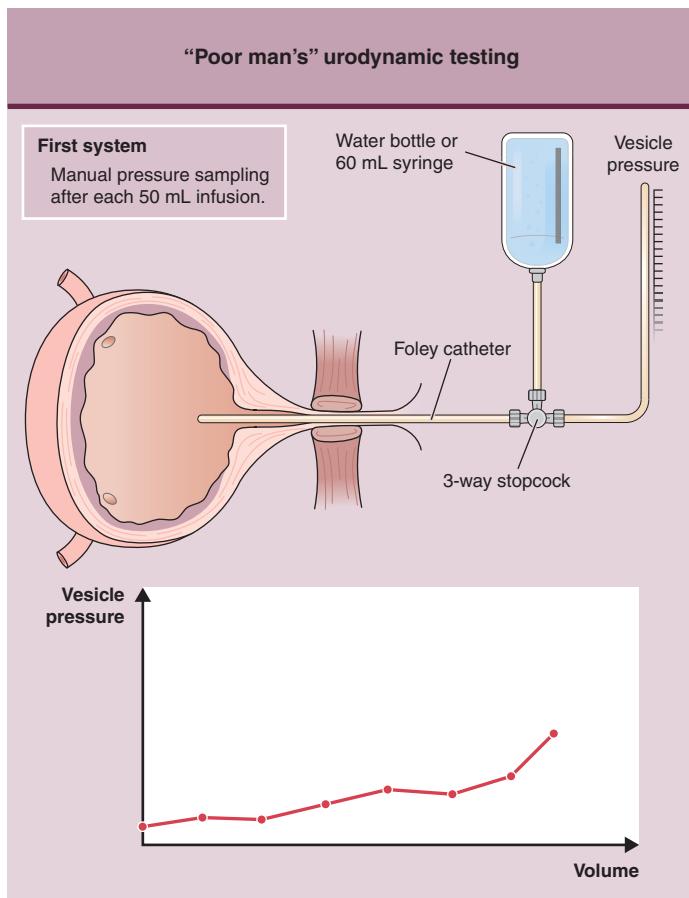

**Figure 28-17 Detrusor sphincter dyssynergia.** Note the electromyographic activity does not diminish and the urethra does not relax during the void. (Courtesy of Medtronic Corporation, Minneapolis, Minn.)

#### Types of Urodynamic Tests

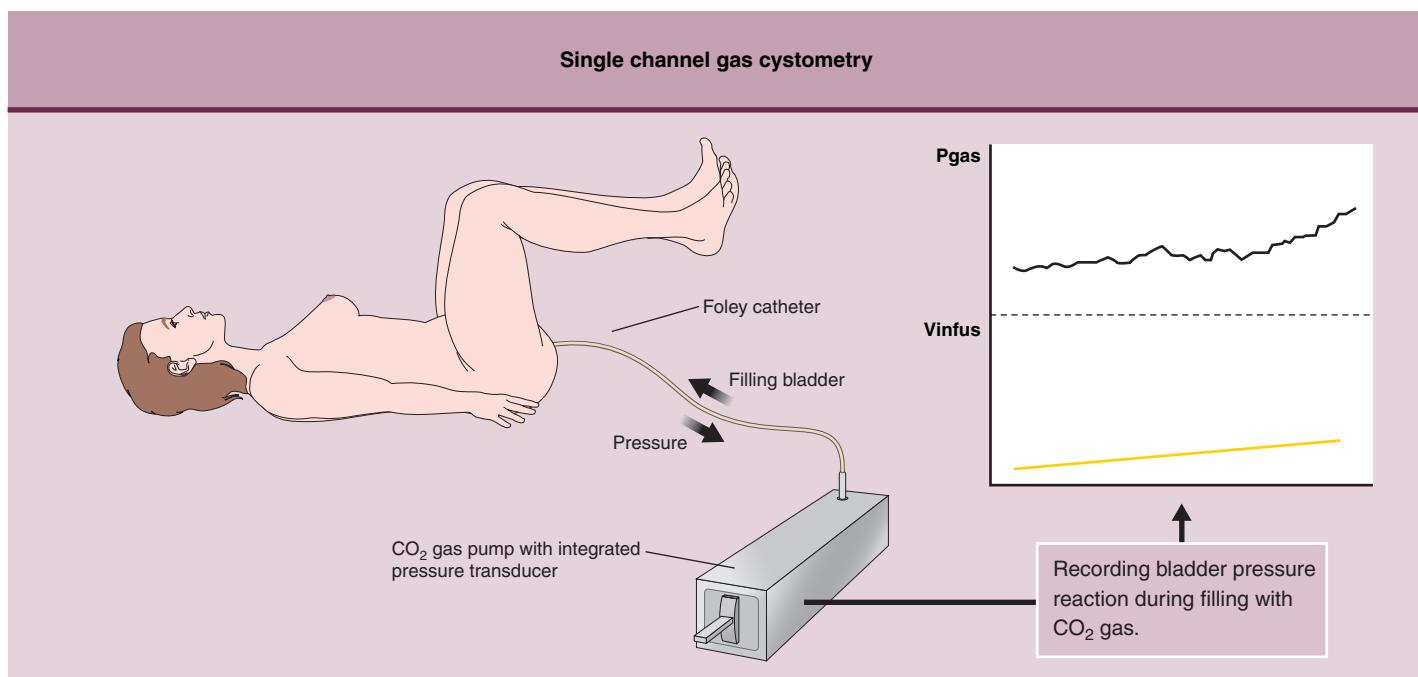

"Poor man's" or *bedside urethrocystometry* is performed with simple office equipment such as a Foley catheter and sterile water or saline (Fig. 28-18). In patients with an uncomplicated incontinence history, this test might be all that is necessary. It requires simple equipment readily available in most offices: a catheter, 60-mL syringe, graduated cylinder, and sterile saline solution. This test can be easily performed in supine lithotomy position using gynecologic stirrups. After a spontaneous void, the patient's urethra is cleansed with povidone-iodine solution and a postvoid residual is obtained and measured with a catheter. An empty supine stress test is performed at this point; if positive, the patient may need more sophisticated multichannel urodynamic testing to rule out the presence of intrinsic urethral sphincter dysfunction.<sup>20</sup> If negative, a 60-mL syringe without the bulb or plunger is connected to the catheter. The syringe is held at a level slightly higher than the bladder and is filled with

sterile saline solution to the 60-mL mark while pinching the catheter. Saline is then introduced into the bladder via gravity. The patient is asked to report the first sensation, first urge, and strong urge. Any rise in the meniscus during the filling is considered to be a sign of detrusor instability (the volume is noted at this point). If no change in meniscus is seen at a strong urge, the catheter is removed and a stress test is performed. Any leakage from the urethra concomitant with the stress event is considered to be positive for genuine stress incontinence. After the stress test is completed satisfactorily, a catheter can be reintroduced and more saline introduced until the maximum cystometric capacity is achieved. If no sign of detrusor instability is seen, provocative measures such as running water should also be carried out.

*Single-channel urethrocystometry* involves the measurement of urethral or bladder pressure only (Fig. 28-19). A single-channel cystometry test is performed in a fashion similar to

**Figure 28-18** “Poor man’s” urodynamic testing. Note that a bladder compliance curve can be drawn by making volume and pressure measurements during each syringe fill. (Courtesy of Medtronic Corporation, Minneapolis, Minn.)

**Figure 28-19** Single-channel cystometry shown with carbon dioxide as a filling media. (Courtesy of Medtronic Corporation, Minneapolis, Minn.)

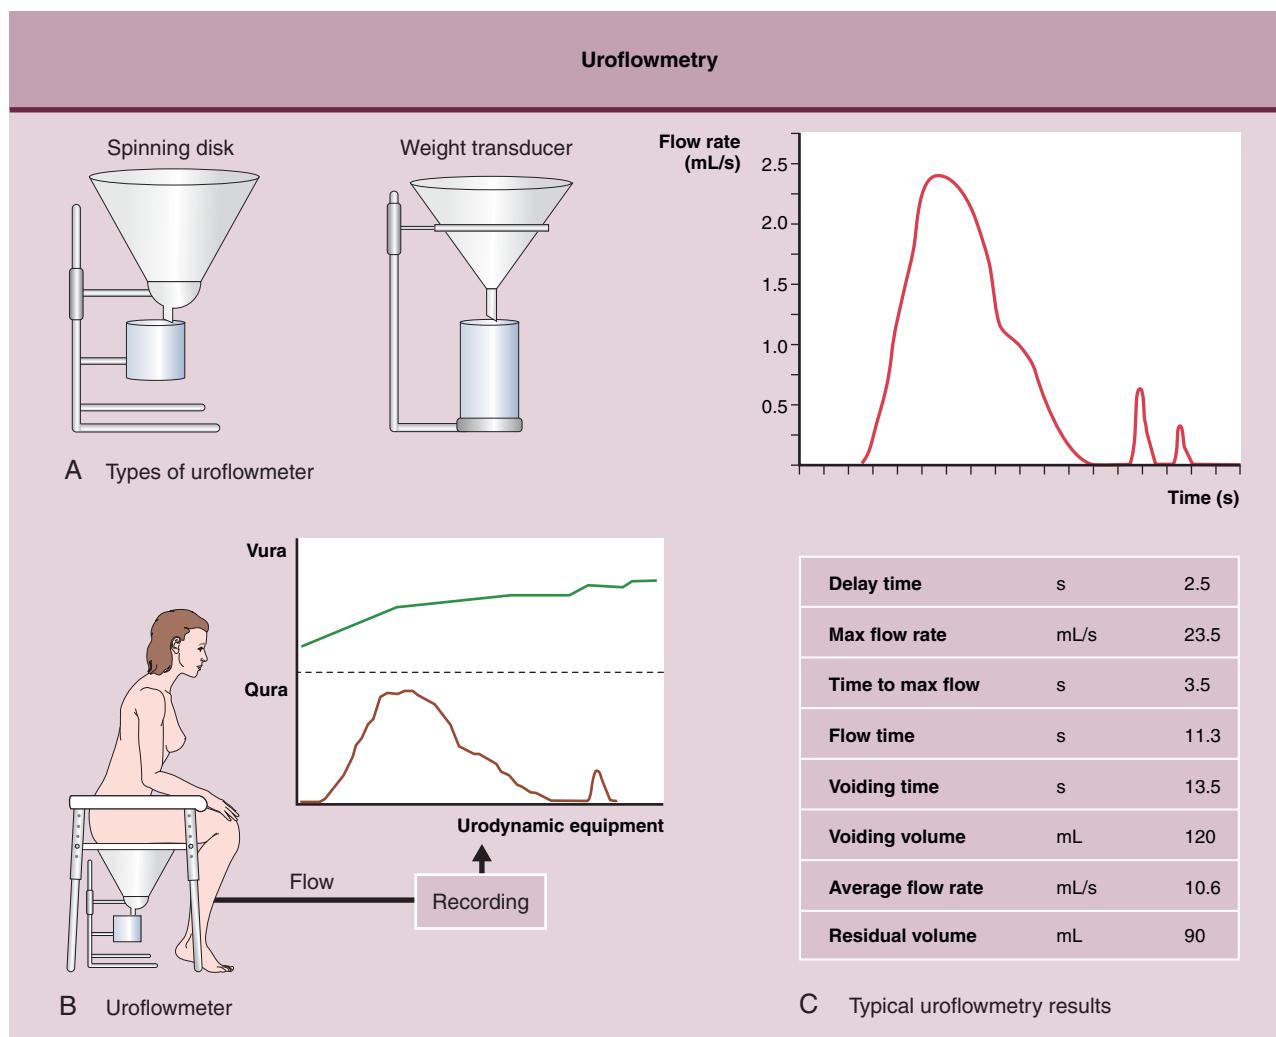

bedside testing with the exception that the pressure and volume measurement are made electronically. A catheter with a single pressure measuring port (see Fig. 28-7) is used to fill the bladder with saline solution or water. Various sensations are noted, as reported by the patient. An abnormal rise in bladder pressure ( $>15$  cm H<sub>2</sub>O at normal capacity) or involuntary contractions are noted along with the patient's sensation at the time. Because abdominal pressure (external pressure on detrusor) is not measured in single-channel cystometry, any rise seen in the pressure cannot be directly attributed to the detrusor muscle. This is the limiting factor of single-channel cystometry.

At bladder capacity the same catheter could be moved along the length of the urethra, either manually or by a mechanical pulley, to obtain a resting UPP. Dynamic UPP can be obtained in a similar fashion while the patient is performing various activities such as coughing or the Valsalva maneuver. Any leakage observed in the absence of a rise in bladder pressure can be diagnosed as

urodynamic stress incontinence. Leakage with a sustained rise in bladder pressure after the cough or Valsalva event may represent induced detrusor instability and require multichannel testing to confirm it.

Finally, voiding pressure studies can also be performed with single-channel testing. Because the urethral and bladder pressures cannot be measured simultaneously, it may be of limited use. Furthermore, if the bladder pressure is monitored during the test one cannot differentiate between Valsalva and/or detrusor effort during voiding.

Aside from cystometry, uroflowmetry is considered the next most important component of the multichannel testing. The patient is asked to come to the laboratory with a full bladder. As the name implies, uroflowmetry is the measurement of voided volume as a function of time (Fig. 28-20). Several measurements can be made from the uroflow including the time to initiate void, maximum and average flow rates, the time to maximum

**Figure 28-20 Uroflowmetry.** A, Types of uroflowmeter. B, Simple uroflowmetry: the measurement of voided volume as a function of time. C, Typical uroflowmetry results. (Courtesy of Medtronic Corporation, Minneapolis, Minn.)

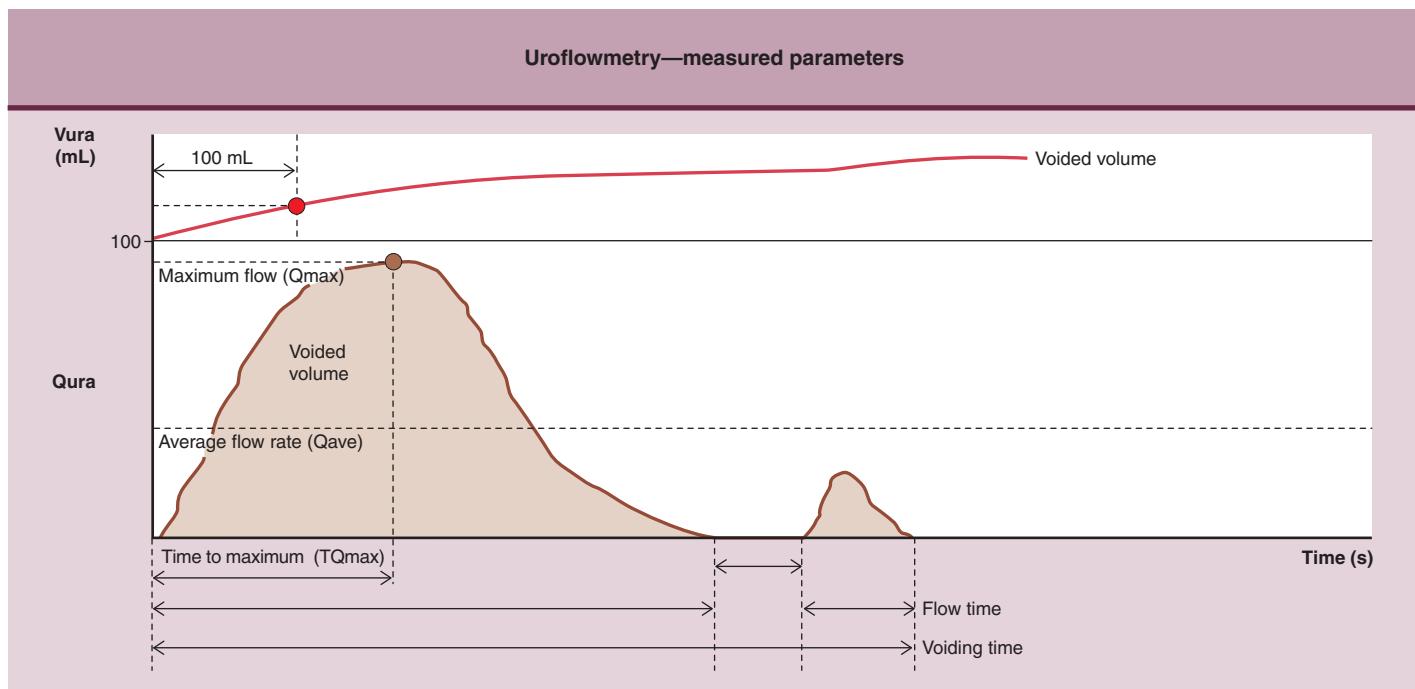

## Urogynecology

flow rate, voided volume, the total time for void, and the pattern of uroflow curve (Fig. 28-21). It is useful to remember the rule of 20s for normal uroflow parameters in female patients. A normal uroflow curve is singleton and bell-shaped. For normal parameters the patient must void at least 200 mL of urine over 20 seconds or less, with a maximum flow rate of at least 20 mL/sec. The uroflow pattern, although not diagnostic, may provide useful information (Fig. 28-22). A pattern with a high peak, indicating very high maximum flow rate, may suggest weak urethral closure pressures, intrinsic urethral sphincter dysfunction, or hypertonic detrusor contraction. Stop-and-go (intermittent) patterns may suggest detrusor sphincter dysynergia, bladder outlet obstruction from advanced prolapse, or Valsalva void. A pattern that is prolonged with a slow maximum flow rate may suggest hypotonic detrusor or increased urethral resistance due to partial obstruction from advanced prolapse or other causes. If the patient has abnormal uroflow parameters, she will need further studies such as the voiding pressure study, urethrocystometry, or an imaging study such as a voiding cystourethrogram to diagnose the etiology for the observed abnormality. This is particularly important in any patient who might be a surgical candidate.

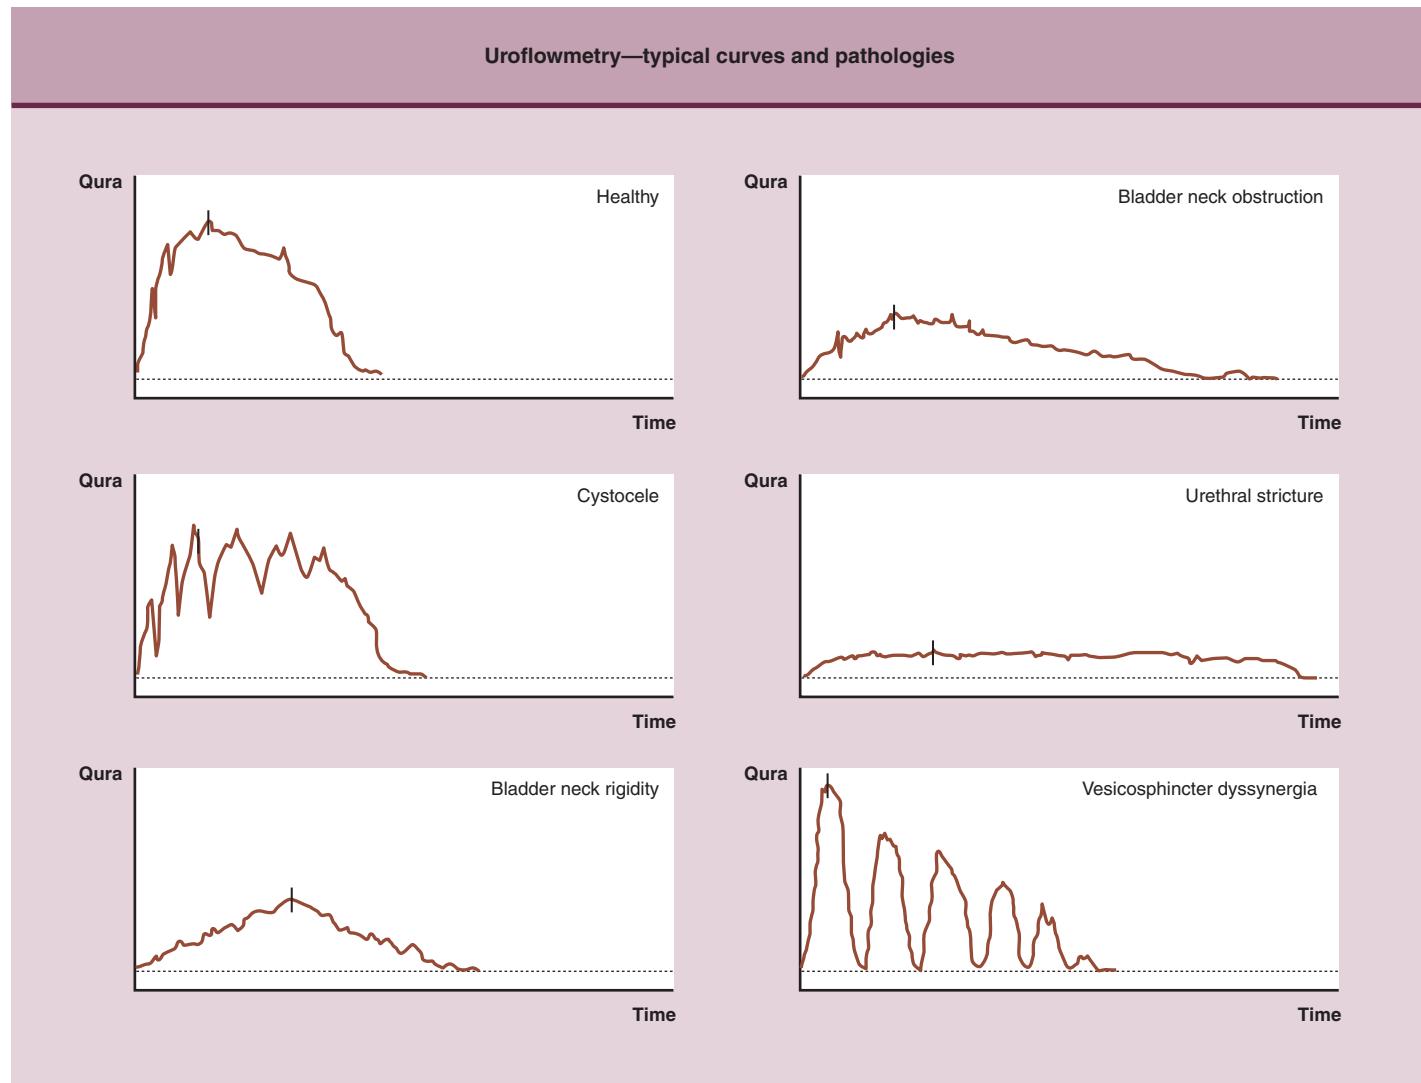

Next the dual-sensor catheter is placed in the bladder, and the single-sensor catheter is placed in the vagina or rectum, electromyogram (EMG) patches and leads are placed and

connected, and finally the bladder catheter is connected to a water source before beginning the next step of testing (i.e., cystometry).

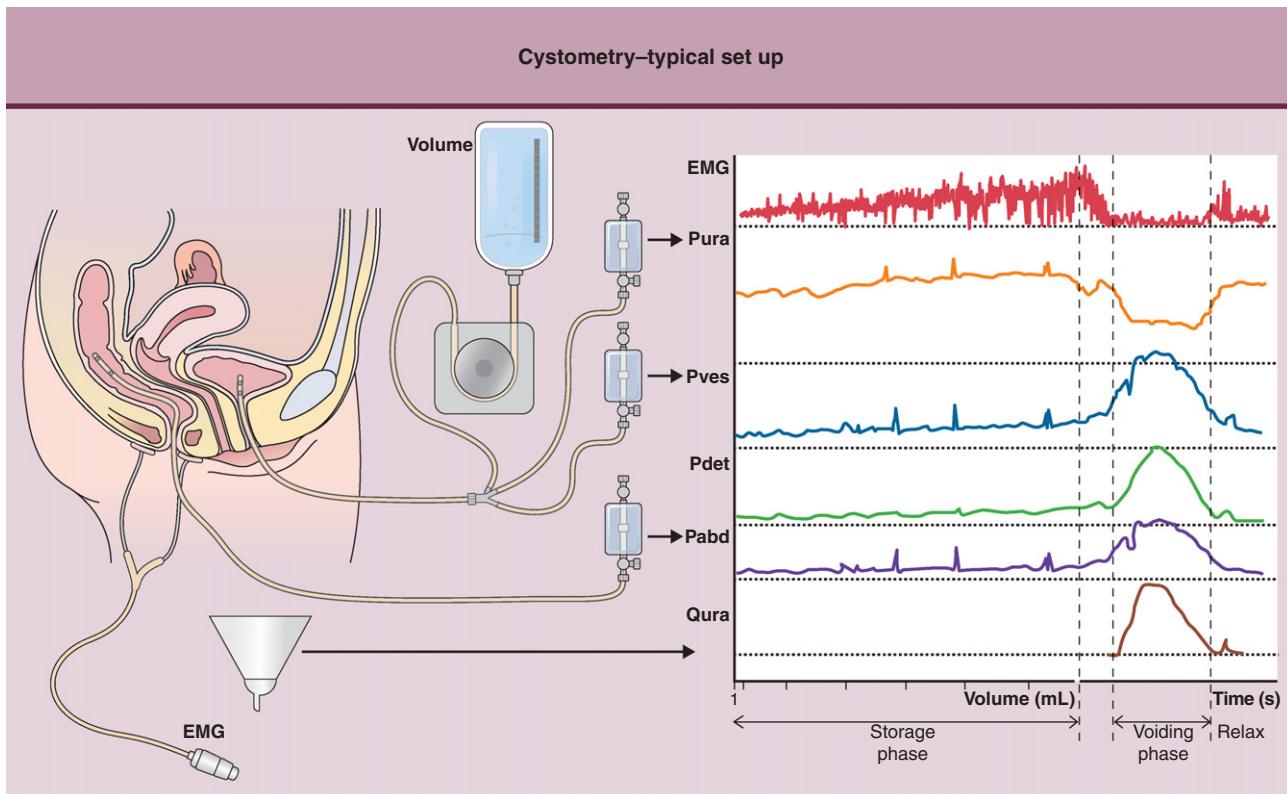

*Multichannel urethrocystometry* involves the simultaneous measurement of abdominal, urethral, and bladder pressures (Fig. 28-23). Cystometry is considered to be the soul of urodynamic testing. It evaluates the pressure/volume relationship (i.e., compliance of bladder during the filling/storage phase). The sole purpose of this test is to reproduce the patient's symptoms of incontinence in the laboratory setting. Assessment of first sensation, first urge, bladder capacity, bladder compliance, involuntary detrusor activity, and urethral stability can be made. Cystometry involves placement of two catheters, a dual-sensor catheter (Fig. 28-24; see also Fig. 28-7) in the bladder and urethra to measure their respective pressures and a single-sensor catheter in either the vagina or rectum to measure abdominal pressure (one must be aware of the artifacts this may cause. Figure 28-25 shows an example of rectal artifact). In the presence of moderate to large prolapse the rectum is used to measure the abdominal pressure; in the absence of significant prolapse the vagina is used to measure the abdominal pressure. Detrusor and urethral pressures are electronically calculated and depicted in real time on the cystometrogram. During the test the bladder catheter is also used to infuse water or physiologic saline at room or body temperature in the bladder. Various

**Figure 28-25 Multichannel cystometry curve depicting rectal hyperactivity artifact and its affect on the Pdet recording.** Also note the normal reflex rise in EMG activity with increased bladder filling. (Courtesy of Medtronic Corporation, Minneapolis, Minn.)

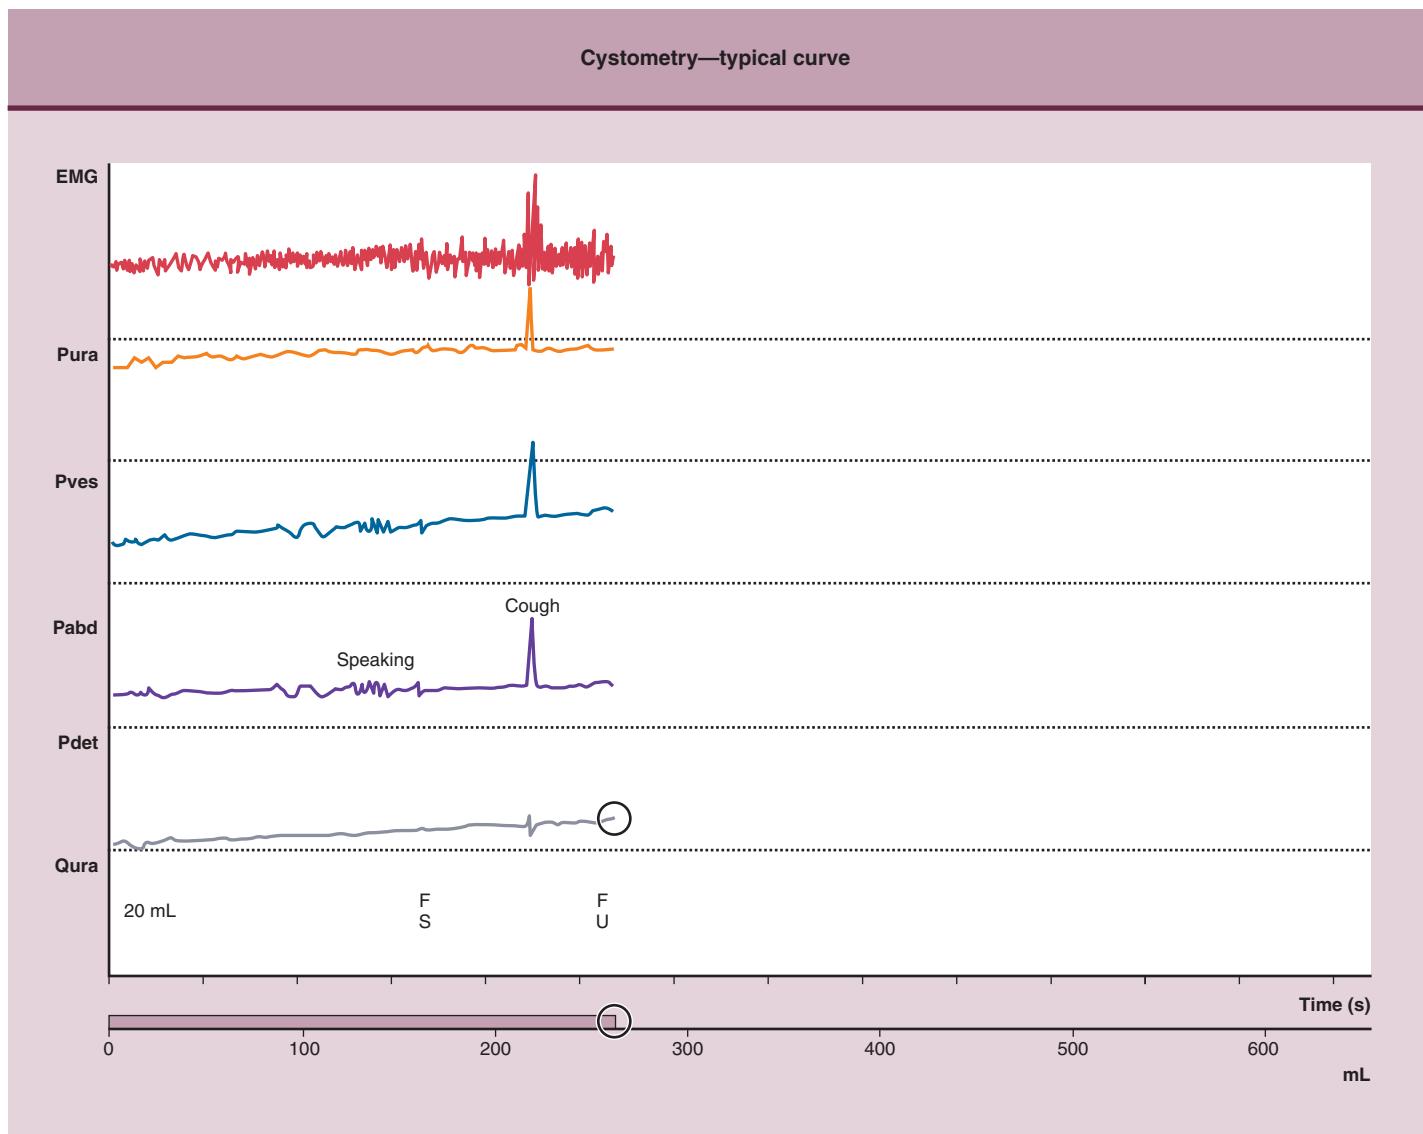

## Urogynecology

sensations (Figs. 28-26 through 28-29) are noted as reported by the patient. Any abnormal rise in bladder pressure ( $>15$  cm H<sub>2</sub>O at normal capacity) or involuntary contractions or involuntary urethral relaxation is noted along with the patient's sensation at the time (Figs. 28-30 and 28-31). If an involuntary contraction has not been shown during the course of the test, provocative measures such as coughing, change in position from sitting to standing, running water, or washing hands in cold water should be performed to increase the diagnostic yield of

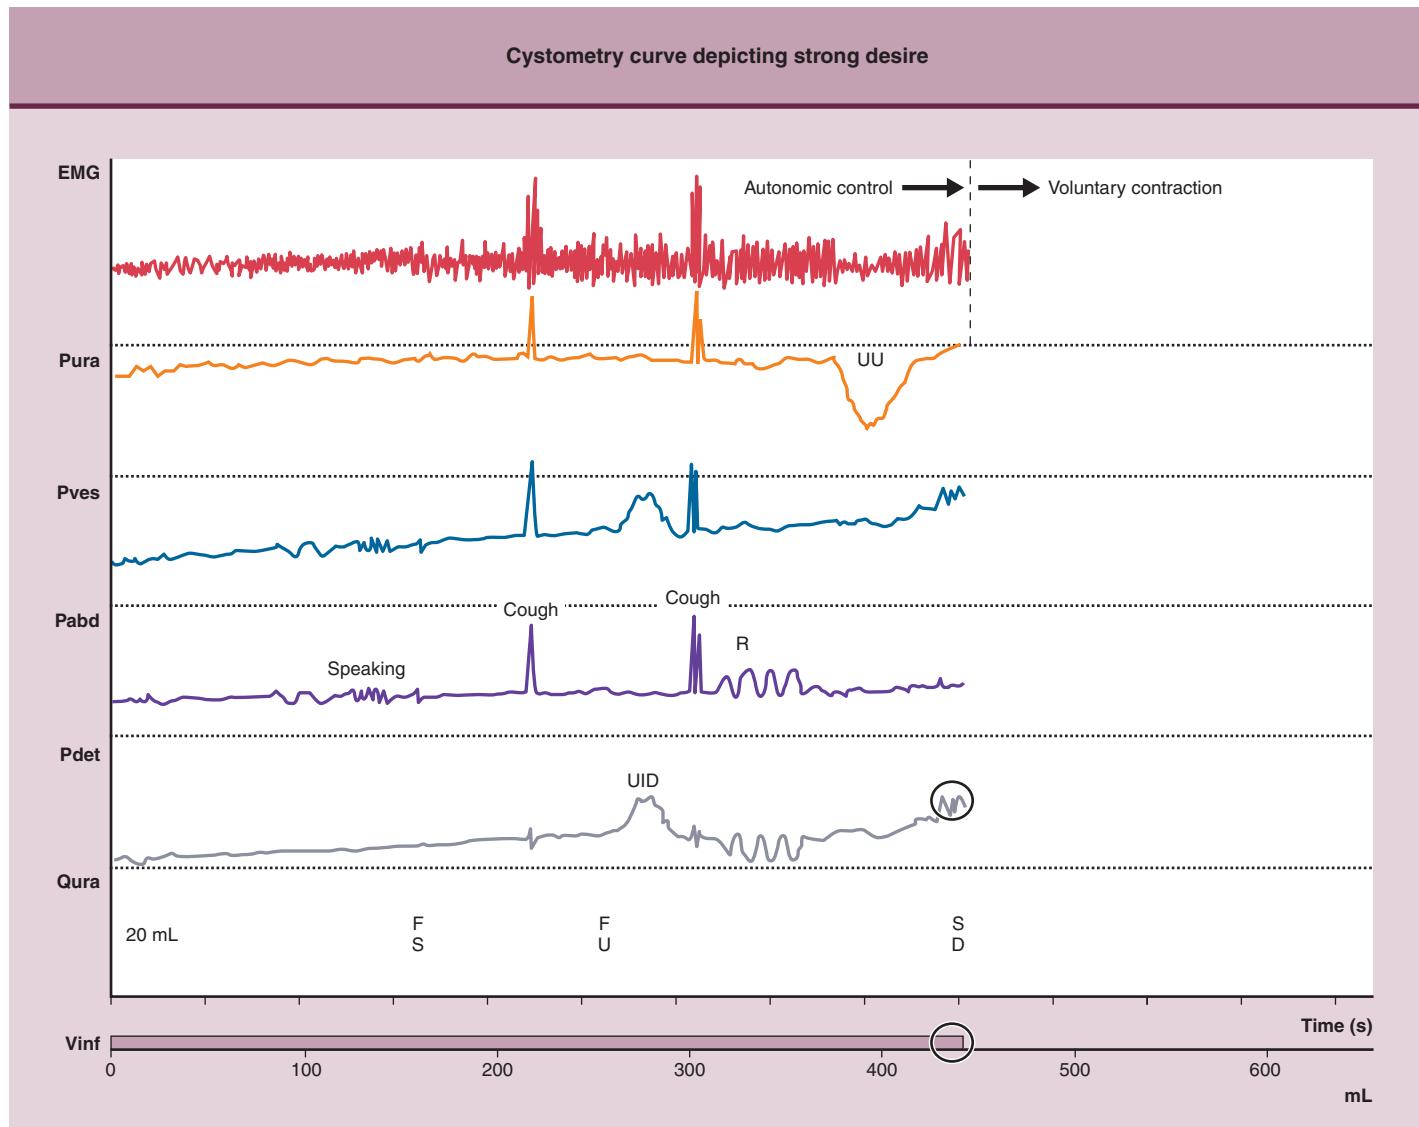

the test and to reproduce the patient's symptoms in an objective fashion.

This test is considered diagnostic only when observations made during the test correlate with the patient's symptomatology. Any observation made in the absence of proper symptoms or symptoms without urodynamic observation may represent a test artifact; or there might be another etiology behind the symptoms. In this instance the test is not diagnostic and could be considered inconclusive or unhelpful.

### Measurement of Urethral Pressure Profile

Urethral pressure profile is performed by withdrawing a urethral catheter at a constant rate by a pulley (Fig. 28-32) while making pressure measurement along the length of the urethra, generating a graph that is called the *static urethral pressure profile*. Significant data can be gathered from this profile, including maximum urethral closure pressure (MUCP), functional urethral length, and location of MUCP in relation to the bladder neck or urethral meatus (Fig. 28-33). MUCP of less than 20 cm is generally regarded as intrinsic urethral sphincter

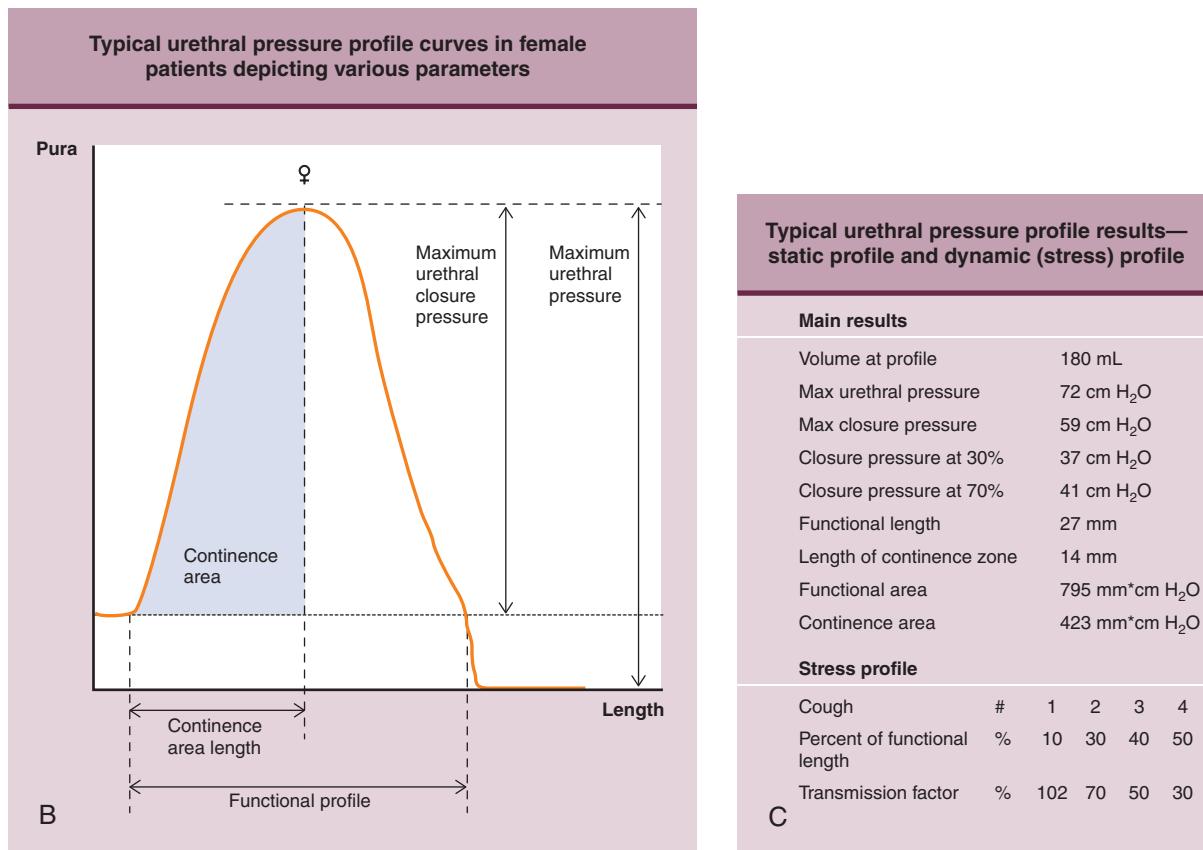

dysfunction, which carries certain therapeutic implications, discussion of which are beyond the scope of this chapter. In general intrinsic urethral sphincter dysfunction carries an implication of a higher failure rate with any therapeutic modality that is utilized. Certain modalities, such as the bladder neck sling operation, might be preferred over others such as the Burch operation. Generally two static profiles are obtained to ensure reliability and reproducibility. When these results are in close agreement, the average value of these two parameters is then utilized for the final report.

**Figure 28-32** Urethral pressure profile measurement in a single-channel setting. Note that the catheter can be withdrawn manually or by a puller (a mechanical puller is depicted here). (Courtesy of Medtronic Corporation, Minneapolis, Minn.)

**Figure 28-33 Urethral pressure profile (UPP).** A, Typical UPP curves: normal curves and curves in various pathologic states.

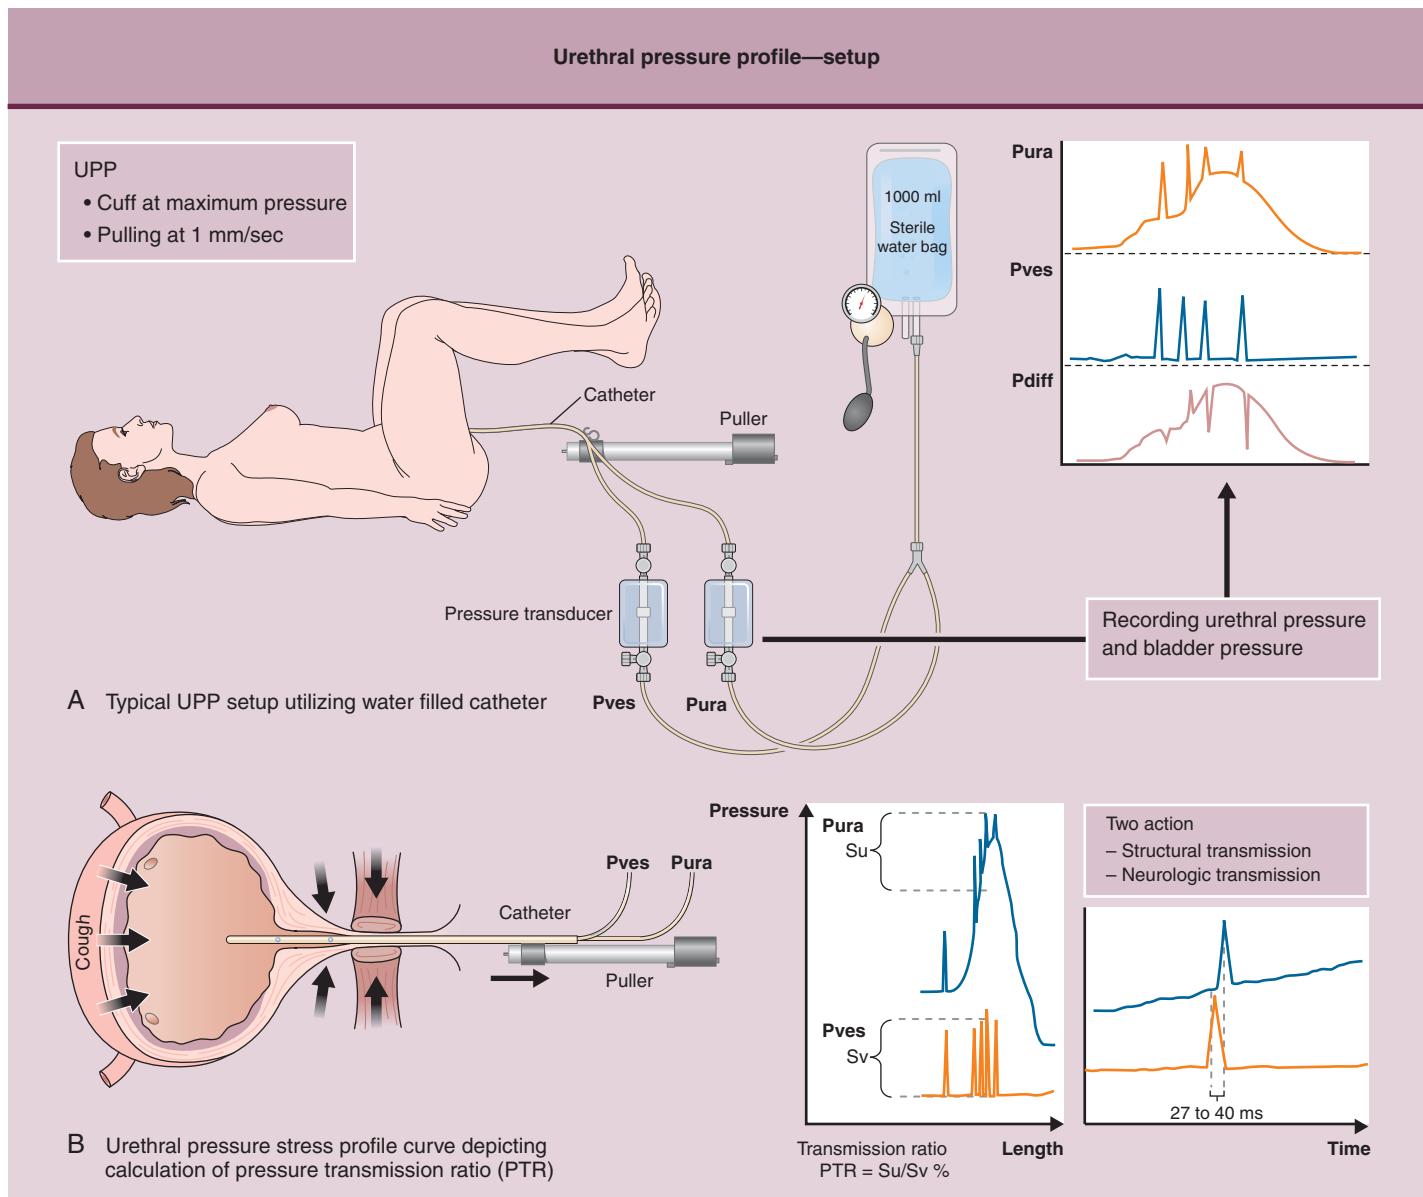

**Figure 28-33, cont'd** B, Typical UPP curves in female patients depicting various measured parameters. C, Typical UPP results: static profile and dynamic (stress) profile. (Courtesy of Medtronic Corporation, Minneapolis, Minn.)

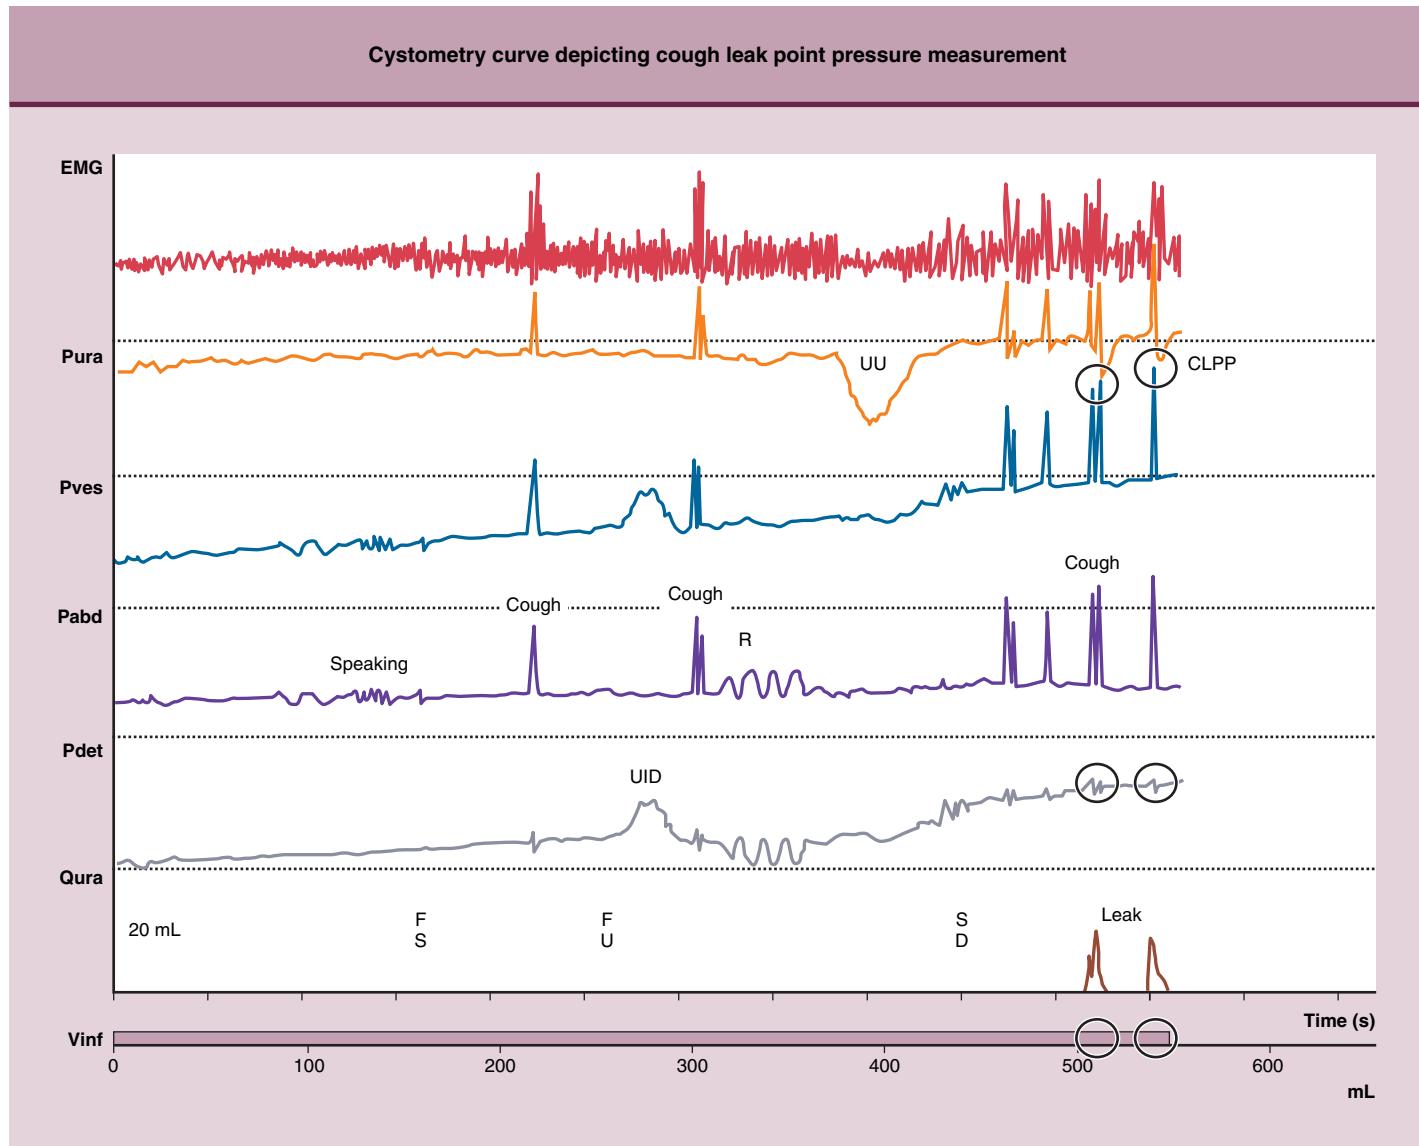

After two initial static profiles are performed, two dynamic cough profiles are obtained to objectively document urodynamic stress incontinence. Dynamic cough profiles (Fig. 28-34) are performed by asking the patient to cough while the urethral catheter is passing through the functional length of the urethra; the urethral meatus is observed for leakage occurring in concert with the cough. The patient is then asked to perform a Valsalva maneuver; again the examiner observes for leakage of urine. First the patient is asked to push vigorously. If leakage is seen, she will slowly perform a Valsalva maneuver until the leakage occurs where she doesn't push any harder. In this fashion two VLPPs are documented (Figs. 28-35 and 28-36).

A *voiding pressure study* or *voiding cystometry* is a pressure flow study of the micturition act (Fig. 28-37). As the last part of multichannel testing, the patient is asked to void voluntarily around the catheter while abdominal, bladder, and urethral

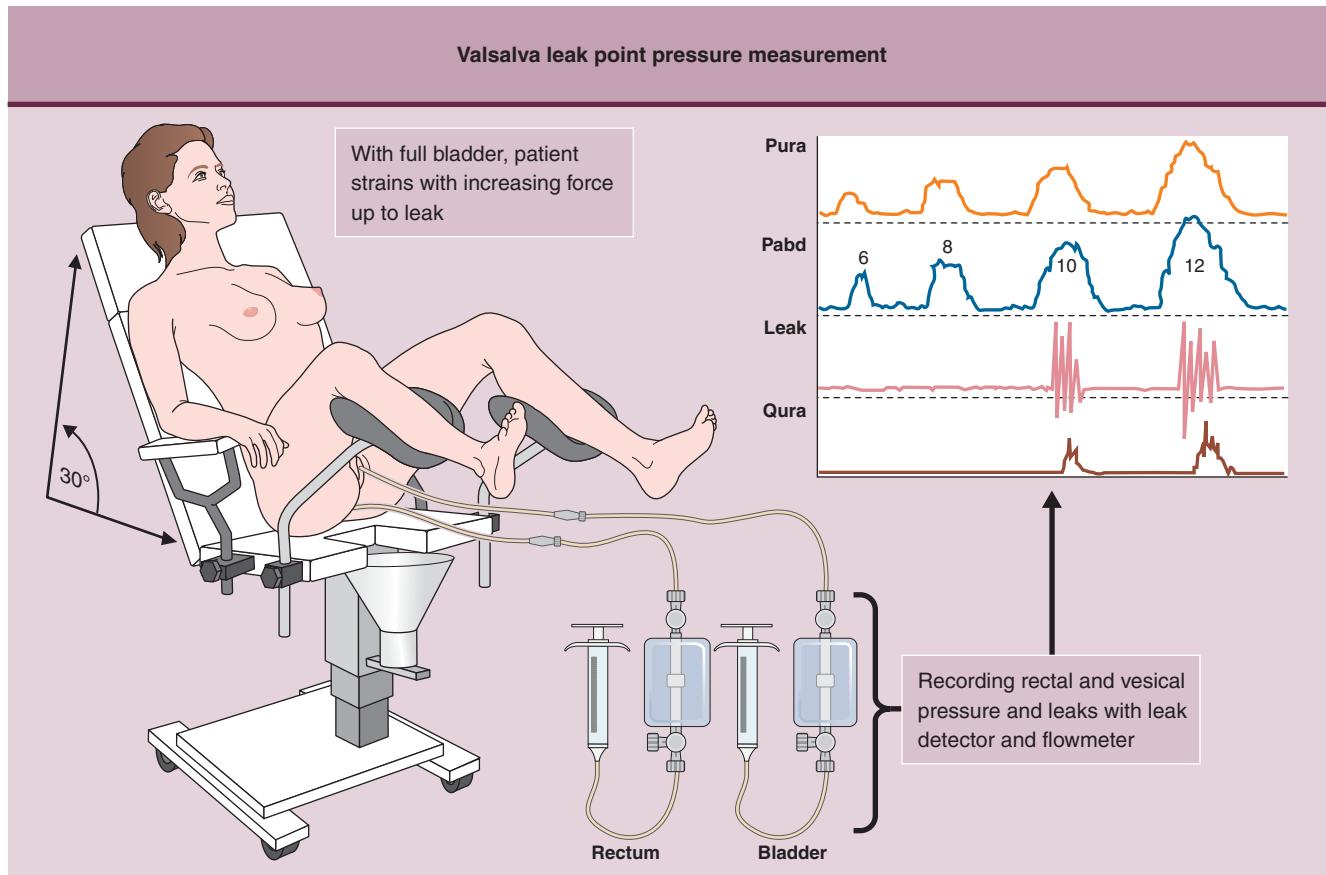

pressures are monitored and uroflowmetry measurements are taken (Fig. 28-38). Detrusor and urethral closure pressures are calculated in real time. This provides information on the patient's exact voiding mechanism. Normal voiding function in females includes urethral relaxation with bladder contraction (Figs. 28-39 and 28-40; see also Fig. 28-38A); Valsalva, urethral relaxation, and bladder contraction (see Fig. 28-37); Valsalva with urethral relaxation; and urethral relaxation only. By defining the exact voiding mechanism, a voiding pressure study may explain the patients' symptoms of voiding dysfunction and abnormal uroflowmetry parameters, and provide a reason for urinary retention. This component of urodynamic testing is useful in defining the etiology of postoperative voiding dysfunction, namely obstruction versus acontractile bladder. Completion of a voiding pressure study generally concludes multichannel testing.

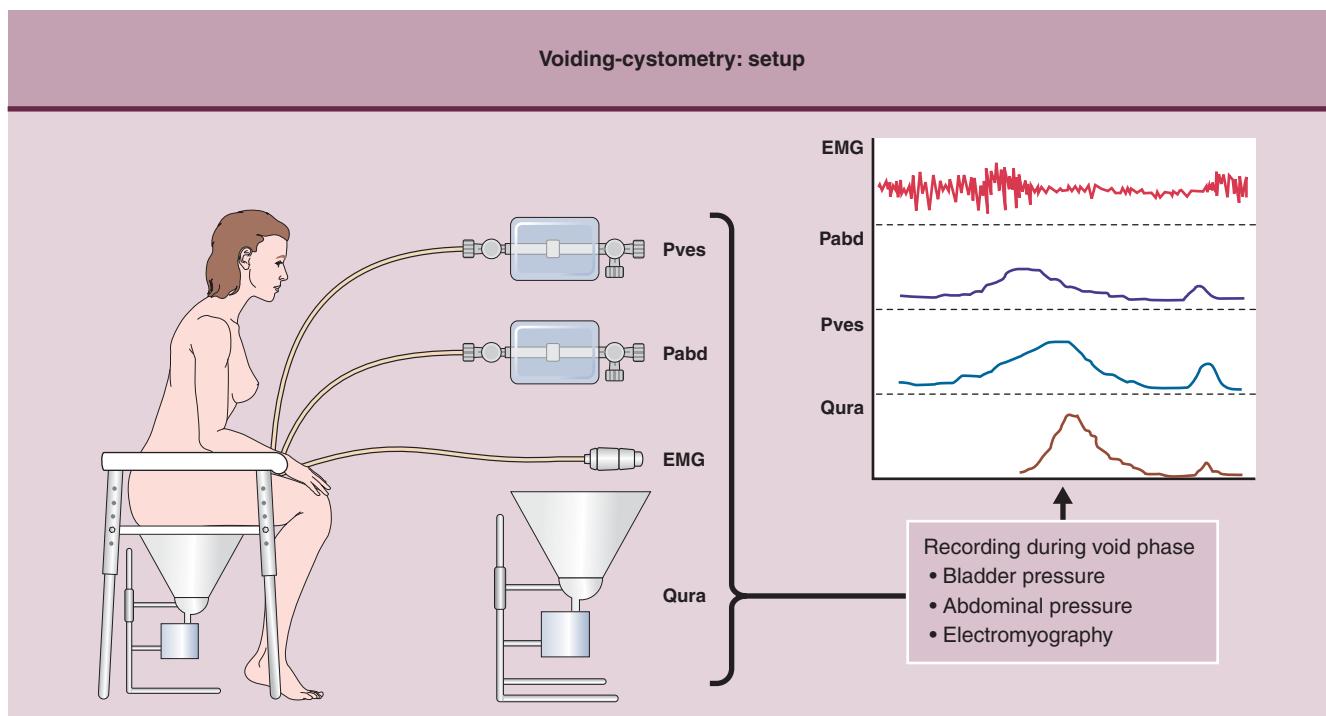

**Figure 28-34 Urethral pressure profile (UPP).** A, Typical UPP setup utilizing water-filled catheter, pressurized water source, and an automatic catheter puller. Note the stress profile on the screen. B, Urethral pressure stress profile curve, depicting calculation of pressure transmission ratio (PTR). (Courtesy of Medtronic Corporation, Minneapolis, Minn.)

**Figure 28-35 Multichannel cystometry curve depicting cough leak point pressure measurement.** VLPP can also be measured in a similar fashion. (Courtesy of Medtronic Corporation, Minneapolis, Minn.)

**Figure 28-36 Multichannel cystometry curve depicting Valsalva leak point pressure measurement.** Note that patient is straining with increased force up to leak in a semisupine position. Also note that Pabd is measured through a rectal catheter and that leaks are detected with leak detector and flowmeter. (Courtesy of Medtronic Corporation, Minneapolis, Minn.)

**Figure 28-37 Typical setup for a voiding-cystometry test.** Note the recording of bladder pressure, abdominal pressure, and electromyography during the voiding phase. (Courtesy of Medtronic Corporation, Minneapolis, Minn.)

*Electromyography* is frequently performed at the time of multichannel testing (Fig. 28-41). The most common indication for EMG is to evaluate patients with a voiding dysfunction or as a therapeutic modality in the form of biofeedback treatment. EMG of the periurethral sphincter muscle is of primary interest during urodynamic testing because it can aid in diagnosis of detrusor sphincter dyssynergia. This test can be performed either directly with a needle, vaginal-surface, or urethral catheter-mounted electrodes or indirectly with an anal plug or perianal skin patch electrode. The latter is the most commonly utilized technique in clinical practice. The striated muscles of the urethral sphincter, external anal sphincter, and pelvic floor are in contracted status at baseline, as reflected by baseline EMG activity at rest. With bladder filling this baseline activity is increased further due to guarding reflex, as shown in Figures 28-19 and 28-27. At the time of voluntary void these muscles will relax, which is seen as diminished or silent EMG activity (see Fig. 28-38). In pathologic conditions causing discoordination between the detrusor and urethral sphincter, named *detrusor sphincter dyssynergia*, EMG activity will persist during a voluntary void (see Fig. 28-17).

#### Video Urodynamic Testing

*Video urethrocystometry* involves the simultaneous measurement of abdominal, urethral, and bladder pressures along with the use of x-ray contrast media as a filling media. Video urodynamic testing is a combination of physiologic measurements made by a multichannel urodynamic test combined with anatomic visualization of the lower urinary tract (see Fig. 28-39). During the test, radiopaque filling media is infused in the bladder in place of water, which then is visualized by fluoroscopy. Thus, fluoroscopy provides a way of detecting leakage of x-ray contrast medium. Visualizing the lower urinary tract may make it easy to understand the complex relationship between anatomy and physiology interplaying in various pathologic conditions. Video urodynamic testing is arguably the Cadillac of urodynamic testing, although the exact indications for this particular modality are not clear.

#### Ambulatory Urodynamics

As the name implies, urodynamic measurements are made in the ambulatory format, similar to Holter monitoring of the heart. Traditional urodynamic measurement is considered by many to be unnatural and embarrassing. Ambulatory testing still involves the invasiveness of catheters, but it is carried out in the patient's natural environment at a natural pace of bladder filling. Bladder and abdominal pressure are measured, and detrusor pressure is calculated. The patient wears a diaper with sensors to measure the volume leaked. The patient is also responsible for keeping a diary of symptoms and activities, as well as marking certain events on the monitor. Due to the labor-intensive nature of this type of testing, its use in daily clinical practice is limited. Other limiting factors for ambulatory testing include unknown indications for this type of testing, lack of standardization of technique, and difficulty in assessing the urethra.

#### Urethral Retroresistance Pressure

Urethral retroresistance pressure (URP) is defined as the pressure required to open and to maintain an open urethral sphincter.<sup>13</sup> URP is not a new concept but has recently been revived, in part

due to lack of correlations between current urethral assessment techniques (UPP, VLPP) and severity of illness as well as treatment outcome measurements. Some limited data is available on URP measurement utilizing the Gynecare Monitor (Gynecare, Johnson & Johnson). The Gynecare Monitor is a small, portable unit that also allows single-channel cystometry and VLPP measurements.

In Figure 28-42, Slack and colleagues recently showed a statistically significant correlation between URP and severity of incontinence as compared to current standard urodynamic measurements to assess the urethra.<sup>21</sup> One needs to be aware of the existence of this technique as well as the fact that the data is quite limited and in need of proof.

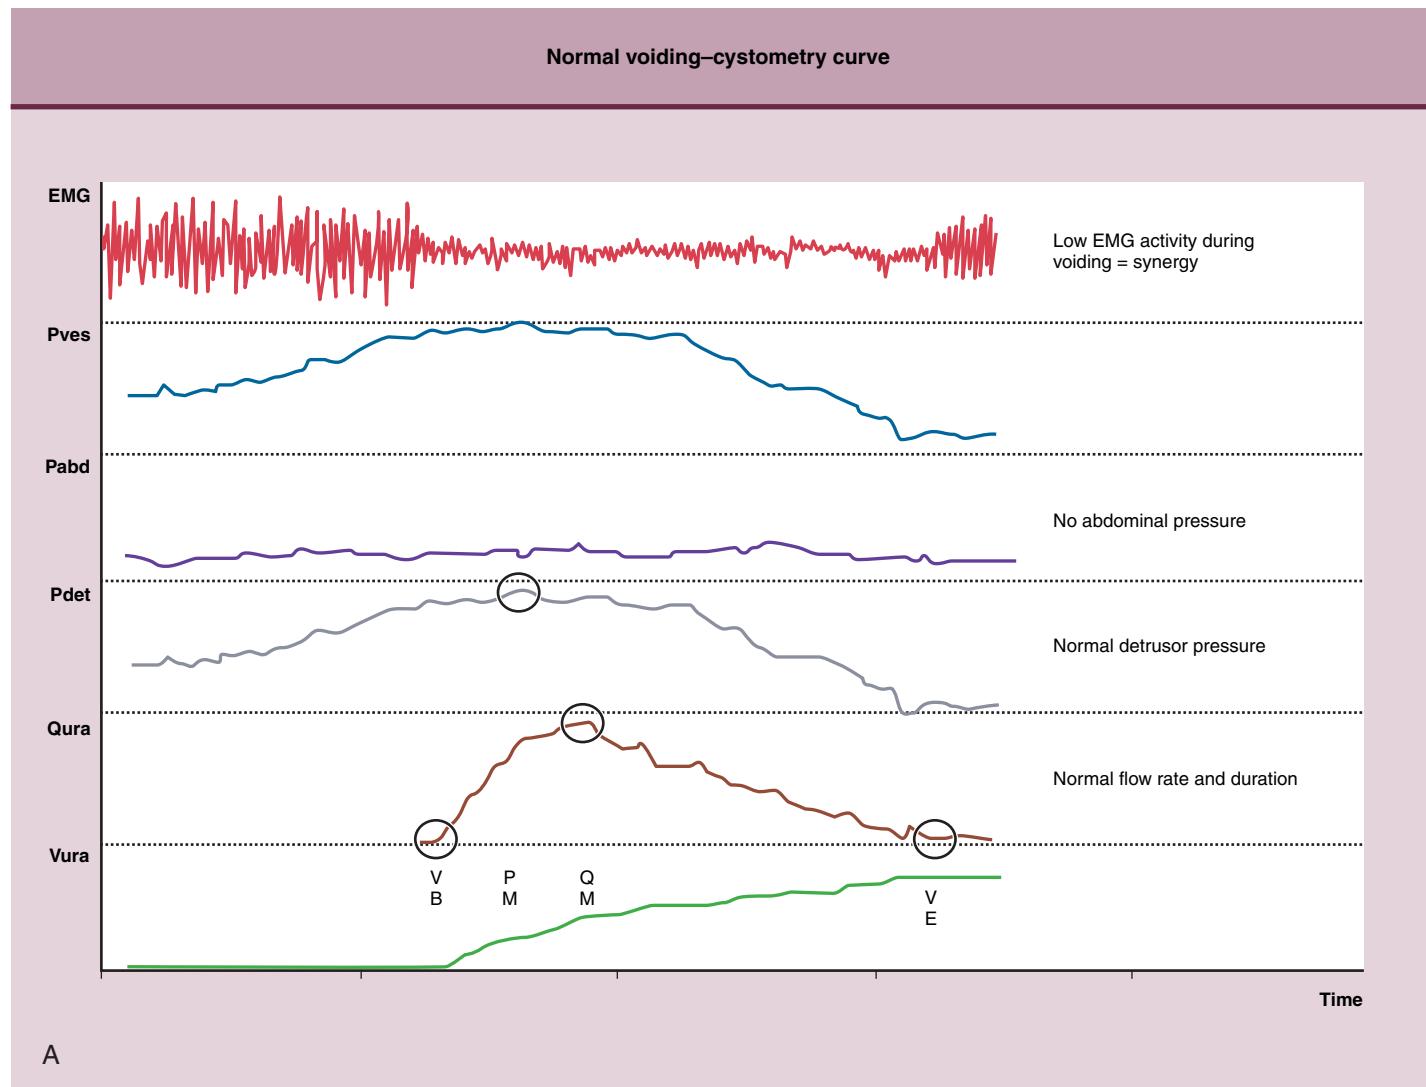

#### Urethrocystoscopy

Cystoscopy has somewhat limited use in primary evaluation of an incontinent female patient. Some clinicians strongly believe that it should be performed in all female patients with irritative bladder symptoms, such as urinary urgency and frequency. We limit performing cystoscopy to patients with microscopic or gross hematuria, recurrent bladder infections, bladder pain with or without irritative bladder symptoms, recurrent urinary incontinence, irritative symptoms that have not responded to appropriate medical therapy, and significant nocturia. Cystoscopy can generally be performed in the office in a female patient without anesthesia with little or no discomfort. A rigid or flexible cystoscopy can be employed. Water, saline, or carbon dioxide can be utilized as distention media. Lenses measuring 0 degrees, 12 degrees, or 30 degrees can be used to inspect the urethra, bladder neck, and trigone; generally the 70-degree lens is used to evaluate the lateral, anterior, and posterior walls and the dome of the bladder. Any suspicious lesion should be biopsied and washing should be sent for cytology. Notes should be made of any ulceration or glomerulation (capillary bleeding) because they may suggest interstitial cystitis. Any other lesions, such as a cyst or raised area, should be noted. Cystoscopic bladder capacity is noted as well and we generally conduct a stress test on patients at this volume. Any bladder contraction, along with the patient's symptoms, is noted. Finally, an appropriate referral is made in the event of abnormal findings.

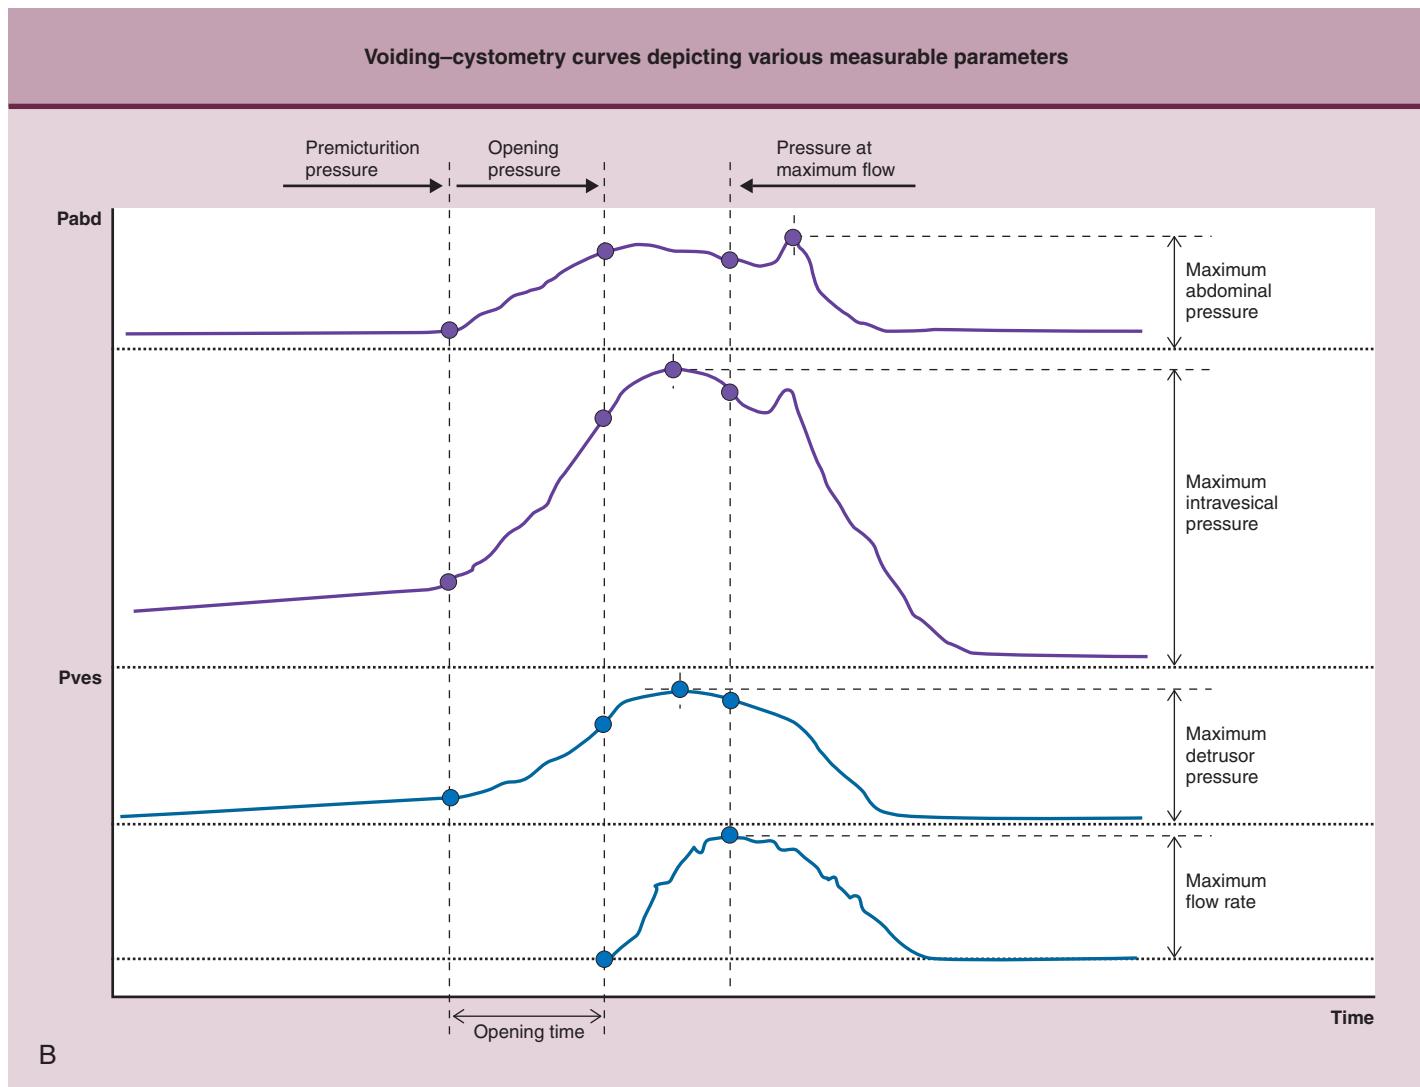

Figure 28-43 (see also Figs. 28-13 through 28-17 and 28-40) depicts some common urodynamic findings for readers to study.

## CONCLUSION

Urinary incontinence is a common and treatable condition that gynecologists frequently encounter. This condition requires a physician to have a basic understanding of various types of incontinence and to understand that, even under the most ideal situation, history and physical examination may not accurately differentiate between various types of incontinence. When diagnosis is uncertain after clinical evaluation, as described in the history and physical examination section of this chapter, further testing may be indicated to objectively reproduce a patient's symptoms and to arrive at an accurate diagnosis. At this point the physician must decide on appropriate urodynamic testing based on the clinical situation at hand. In complex cases consultation with a urogynecologist or urologist should be considered.

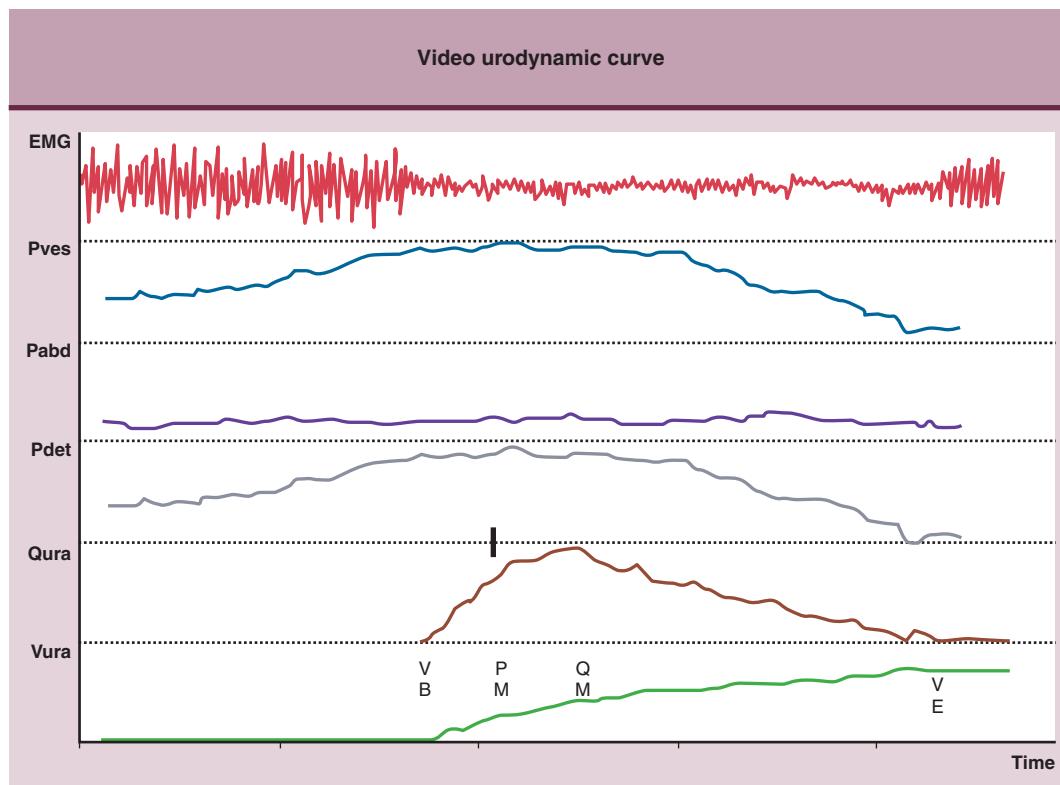

**Figure 28-38** A, Normal multichannel voiding-cystometry curve. Note the low EMG activity due to pelvic floor relaxation during voiding.

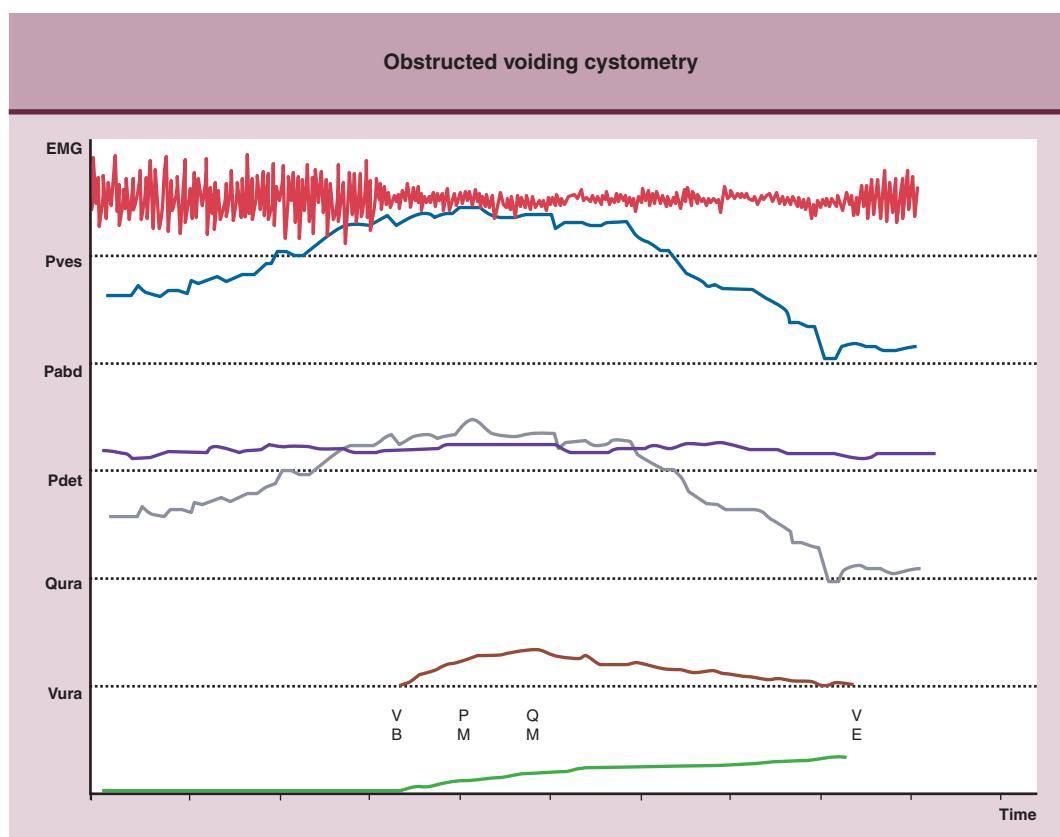

Typical voiding cystometry results		
Voiding phase		
Max flow rate	QM	18.5 mL/sec
Average flow rate		9.5 mL/sec
Voided volume		210 mL
Voiding time		22 sec
Flow time		22 sec
Time to max flow		7 sec
Residual volume		300 mL
Pves at opening	VB	30 cm H <sub>2</sub> O
Pves at max flow	QM	32 cm H <sub>2</sub> O
C Max Pdet	PM	25 cm H <sub>2</sub> O

## KEY POINTS

- Vesicovaginal fistulas occur most commonly following obstructed labor in developing countries.
- Although rare overall, an obstetric etiology is still common for rectovaginal fistulas in developed countries.
- In the developed world, urogenital fistulas occur rarely, but most likely following prior pelvic surgery.
- The treatment of genital fistulas is primarily surgical. The optimal timing, approach, and surgical techniques have not been established, therefore individualization is suggested.
- Further diagnostic tests to rule out inflammatory and/or neoplastic processes are required in patients that have recurrent fistulas.

## UROGENITAL FISTULAS

It is likely that women have suffered from urogenital fistulas since they have been giving birth. Findings of a vesicovaginal fistula have been identified in mummified remains from ancient Egypt. Since the mid-19th century, various attempts at surgical cure of urogenital fistulas as described by Marion Sims, Howard Kelly, and others have challenged gynecologic surgeons. It has long been recognized that women with vesicovaginal fistula are severely afflicted physically, socially, and emotionally owing to the constant uncontrollable dribbling of urine. While prone to litigation, patients with vesicovaginal fistulas remain among the most grateful of patients once they are cured. Although the published literature regarding urogenital fistulas is voluminous, very little scientifically validated research is available, and most of the data relies on retrospective case series and expert opinion. The various types of urogenital fistulas are listed in Table 29-1.

### Epidemiology

Genitourinary fistulas can be congenital or acquired. Congenital fistulas are rare, with only a few case reports in the literature. Most reported cases are associated with other urogenital anomalies.<sup>1,2</sup> Acquired fistulas may be the result of childbirth, pelvic surgery, malignancy, irradiation, infection, and an assortment of unusual presentations (Table 29-2).

In the developing world, the most common predisposing factor is obstructed childbirth, accounting for over 80% of genitourinary fistulas.<sup>3</sup> These difficult, often large fistulas have become exceedingly rare in developed countries owing to improvements in access to and delivery of obstetric care.

Ibrahim et al report that the mean age at diagnosis was 15 years, patients were in labor for 4 days on average, and the fetus died in 87% of cases.<sup>4</sup> In a rural, population-based study of parturients in Senegal, the incidence rate was 124 per 100,000 deliveries, whereas no fistulas were noted in six major cities in West Africa. It is estimated that over 33,400 new cases of obstetric fistulas occur annually in sub-Saharan Africa, with an incidence of over 120 per 100,000 births.<sup>5</sup> Worldwide, as many as 2 million fistulas may occur annually.<sup>6</sup> Risk factors include short stature, lower education and socioeconomic levels, and young maternal age.<sup>7</sup>

Hilton reviewed vesicovaginal fistulas in developing countries and outlined management strategies to include immediate catheter drainage as long as the tract has not yet epithelialized, perhaps even prophylactically following obstructed labor with evident vaginal sloughing. Attention to adequate vulvar skin care, nutrition, lower extremity rehabilitation, and counseling are important adjuncts in the care of fistula patients.<sup>8</sup> Arrowsmith et al similarly remind us of the spectrum of additional trauma sustained by the fistula patient and the need to address more than just the “hole in the bladder.”<sup>9</sup> Surgical correction is curative in the first operation for obstetric vesicovaginal fistula in about 80% of cases. Multiple attempts may be necessary to achieve a success rate over 95% for large fistulas.<sup>3</sup>

The traditional tribal practice of “gishiri cutting” also is associated with formation of urogenital fistulas and is common in many parts of northern Nigeria. It involves cutting the anterior vagina with a razor or knife blade and has been noted to be the primary cause of fistula formation in 13% to 15% of cases.<sup>10,11</sup>

Other obstetric events and procedures have been noted to be associated with urogenital fistula formation worldwide. Cesarean section may result in formation of a vesicouterine fistula (Youssef’s syndrome). Although over 700 cases have been reported in the literature, this complication is considered rare, since it represents only 1% to 4% of all genitourinary fistulas.<sup>12,13</sup> Vesicovaginal fistulas have also been reported following cesarean section, with or without associated hysterectomy.<sup>14</sup> Even more rarely reported are vesicocervical, urethrovaginal, and uretero-uterine fistulas following cesarean section.<sup>14–16</sup> Operative vaginal delivery may result in vesicouterine fistula in the patient undergoing vaginal birth delivery after cesarean section (VBAC).<sup>17–19</sup> Cervical cerclage for the treatment of cervical incompetence rarely has been associated with vesicovaginal or vesicocervical fistulas.<sup>20–22</sup>

Nonobstetric urogenital fistulas have been reported as a consequence of gynecologic, urologic, and general surgical procedures and are the most commonly seen in developed countries with hysterectomy being the most common cause. Lee et al showed that benign hysterectomy was associated with 65% of

**Table 29-1**

  - Vesicoureterouterine
  - Vesicovaginorectal

303 genitourinary fistulas. Of 190 patients with vesicovaginal fistulas, 82% occurred following surgical treatment for benign gynecologic conditions and 11% from obstetric procedures.<sup>23</sup>

Harkki-Siren et al reviewed the incidence of urinary tract injuries from a Finnish national database of 62,379 hysterectomies with a vesicovaginal fistula incidence of 0.8 per 1000. Specific incidences based on the type of hysterectomy can be seen in Table 29-3.<sup>24</sup> In a retrospective single-institution series, Armenakas et al report on 65 patients over a 12-year period with iatrogenic bladder perforations. Obstetric and gynecologic procedures account for 62%, general surgical procedures 26%, and urologic procedures 12% of bladder perforation, excluding

all endourologic procedures. Of the 40 patients from the obstetrics and gynecology service with bladder injury, there were 13 (32.5%) simple abdominal hysterectomies, 3 (7.5%) radical hysterectomies, 12 (30%) resections for pelvic mass, 10 (25%) cesarean sections, and 2 (5%) laparoscopies. Anterior vaginal repairs (done on the urology service) accounted for 6 (9%) cystotomies. All 17 cystotomies on the surgical service were sustained during colon resections. Sixty-three of the total 65 patients (97%) had their cystotomies recognized and repaired intraoperatively. With an average follow-up of 36 months, one subsequent vesicovaginal fistula occurred (1.5%).<sup>25</sup> Carley et al reported a 1% incidence of recognized bladder injury during

**Table 29-2**  
**Associated Conditions Related to Development of Urogenital Fistulas**

**Obstetric conditions or procedures**

- Prolonged, obstructed labor
- Placenta percreta
- Cesarean section (especially repeat cesarean section)
- Cesarean hysterectomy
- Operative vaginal delivery
- Cervical cerclage

**Gynecologic procedures**

- Hysterectomy
- Suburethral slings
- Anterior colporrhaphy
- Periurethral bulking
- Burch colposuspension
- Urethral diverticulum repair
- Myomectomy
- Loop excision of the cervix
- Voluntary interruption of pregnancy

**Pelvic conditions**

- Endometriosis
- Gynecologic cancer
- Pelvic irradiation
- Bladder stone
- Infection
  - Schistosomiasis
  - Tuberculosis
  - Lymphogranuloma venereum
- Intrauterine device
- Neglected pessary

Table 29-3 Incidence of Vesicovaginal Fistula and Bladder Injury by Type of Hysterectomy, with Associated Failure Rates of Primary Repair				
	Failure Rate			
	Laparoscopic N = 2741	Total Abdominal N = 43,149	Subtotal Abdominal N = 10,854	Vaginal N = 5636
Incidence of vesicovaginal fistula	2.2 per 1000	1 per 1000	0	0.2 per 1000
Incidence of bladder injury	6.6 per 1000	0.2 per 1000	0.3 per 1000	0

Data from Harkki-Siren P, Sjoberg J, Tiitinen A: Urinary tract injuries after hysterectomy. *Obstet Gynecol* 1998;92:113-118.

hysterectomies at Parkland Hospital. Of 1722 abdominal hysterectomies, the cystotomy rate was 0.58%, of 590 vaginal hysterectomies the rate was 1.9%, and of 117 obstetric hysterectomies the rate was 5.1%.<sup>26</sup> A recent retrospective single-institution review of 1647 total laparoscopic hysterectomies reports 16 recognized bladder lacerations (1%) and 2 vesicovaginal fistulas (0.1%).<sup>27</sup>

In a review of 110 vesicovaginal fistulas following hysterectomy, Tancer reported that 92 occurred following abdominal hysterectomy, while 18 following vaginal hysterectomy. Twenty-four of these fistulas occurred despite intraoperative recognition and repair of cystotomy. In 77 of these fistulas, no risk factors such as prior cesarean section, endometriosis, recent cervical conization, or prior irradiation were identified.<sup>28</sup> A retrospective review of 17 urogenital fistulas following gynecologic surgery over a period of 15 years in Dublin found 12 vesicovaginal and 5 ureterovaginal fistulas. Of the vesicovaginal fistulas, three followed radical hysterectomy, one followed salpingo-oophorectomy, two followed vaginal hysterectomy, and six followed total abdominal hysterectomy. Of the ureterovaginal fistulas, three were preceded by radical hysterectomy, and one each by vaginal and total abdominal hysterectomy. It was calculated that the risk of vesicovaginal fistula is 1/605 (0.16%) of total abdominal hysterectomies, 1/571 (0.17%) vaginal hysterectomies, and 1/81 (1.2%) of radical hysterectomies.<sup>29</sup>

Unfortunately, not all recognized cystotomies that are repaired prevent subsequent vesicovaginal fistula formation. In their data on over 43,000 total abdominal hysterectomies, Harkki-Siren et al report failure of primary bladder repair 18% of the time.<sup>24</sup> Armenakas et al in their recent review of 65 iatrogenic bladder injuries that were repaired by urologists, 13 cystotomies occurred after benign abdominal hysterectomy. Of these, one vesicovaginal fistula occurred, for a postcystotomy repair failure rate of 7.7% among total abdominal hysterectomy patients.<sup>25</sup>

Urethrovaginal fistulas are less common than vesicovaginal fistulas, with an incidence ratio of 1 per 8.5.<sup>14</sup> In the developed world, the most common predisposing event is surgery for urethral diverticulum, anterior vaginal prolapse, incontinence, radiation therapy, or trauma. Operative vaginal delivery and more rarely cesarean section also have been reported to precede urethrovaginal fistula formation.<sup>30</sup>

Urethrovaginal fistulas can occur from a variety of urogynecologic procedures such as anterior colporrhaphy,<sup>25,31</sup> suburethral slings,<sup>32,33</sup> Burch colposuspension,<sup>14</sup> and periurethral collagen

injections.<sup>34,35</sup> More recently, a urethrovaginal fistula has been reported following tension-free vaginal tape.<sup>33</sup> It is expected that urethrovaginal fistulas may become more common with the increasing popularity of mid-urethral tapes for the treatment of stress incontinence.
