Additional gynecologic procedures associated with urogenital fistulas, although with greater rarity (see Table 29-2), include myomectomy,<sup>36</sup> large loop excision of the cervical transformation zone for CIN,<sup>37</sup> and voluntary interruption of pregnancy.<sup>38</sup> Fistulas are noted following radiation therapy for gynecologic cancers.<sup>39</sup> Fistulas that form within a previously irradiated field are more prone to recurrence, and most surgeons would agree that additional pedicled flaps are needed in their surgical repair because of the microvascular compromise.<sup>40,41</sup>

An assortment of unusual presentations can be found in the literature associated with urogenital fistulas mostly in the form of case presentations. These include uterine artery embolization,<sup>42,43</sup> Behcet's syndrome,<sup>44</sup> infections such as schistosomiasis,<sup>45</sup> tuberculosis,<sup>46,47</sup> lymphogranuloma venereum,<sup>48</sup> accidental trauma,<sup>49-51</sup> sexual trauma,<sup>52,53</sup> masturbation,<sup>54</sup> retained foreign objects,<sup>55,56</sup> endometriosis,<sup>57,58</sup> neglected diaphragm,<sup>59</sup> neglected pessary,<sup>60,61</sup> intrauterine device,<sup>62,63</sup> and bladder calculus.<sup>64</sup>

### Pathogenesis

The precise pathophysiologic mechanism of fistula formation is elusive and poorly understood. Etiologies have been proposed based on interpretation of the epidemiologic data and risk factors previously discussed. Vascular compromise and epithelial necrosis are evident from cases of prolonged obstructed labor seen in developing countries. The pathophysiology of genital fistulas noted in developed countries, however, is more difficult to ascertain with certainty. Vascular compromise and impaired healing may be the basis of fistulas caused by infection and subsequent urethral erosion of various graft materials used for suburethral sling and tape procedures, which then result in urethrovaginal fistula formation. Similarly, vascular compromise may explain fistulas that form following periurethral collagen injection and irradiation. In posthysterectomy fistulas, it has been suggested that undiagnosed bladder injury, especially in the posterior wall, would result in vesicovaginal fistula formation, as would an inadvertently placed suture that incorporates the bladder and vagina. Direct injury with healing of the surfaces in a way to allow formation of a fistula may also explain formation

## Urogynecology

of fistulas following trauma. It must be understood, however, that these explanations represent opinion rather than scientifically proved pathophysiology. A few studies have attempted to answer this question in animal models.

Meeks et al demonstrated in a rabbit model that fistula formation did not occur when absorbable sutures were placed incorporating full-thickness bladder and vaginal cuff.<sup>65</sup> This tends to contradict the notion that an errant suture alone is sufficient to result in fistula formation. In a laparoscopic dog model, no dogs developed a fistula after bipolar cautery injury to the bladder base, nor when absorbable sutures were placed through the bladder and vaginal cuff. Fistula formation, however, was noted in the dogs that had a monopolar cautery-induced bladder base laceration and had repair either with single-layer absorbable suture in the normal fashion or with suture that incorporated the anterior vaginal wall.<sup>66</sup> This suggests a possible role for microvascular compromise as an important cofactor in the pathophysiology of vesicovaginal fistula. It should be noted that these animal models of hysterectomy, because of anatomic differences, do not require any dissection of the bladder off the uterus, and in that respect may be different from humans undergoing total hysterectomy.

### Clinical Presentation

The classic presentation of urogenital fistula is continuous urinary leakage from the vagina. This may occur in the absence of urinary urgency, Valsalva maneuvers, or changes in body position. The degree to which leakage presents depends primarily on the precise location and size of the fistula, perhaps the pliability and healing of the surrounding tissue, and the condition of the rest of the vagina. Patients have a spectrum of leakage from truly continuous to intermittent primarily at bladder capacity with attendant urinary odor. Although it is generally accepted that the larger the fistula, the worse the leakage, it is always surprising to see how much urine can leak even through a small fistula. In developed countries, a precedent gynecologic, urologic, or general surgical procedure involving the pelvis will be noted. Delivery by the operative vaginal or, more commonly, cesarean section route may precede the onset of symptoms. The vast majority of cases will present in 1 to 10 days following surgery although the authors have seen patients manifest symptoms as much as 3 months postoperatively. The increasing prevalence of multiple procedures undertaken at the same time for complex pelvic floor disorders (often by multiple surgeons) may complicate the diagnosis of subsequent fistula formation, related to multiple potential sites of injury, preexisting symptoms, and added potential postoperative urinary complications. Other factors that may potentially increase the likelihood of fistula formation are the increasing use of permanent graft materials in reconstructive and incontinence surgery placed between the lower urinary tract and the vagina, as well as the increasing complexity of laparoscopic surgery. Other potential causes of postoperative urinary leakage should be considered and ruled out, as listed in Table 29-4.

Many patients develop coexisting urinary tract infections and symptoms of frequency, urgency, and dysuria. The predominant organism is *Escherichia coli* in most cases. Urinary leakage from any genitourinary fistula may be accompanied by hematuria. Vesicouterine fistulas tend to present with cyclic hematuria, and

**Table 29-4**  
**Differential Diagnosis of Postoperative Urinary Incontinence**

- Urogenital fistula
- Stress incontinence
- Urge incontinence
- Overflow incontinence
- Vaginal discharge/erosion of mesh

if the fistula is located above the cervix, amenorrhea may occur if all the menstrual blood is redirected into the bladder because of a closed cervical canal. Patients with coexistent mesh erosion into the urinary tract experience urgency, frequency, voiding dysfunction, and pain. If there is concurrent erosion into the vagina, coital discomfort and a vaginal discharge may occur as well.

Urine leakage for even a short period of time may result in significant irritation of the vagina, vulva, or perineum. This often occurs, despite the patient's attempt at frequent cleansing. If urine leakage persists, severe perineal dermatitis may result owing to exposure of the skin to ammonia. Phosphate crystallization may precipitate on the vagina and vulva, further irritating the area.

### Diagnosis

Often the diagnosis of urogenital fistula is straightforward based on history and demonstrable pooling of urine in the vaginal vault; occasionally, however, the diagnosis is elusive. In all cases it is necessary to evaluate the fistula with regard to its size, precise location, degree of epithelialization, whether it is simple or complex, accessibility, and the overall health status and mobility of the surrounding tissues. In the instance of a recurrent fistula, precise knowledge of prior nonsurgical management and a detailed surgical description of prior repair attempts are mandatory for appropriate surgical planning. If no prior documentation is available to rule out upper urinary tract injury, this should be obtained by an intravenous urogram or computed tomography (CT) scan.

In the case of clinical suspicion of a urogenital fistula that cannot be verified on initial speculum examination, the physician can try concurrent Valsalva maneuvers and partial closure of the speculum to reduce the tension on the vaginal walls. If this is not helpful in visualizing vaginal leakage, then a dye test should be tried. Indigo-carmine or methylene-blue-dyed sterile water is instilled via a transurethral Foley catheter (16 French) with great care taken to avoid spilling the dye externally. Once the vagina and vulva are cleaned, a tampon is placed and the patient asked to ambulate and wait for one-half hour. The tampon is removed and inspected for presence of blue dye; if the tampon is wet with urine but not dyed then a ureterovaginal fistula is suspected and is best diagnosed by intravenous urography. On rare occasions, these office diagnostic procedures are non-diagnostic despite a compelling history. In this case, the patient is asked to take phenazopyridine (Pyridium) and wear a series of tampons at home over a longer period of time with varying degrees of physical activity. The tampons are placed individually in plastic bags and brought in to be inspected. The patient

must be counseled regarding careful use of the tampons to eliminate the possibility of dye contamination during insertion or removal.

Radiologic studies are not routinely helpful in the diagnosis of urogenital fistula. However, it is often necessary to evaluate the upper urinary tract once a fistula is identified, and that is usually accomplished by an intravenous pyelogram (IVP) or contrast CT scan. Cystourethrography may be utilized to show a vesicovaginal or urethrovaginal fistula, but it is rarely needed to make an initial diagnosis. It has been occasionally helpful in delineating a complex fistula with multiple channels and openings. Volkmer et al describe the use of Doppler ultrasound to diagnose vesicovaginal fistulas with a sensitivity of 92%. Although this modality may be useful in the follow-up of patients undergoing conservative bladder drainage (in one of four such patients they demonstrated resolution of the fistula after 6 weeks), it too is rarely necessary to make an initial diagnosis.<sup>67</sup>

All patients should undergo cystourethroscopy to delineate the fistula's location and size, to determine whether it is simple or complex, and to evaluate ureteral patency and location. Although this could be done in the office, it is preferable to examine the patient under anesthesia when possible, which also allows better determination of fistula accessibility to the vaginal route of repair. If the fistula is large and does not allow adequate distention of the bladder during fluid-filled cystourethroscopy, placing a vaginal pack is helpful in allowing better visualization. When there is clinical suspicion of a vesicouterine fistula, hysteroscopy or hysteroscopy may be helpful in making the diagnosis. If the patient is taken for examination under anesthesia and cystourethroscopy, then diagnostic hysteroscopy may help further delineate the course of such a fistula. Improved surgical planning and informed consent may be obtained when the definitive operation is done at a later time, especially in complex or recurrent cases.

Some have advocated urodynamics testing prior to repair of a urogenital fistula on clinical and medicolegal grounds.<sup>68,69</sup> Hilton reports abnormalities on preoperative urodynamics in most patients with urogenital fistulas. Urodynamically proved stress incontinence was noted in 75% of patients with urethral or bladder neck fistulas ( $n=12$ ) and 36% with vesicovaginal fistulas ( $n=14$ ), with detrusor instability, impaired bladder compliance, and voiding dysfunction noted frequently as well. Of the 24 patients who were anatomically cured in this series, 1 (4%) had stress incontinence and 9 (38%) had urgency or urge incontinence.<sup>68</sup> Preoperative urodynamics should be performed only if surgical management will be influenced by the results. The authors do not routinely perform urodynamics preoperatively, since we would not usually advocate a concurrent continence procedure at the time of fistula repair even in the face of urodynamic stress incontinence. Every patient is carefully counseled regarding the variety of lower urinary tract problems that can occur or persist following such surgery, even when deemed successful.

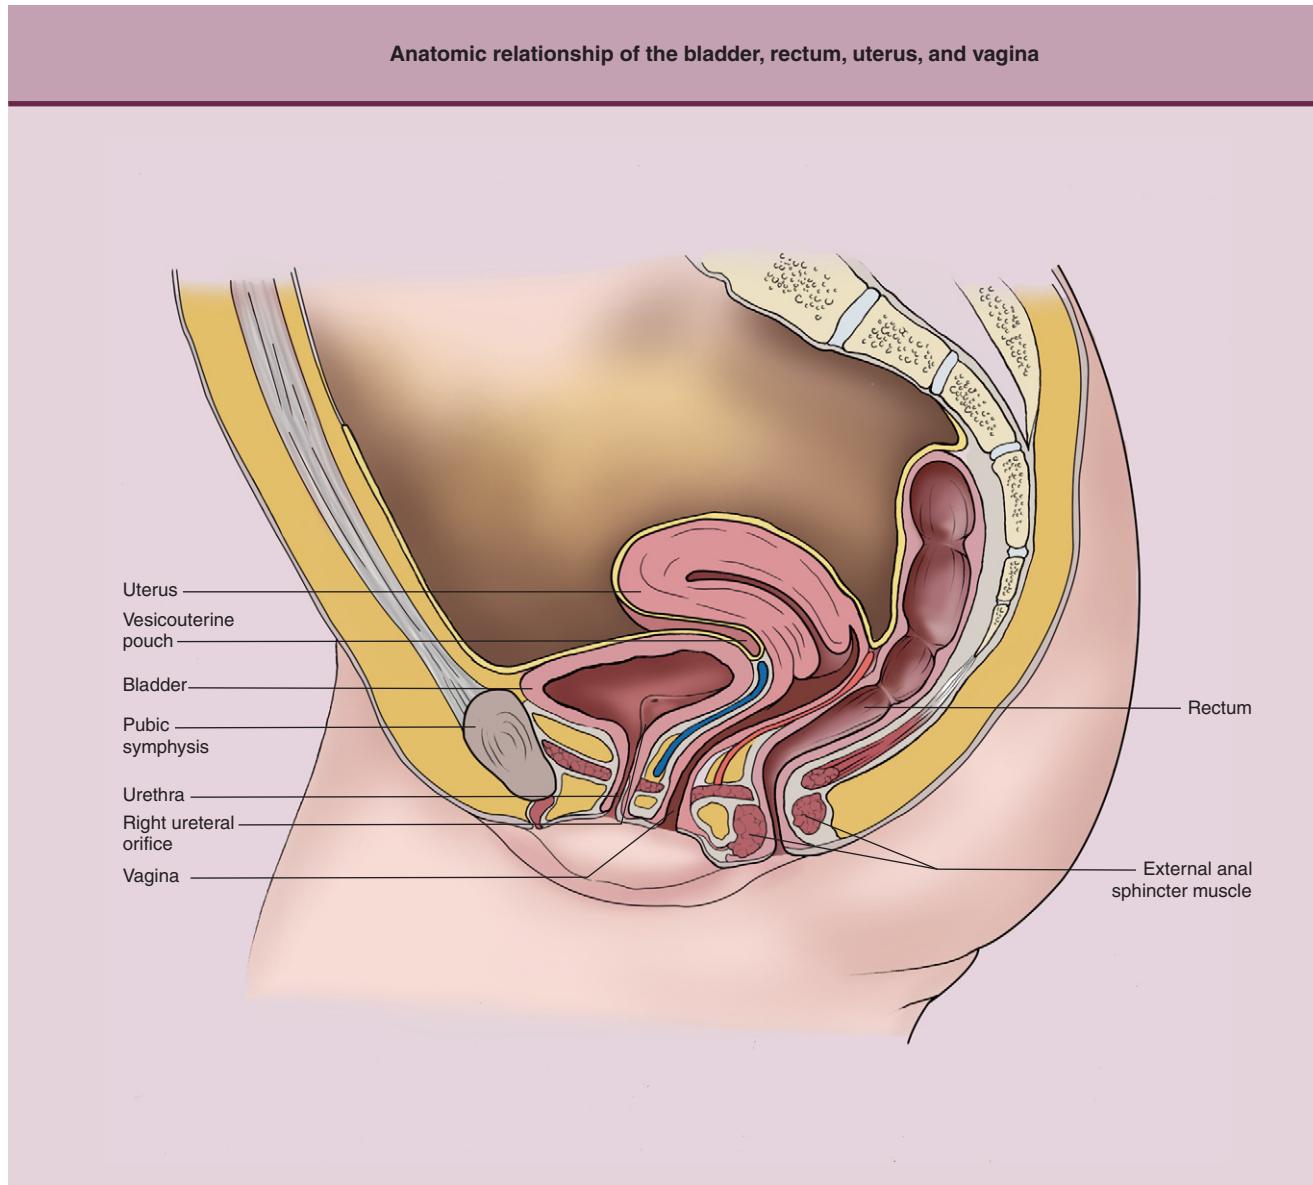

### **Prevention**

Since the occurrence of a cystotomy is considered intuitively to predispose a patient to subsequent fistula formation, prevention is discussed primarily in terms of preventing a cystotomy or adequately detecting and closing one if it occurs. Careful con-

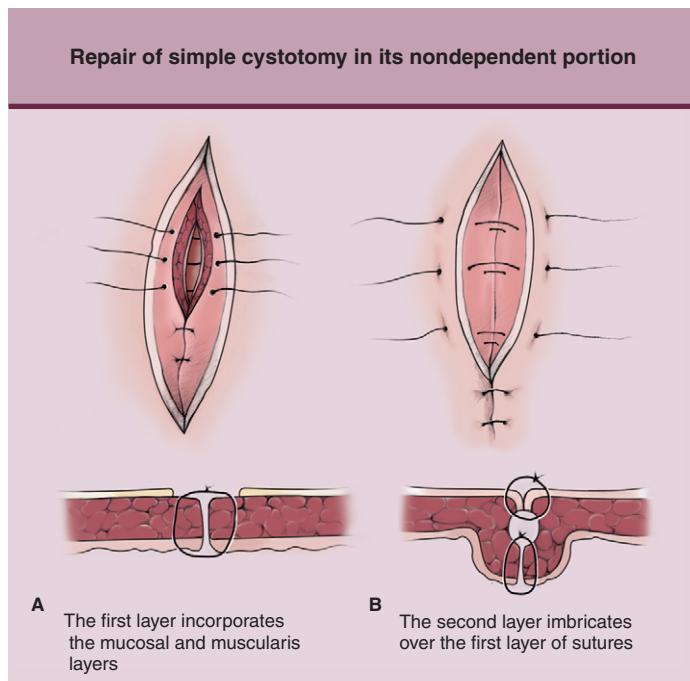

sideration of the bladder, trigone, and ureteral anatomy in relation to the anterior vagina is important to maintain during a total hysterectomy (Fig. 29-1). The bladder base overlies the uterine isthmus and the cervix, the bladder trigone is positioned anterior to the upper third of the vagina, and the external cervical os is proximal to the base of the trigone (the interureteric ridge). During a simple hysterectomy, mobilization of the bladder does not involve the upper third of the vagina and therefore rarely puts the trigone at risk. A subtotal (supracervical) hysterectomy requires no bladder mobilization and indeed resulted in no fistulas in a large series (see Table 29-3). This is not the case, however, with anterior colporrhaphy or vaginal paravaginal repair, where the anterior vaginal dissection is carried more distally and laterally.

The likelihood of cystotomy is reduced when blunt dissection is avoided at the time of bladder mobilization during hysterectomy, especially when the vesicovaginal space is scarred from prior cesarean section. The precise direction of forces cannot be as well controlled when blunt dissection is used, as compared with sharp dissection. Gentle traction and countertraction are helpful in dissecting the correct plane and thereby preventing bladder injury, as is utilizing an intrafascial hysterectomy technique. Another cause of bladder injury may be direct trauma due to retractors, which should be used with appropriate caution. In his report of urogenital fistulas, Tancer noted an absence of typical risk factors during the index surgery in 70% of cases.<sup>28</sup> Therefore, although it still is somewhat controversial, the authors advocate routine cystoscopy to assess for bladder and ureteral injury following hysterectomy, and certainly after surgery for pelvic prolapse or urinary incontinence.

In the event of a cystotomy, the location and size seem to be crucial to the possibility of subsequent vesicovaginal fistula formation. A small anterior bladder injury does not result in urogenital fistula formation as observed following removal of suprapubic catheters where the defect resolves spontaneously. Similarly, cumulative experience with trocar injuries from midurethral slings shows little or no consequence of leaving these small lateral and anterior defects to heal spontaneously, even when managed with no additional catheter drainage. Since these injuries are 0.5 cm or less in diameter, any bladder injury greater than that may benefit from primary repair. Owing to the dependent position of the bladder base, however, any recognized injury in this region requires suture closure and bladder drainage. Once a cystotomy is recognized, it may be repaired immediately or delayed until the hysterectomy or other surgical procedure is completed. The benefit of immediate repair is that blood and urine do not continually flow into the surgical field; however, with continued surgery and retraction there may be potential compromise to the fresh suture line, and this must be avoided. Adequate dissection of the bladder off the vagina is usually necessary to ensure tension-free closure and allow enough space for a second layer. The first layer can be accomplished with 2-0 or 3-0 absorbable suture placed in an interrupted or running fashion. There is continued controversy regarding whether this first layer can be placed through the mucosa, or should remain extramucosal. It is thought that the extramucosal technique may decrease the likelihood of subsequent fistula formation, although this has not been demonstrated. Sokol et al suggest that double layer closure is superior to single layer closure in

**Figure 29-1 Anatomic relation of the bladder, rectum, uterus, and vagina.** See text for details.

**Figure 29-2 Simple cystotomy closure.** Two-layer bladder closure with the first layer placed full thickness through the bladder epithelium (A) and the second suture line imbricating the muscularis and serosal layer over the first to reinforce it (B).

preventing vesicovaginal fistula in an experimental laparoscopic hysterectomy model of electrocautery-induced bladder injury with laparoscopic repair in dogs.<sup>70</sup> The second layer placed to imbricate the first is thought to diminish tension on the suture line (Fig. 29-2). Cystoscopy is important to evaluate ureteral and bladder integrity following completion of the repair. Transurethral or suprapubic catheter drainage must prevent bladder filling to avoid stretch on the suture line. The lack of reliable postoperative catheter drainage as a cause of failure was discussed at length by Sims in his landmark paper regarding urogenital fistulas in 1852.<sup>71</sup> Judgment should be exercised regarding duration of drainage, based on the extent of injury, its location, the security of the closure, and any factors that may impact the normal healing process. Some advocate use of a cystogram prior to catheter removal.

## Management

### Nonsurgical Management of Urogenital Fistula

Once a urogenital fistula has been diagnosed, a trial of conservative management should be offered. This is particularly true for small fistulas that present early and have no evidence of epithelialization of the tract. Transurethral bladder drainage may help small early vesicovaginal fistulas resolve spontaneously and may be tried for 4 to 6 weeks as long as catheterization is seen to resolve the vaginal leakage. Medical management should include optimizing nutrition, correcting anemia, and improving vaginal estrogenization.<sup>72</sup> Some success has been reported with laser treatment of vesicovaginal fistula,<sup>73</sup> as well as fibrin glue and collagen.<sup>74,75</sup> These novel approaches have not yet been adequately studied but may be considered in selected cases. The use of various collection devices have been tried with limited

success but may be offered for temporary relief of constant urinary leakage.

### Surgical Correction of Urogenital Fistula

When conservative therapy fails or the patient is not a candidate for conservative therapy, surgical repair is the only alternative to relieve the patient's condition. Prior to surgery, some advocate the need to remove any transurethral catheterization for several days to clear the urine of any infection. This may be considered as long as the patient is able to adequately prevent skin excoriation and tolerate the increased leakage.

The pelvic surgeon must determine the optimal timing, technique, and route of repair. No well-designed trials adequately address any of these dilemmas. Several general principles may apply and are discussed. Although traditionally, delayed repair for several months was the norm to allow the tissue to heal from the inciting surgery, more recently surgeons have undertaken earlier repair following surgical fistulas as long as there is no evidence of infection, inflammation, or necrosis in the tissue bed.<sup>76-79</sup> Obstetric and radiation injuries, however, require more time to heal prior to an attempt at fistula repair. It is generally agreed that the first attempt at cure is also the best chance of cure.

In Sims' classic article regarding the surgical treatment of vesicovaginal fistulas, he emphasized the need to excise all scar tissue within the fistula and create fresh tissue edges for reapproximation. Additional surgical principles include tension-free closure of the wound with wide mobilization of the bladder to help achieve this, careful handling of tissues, ensuring excellent hemostasis, and maintaining good bladder drainage postoperatively.<sup>71</sup>

Despite these original tenets, there is no consensus about whether to excise the margins of the fistula. Several series have reported success with preservation of the fistula margin, and some surgeons are concerned about making the fistulous opening larger, as occurs when the fistulous tract is trimmed.<sup>31,80</sup> Others have continued to report their experiences with excision of the tract.<sup>14,81</sup> The purported benefit is allowing fresh tissue edges to be approximated, thereby promoting healing of these surfaces and reducing failure rates. Whereas there are no adequate studies that would conclusively show superiority of either of these techniques, it is interesting to note that there is limited discussion regarding retaining the fistula collar when operating transabdominally, reserving this debate primarily for the transvaginal approach. In the case of excision, another technical dilemma is whether to permit through-and-through suture reapproximation or insist on excluding the mucosal layer from the stitch. Concern over incorporating the mucosal layer stems from the possibility that it would increase the likelihood of failure and may lead to stone formation given that this region is the most dependent portion of the bladder and is always in contact with urine. The potential benefits of a through-and-through stitch are its ease and better hemostasis at the incision site. It should also be noted that transvesical techniques used to perform complex procedures such as ureteroneocystostomy routinely make use of intravesical suture, albeit in more non-dependent areas of the bladder, with no clear adverse effects. It remains for the operating surgeon to decide individually how to close the suture line.

## Urogynecology

Perhaps the most intense debate has been surrounding the route of vesicovaginal repair—transabdominal or transvaginal. There seems to be general agreement that the vaginal repair is more convenient for the patient in terms of recovery, length of hospital stay, and cosmetic issues, but little agreement regarding which is the better operation. Absolute indications for an abdominal approach include conditions that require bladder augmentation (a small capacity or poorly compliant bladder, as may occur following irradiation), a fistula involving or very close to a ureter that requires ureteral reimplantation, a combination fistula involving other intra-abdominal organs, inability to adequately expose the fistula transvaginally due to positioning, or other access problems (Table 29-5). It is also noted that the majority of vesicovaginal fistula repairs are in fact amenable to the vaginal approach.<sup>82</sup> Some have concluded that abdominal approaches are outright superior<sup>83–85</sup> while others prefer the vaginal approach as their routine.<sup>31,78,86</sup>

Success rates have been reported in different ways; it may be for the first surgical attempt or the ultimate rate that allows for multiple attempts. In this chapter, quoted rates are for the first attempted repair, unless otherwise stated. Through an abdominal approach the physician can do a transvesical-transperitoneal approach made popular by O'Conor<sup>87</sup> or a more limited transvesical repair introduced by Landes.<sup>88</sup> Success rates for the transvesical-transperitoneal approach have been between 68% and 100% for benign, nonirradiated fistulas.<sup>79,84,85</sup> A different abdominal operation for vesicovaginal fistula repair is the transvesical approach. For data pooled from three studies reporting variations of this technique, with a total of 91 fistula patients (primary and recurrent), the success rate is 100%.<sup>83,88,89</sup> However, a non-technique-specific series reports a 91% success rate for the transvesical approach.<sup>14</sup>

Vaginal repair reveals success rates of 77% to 99%.<sup>14,23,31,90</sup> These vaginal procedures encompass various techniques. No comparative studies are available to determine which specific vaginal procedure, if any, is superior.

Indeed with the initial success rates being comparable, there is no consensus regarding the optimal approach to repair vesicovaginal fistulas. It is clearly important that surgeons who repair these lesions be comfortable with several different approaches and individualize their techniques to the particular case at hand.

Various techniques have been described to augment fistula repairs, both for the transabdominal and transvaginal approaches. This is thought to bring additional tissue to interpose between the bladder and the vagina and with it, a healthy blood supply. Occasionally, such grafts also serve to fill in dead space, as with large fistulas where a great amount of tissue is lost. The routine use of interposition grafts has been advanced by some; however,

most surgeons use these adjuncts based on individualized clinical judgment. It is generally agreed that tissue interposition is needed in irradiation-induced fistulas or in other instances where there is local vascular compromise, such as recurrent, severely scarred, or previously infected fistulas. Transabdominally the omentum or peritoneum is most often used with excellent results. Evans et al reported a 100% (10/10) success rate with such interposition grafts compared with 63% (12/19) when grafts were not used in benign vesicovaginal fistulas repaired transabdominally in a urologic residency program.<sup>91</sup>

Rangnekar et al report on Martius bulbocavernosus fat pad grafting to reinforce 21 obstetric urethrovaginal and vesicovaginal fistula repairs done transvaginally. Although they showed better success rates for both types of fistulas with use of the graft, because of the small sample size, statistical significance cannot be reached. Seven patients of 8 (87%) were cured of their urethrovaginal fistula, whereas all 13 patients (100%) with vesicovaginal fistulas were cured with use of the Martius graft.<sup>92</sup> For extremely large defects, Punekar et al reported four patients who had a myocutaneous modification of the Martius bulbocavernosus graft. The island of skin after sublabial transfer was sutured to the defect in the vaginal wall. This modified repair has been suggested for large obstetric or irradiation-induced fistulas.<sup>93</sup> Eilber et al report long-term results of transvaginal repair of complex or recurrent vesicovaginal fistulas with either peritoneal interposition graft for fistulas high in the vault or Martius flap or labial flap for distal defects. Cure rates were 96% of 83 patients with peritoneal graft, 97% of 34 patients with Martius fat pad graft, and 33% of three patients with a full-thickness labial flap that was rotated onto the defect and used mainly for very complex cases with multiple attempts at repair where there was insufficient vaginal epithelium to cover the fistula. Alternative flaps have been described, such as gracilis or rectus abdominis myocutaneous grafts in difficult circumstances.<sup>94,95</sup> In six patients who failed urethrovaginal fistula closure with Martius transposition, Bruce et al report 100% successful resolution of the fistula when treated with a pedicled, tubularized rectus abdominis muscle flap interposed suburethrally.<sup>96</sup>

When preparing patients for surgical correction of a urogenital fistula, detailed informed consent and discussion are very important. Patients with urogenital fistulas as complications of benign pelvic surgery have already experienced an adverse outcome that they may or may not have been prepared for. They invariably have some degree of frustration, anxiety, and suspicion. All aspects of operative risk should be discussed with the patient prior to fistula repair, including the likelihood of fistula recurrence. Even in the event of successful anatomic repair, the occurrence or persistence of lower urinary tract symptoms such as incontinence, overactive bladder, voiding dysfunction, and bladder pain should be discussed. Discussing the expected recovery course of the various available approaches and potential adverse consequences of associated procedures such as episiotomy or Schuchardt incisions, disfigurement from flaps, and discomfort from suprapubic and transurethral catheters seems to prepare patients for some of the difficulties that may lie ahead. This information should be incorporated into the decision of the route of repair, which the patient should ideally be a partner in. When ureteral reimplantation may be

Table 29-5

## Indications for Abdominal Vesicovaginal Fistula Repair

- Small capacity or poorly compliant bladder requiring bladder augmentation
- Fistula involving or very close to a ureter requiring ureteral reimplantation
- Combination fistula involving other intra-abdominal organs
- Inability to adequately expose the fistula transvaginally

required, the need for stenting and subsequent cystoscopic stent removal should be discussed as well as the need for drains, the risk of ureteral stenosis, and the need for subsequent radiologic follow-up. Patients undergoing a vaginal repair should be made aware of the possibility of conversion to an abdominal procedure, although this is a rare occurrence.

### Vaginal Procedures

#### Vesicovaginal Fistula Repair

The patient is placed in the dorsal lithotomy position using candy-cane stirrups. Examination under anesthesia is performed with water cystoscopy. The 30° or 70° lens is used to best visualize the fistula intravesically and identify any associated abnormalities. Identifying the intravesical and the vaginal openings and assessing the tract's angle is important, since the next step is cannulation of the fistula. The fistula's proximity to the ureters is assessed, and transvaginal repair is continued if it is not too close. Ureteral stenting may be done to continuously identify the ureters if needed. Dilation of the fistulous tract allows an 8 French Foley catheter to be inserted and the balloon inflated. Appropriate traction allows the fistula to be brought distally for better access and exposure. When the tissue surrounding the fistula is extensively scarred, subepithelial injection of saline may be used to facilitate dissection of the vaginal flap. Some authors advocate the use of epinephrine to diminish surgical bleeding.

The vaginal mucosa is incised circumferentially around the fistulous opening; the vaginal mucosa is then carefully dissected off the bladder to a distance that will allow tension-free multiple-layer closure, approximately 1 to 2 cm radially around the circumferential incision. All tissue must be handled delicately with fine instruments that are of sufficient length to reach all levels of the fistula and the dissected tissues. Excellent hemostasis is best achieved with liberal use of pressure and subsequent suture closure, avoiding the use of electrocautery if at all possible. The fistula collar is excised and sent for pathologic evaluation. Repeat cystoscopy verifies the location of the ureters in relation to the somewhat larger fistulous opening. A suprapubic catheter is then placed. The bladder mucosa is closed in the direction of least tension (side to side, or proximal to distal) with interrupted 3-0 or 4-0 delayed absorbable sutures, placed approximately 0.5 cm apart. Proximal to distal orientation is chosen if the ureters are in close proximity to the defect once the fistula is excised. If extramucosal suturing is possible, it is done; however, if desired or if mucosal edge bleeding is encountered, through-and-through suturing is not contraindicated. A second layer of bladder muscularis is brought together over the first suture line so it imbricates over it. This is achieved with interrupted suture that is placed staggered in between the underlying stitches on the first layer (Fig. 29-3). If the bladder peritoneum can be mobilized over the repair, it is accomplished at this point. If a Martius fat pad transposition is desired, this may be done instead of the peritoneal layer at this time. The vaginal mucosa is then closed with interrupted suture again staggered from the second bladder layer. At all stages of the closure, the absence of tension on each level is paramount to successful repair, as is hemostasis and verification of healthy, well-vascularized tissue for apposition.

The Latzko procedure begins in a similar fashion with a circumscribing incision and dissection of the vagina off the

cervicovaginal fascia. Instead of excising the fistulous tract, it is imbricated into the bladder cavity with sequential layers of interrupted 3/0 or 4/0 delayed absorbable suture on a small tapered needle. Care should be taken to stagger the sutures so none lay atop the next layer (Fig. 29-4). Cystoscopy should be used to verify water-tight closure of the fistula and integrity of the ureters.

#### Urethrovaginal Fistula Repair

The same principles of careful handling of tissues, good hemostasis, and tension-free apposition of tissues must be maintained with surgical correction of urethrovaginal fistulas. A distal fistula may be closed in a proximal to distal orientation to limit the possibility of urethral stenosis; otherwise these lesions are closed side-to-side in layers. Eversion of the fistula edges into the limited urethral lumen is not recommended, and transmucosally placed suture is avoided if at all possible. If there is adequate substance, the fistula is minimally excised, but often there is enough loss of urethral wall that this may be impossible without resultant stricture formation (Fig. 29-5). The authors recommend liberal use of the Martius flap to support these repairs, and a pedicled rectus muscle flap for recurrent urethrovaginal fistula, if a previous Martius flap was employed and failed. The technique used for Martius fat pad transposition is depicted in Figure 29-6.

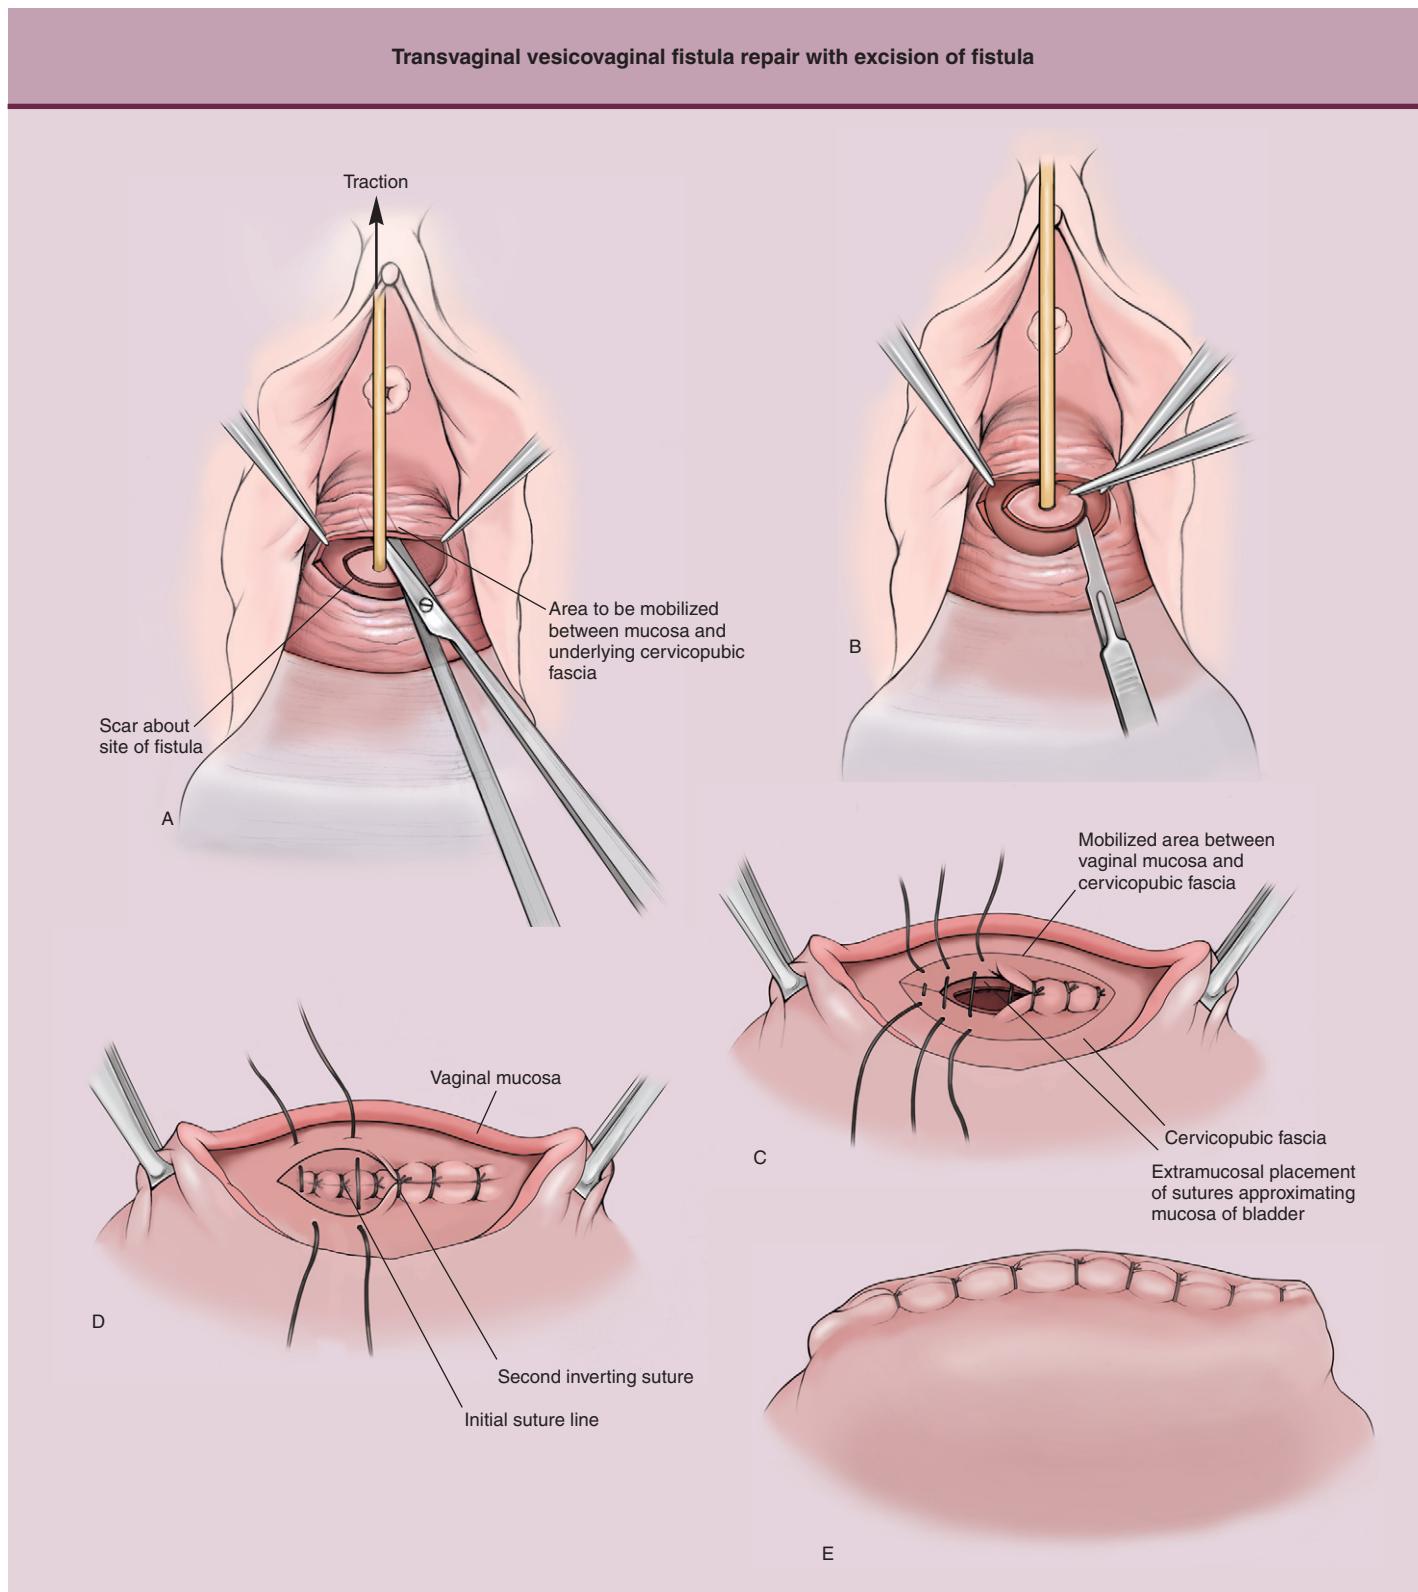

### Abdominal Procedures

#### Retropubic Transvesical Vesicovaginal Fistula Repair

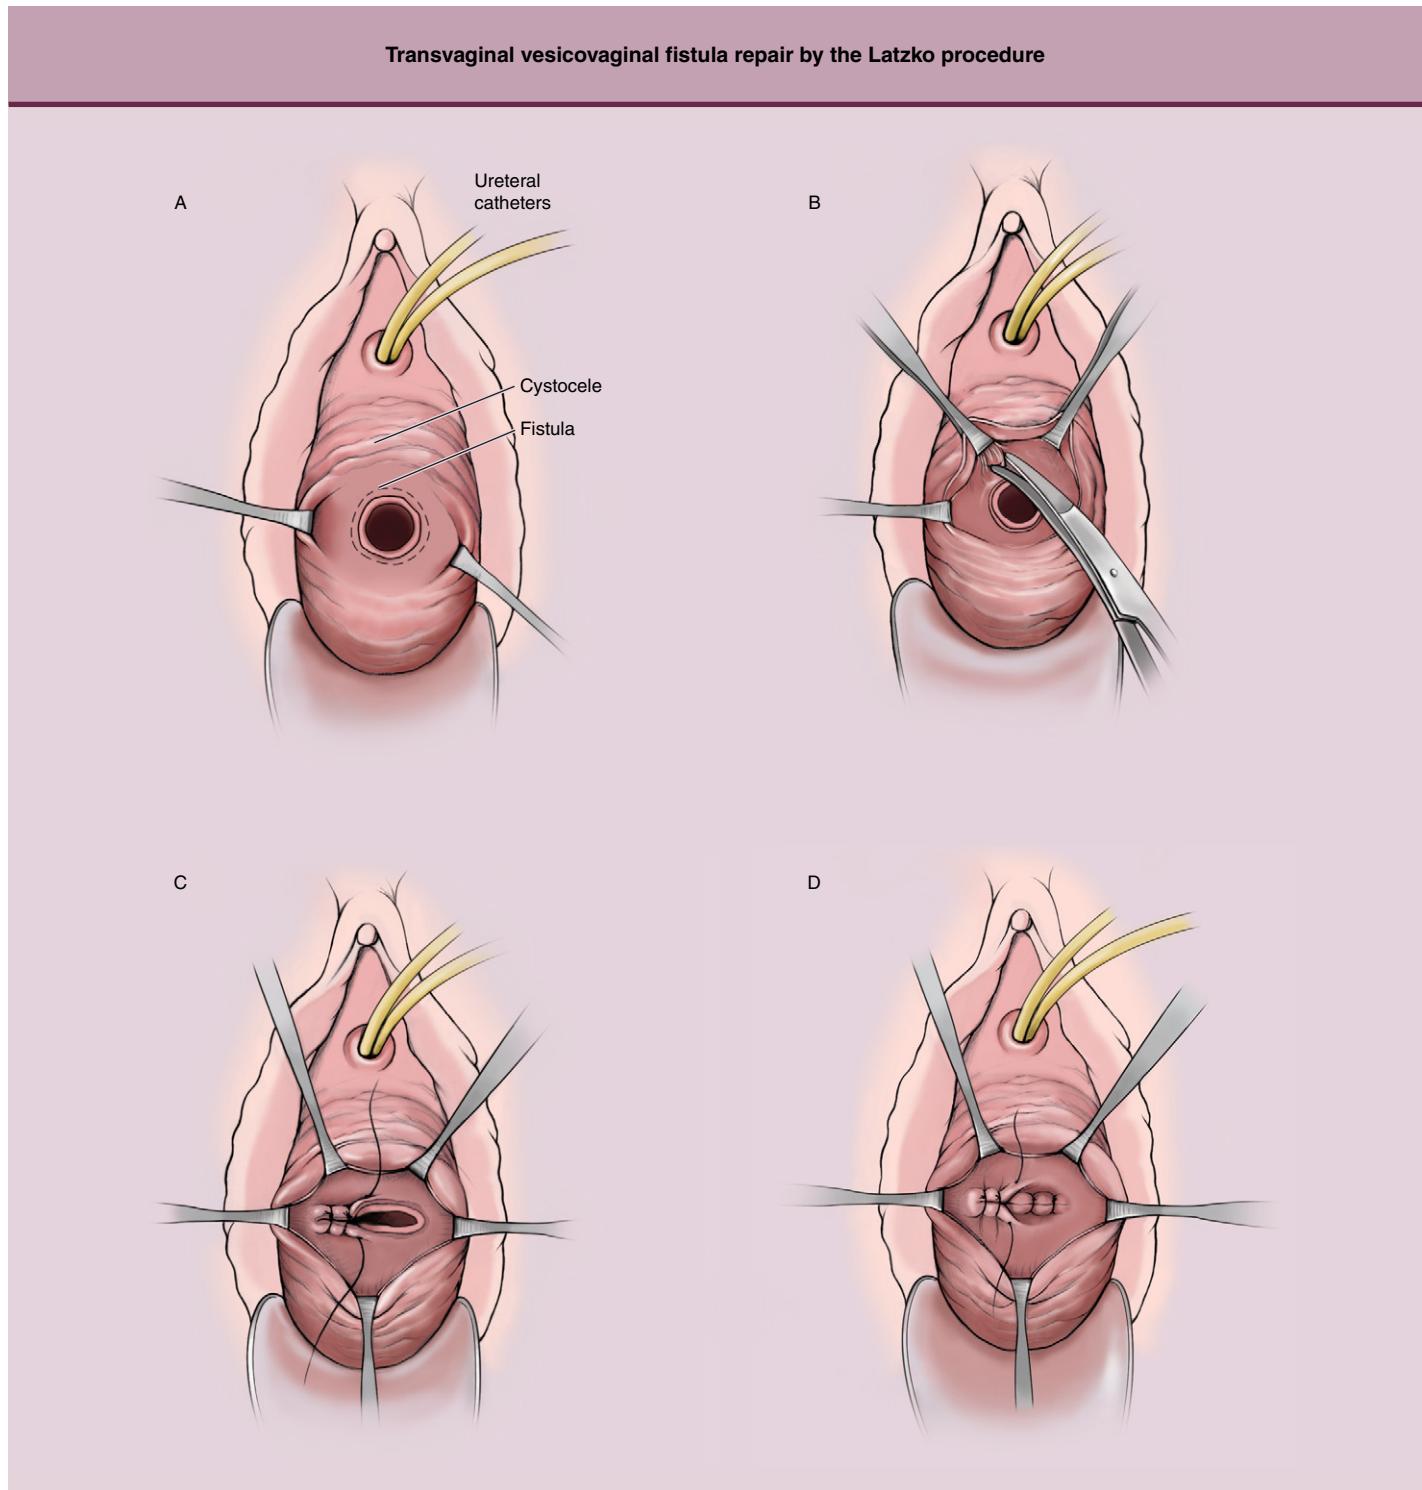

This procedure is indicated for simple posthysterectomy vesicovaginal fistula (VVF) when adequate vaginal exposure cannot be obtained or can be obtained only with a Schuchardt or episiotomy incision and the patient prefers an abdominal approach. A Cherney or midline abdominal wall incision is made, the retropubic space is entered, and a midline vertical incision is made in the bladder. The ureteral orifices are inspected and catheterized if needed. The fistula is identified and dilated to admit an 8 French pediatric Foley catheter after the position of the ureters is verified and the balloon inflated. A circumscribing incision is made 2 to 3 mm from the fistula and the vesicovaginal space dissected circumferentially 1 to 2 cm outward. The fistula is excised and the defect closed in layers with the vaginal layer first using interrupted delayed-absorbable 3-0 suture and the knots placed within the vaginal lumen. The bladder serosa and muscularis is closed next with knots placed in the vesicovaginal space. A third row incorporating bladder muscularis and mucosa is closed with 4-0 suture (Fig. 29-7). Ureteral integrity is verified. A suprapubic catheter is placed through a separate incision. The bladder incision is closed with running delayed-absorbable suture in two layers. Cystoscopy is used to verify water-tight closure and ureteral integrity prior to wound closure.

#### Transvesical-Transperitoneal Vesicovaginal Repair

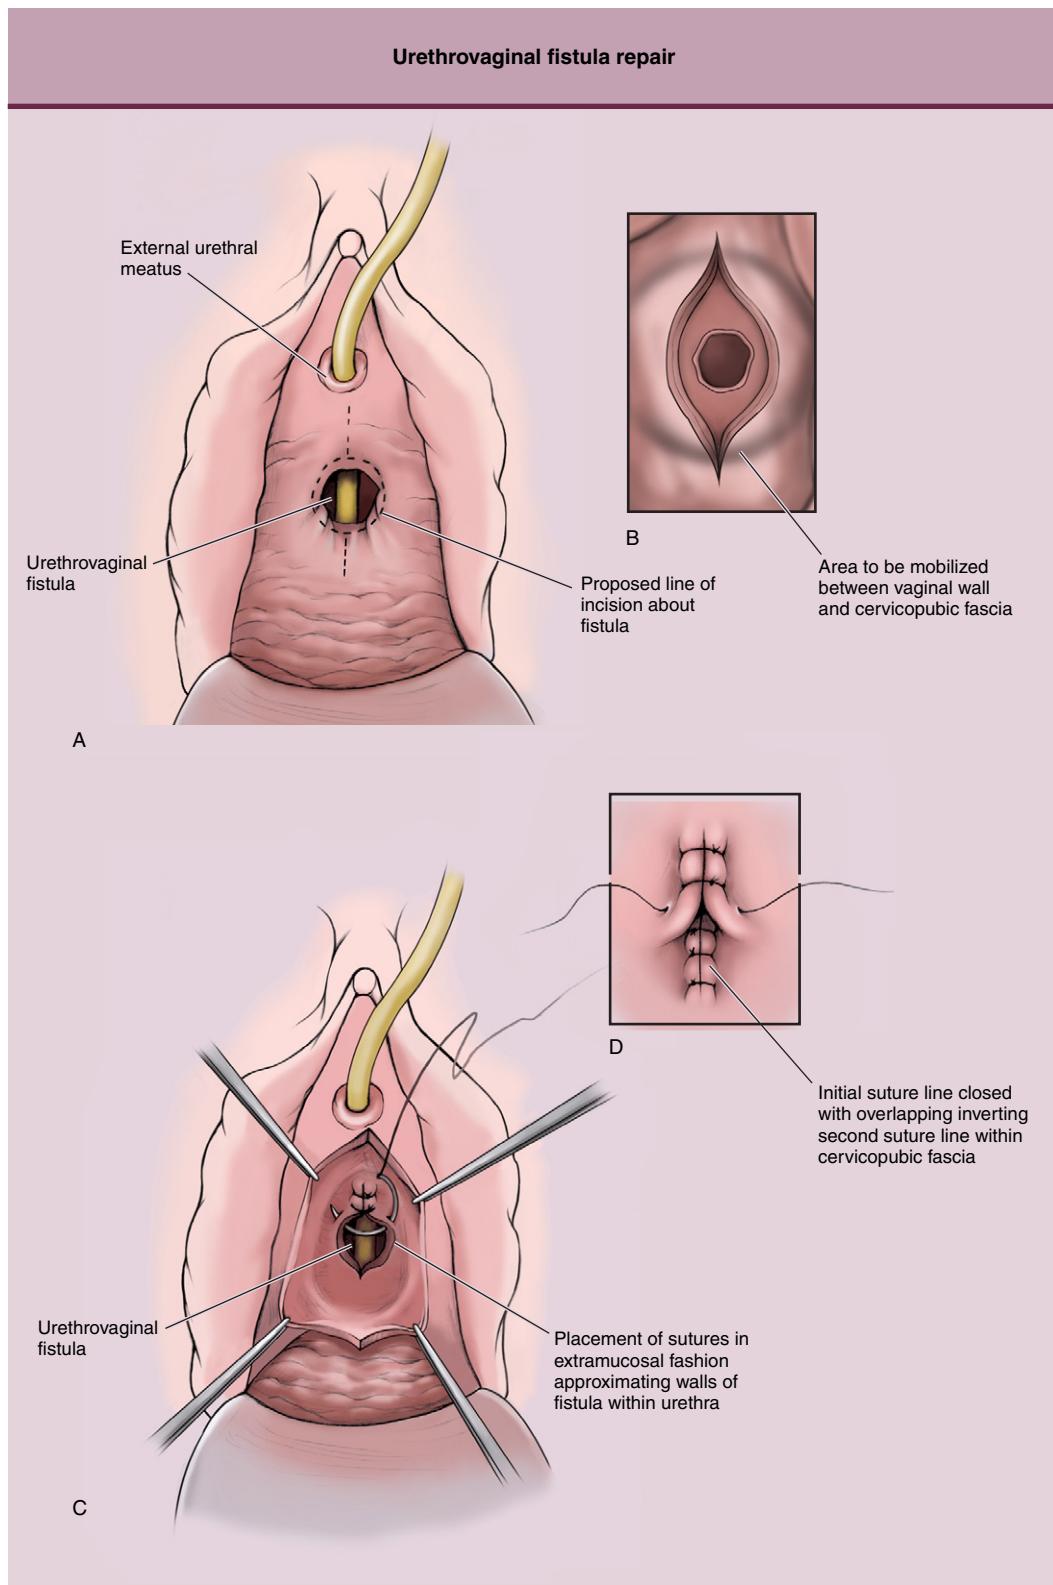

Cystoscopy is used to identify the pertinent anatomy and the fistula is cannulated with a stent. The bladder is vertically bisected in the midline starting at the retropubic portion and continues posteriorly in its peritoneal portion until it reaches the vesicovaginal space. This space needs to be dissected laterally and distally until the fistula is encountered, using digital traction within the bisected bladder. The fistula is identified with the aid

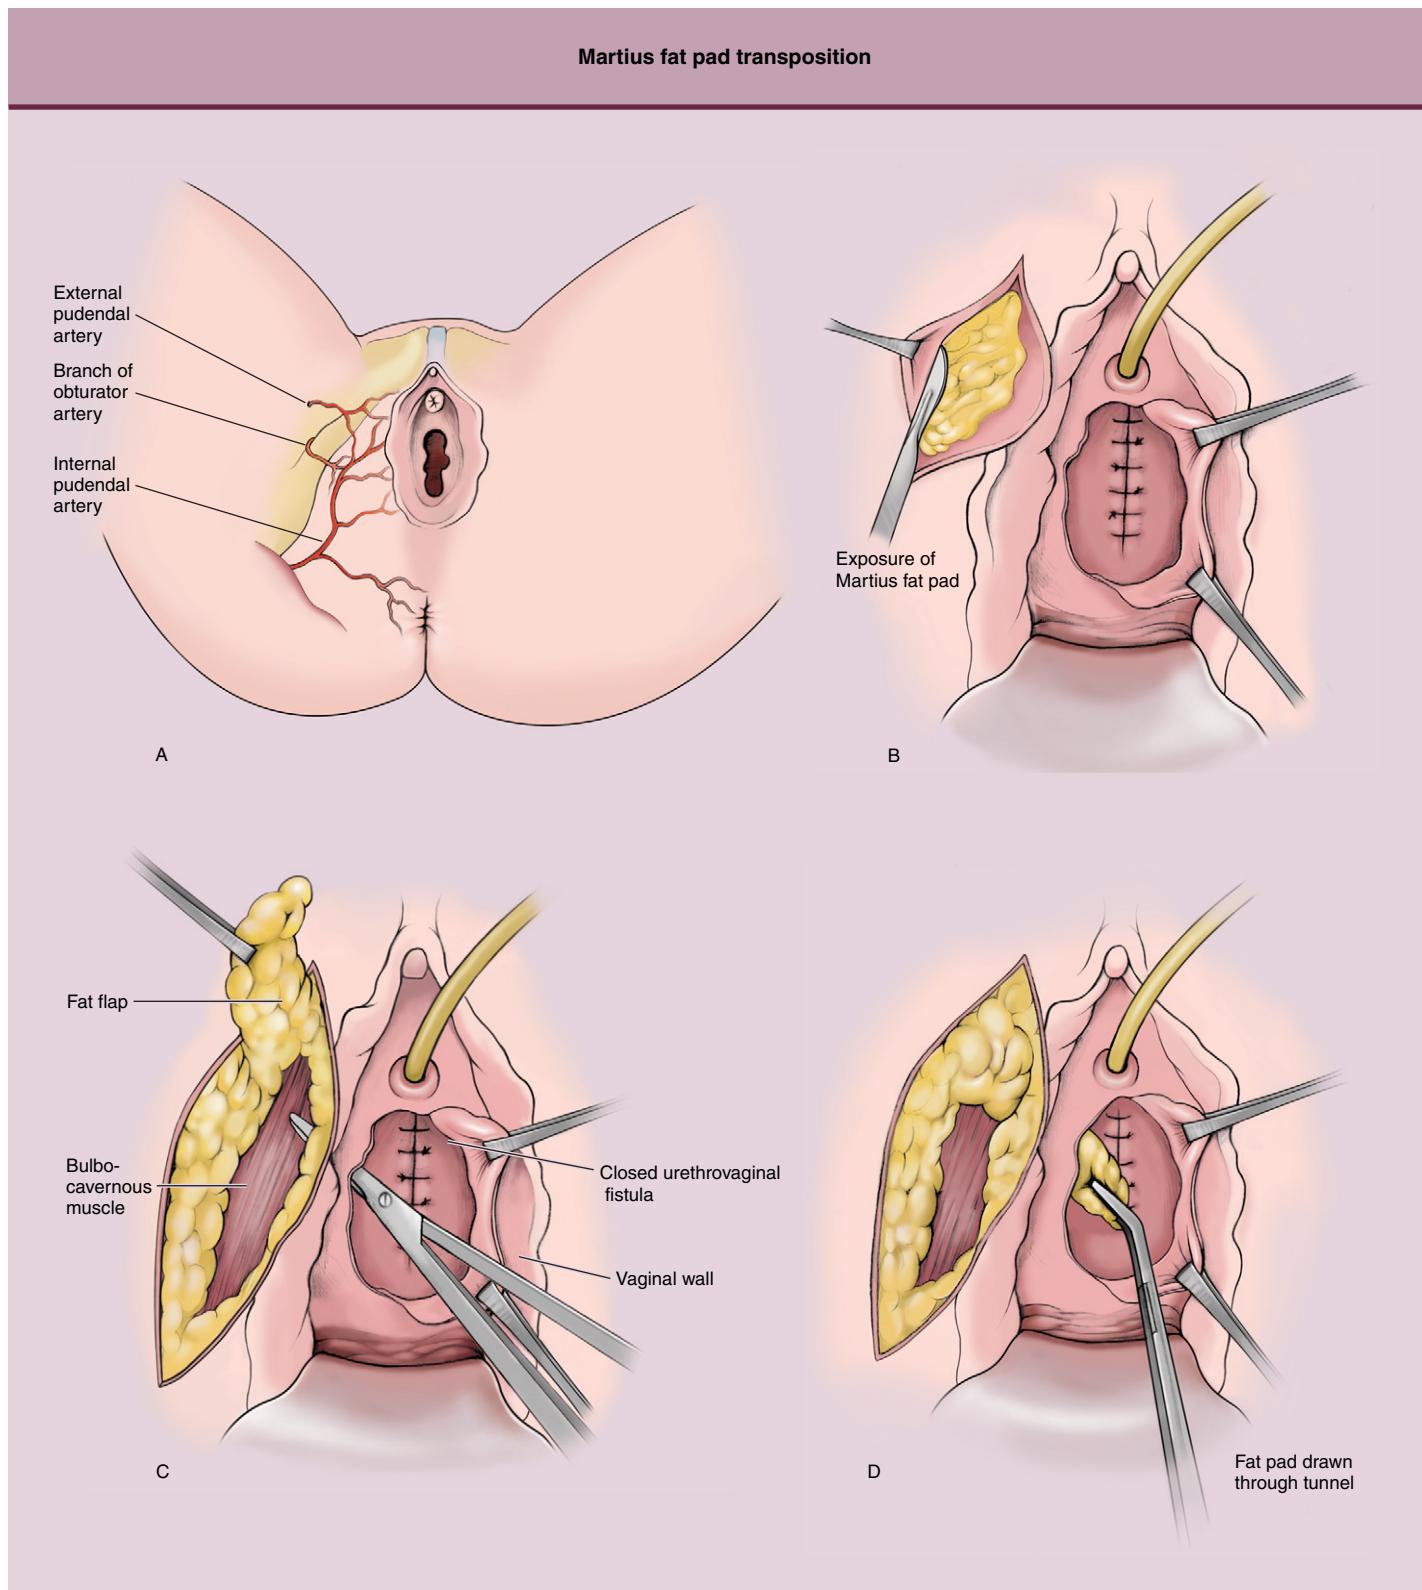

**Figure 29-3 Traditional vesicovaginal fistula repair.** *A*, Initial incision of a circumferential collar around the fistulous opening. The vaginal mucosa is sharply dissected radially from the collar. *B*, The fistula is excised sharply, making sure that healthy vaginal tissue is left to be reapproximated. Excessive trimming, increasing the loss of tissue, should be avoided. *C*, Interrupted fine, delayed-absorbable suture on a small tapered needle is used, extramucosally if possible, to close the first layer. Stitches are placed approximately 0.5 cm apart with sufficient purchase of tissue to securely close the incision. *D*, The second layer imbricates over the first with suture being placed in a staggered fashion. *E*, The mucosa is closed with moderate-caliber, interrupted delayed-absorbable suture.

**Figure 29-4 Latzko procedure.** A-D, Note that the fistulous tract is left in situ and the collar of tissue is imbricated into the bladder viscus with interrupted fine, delayed-absorbable suture on a small tapered needle. The second layer further imbricates the first, and the vaginal mucosa is closed last, also with interrupted suture.

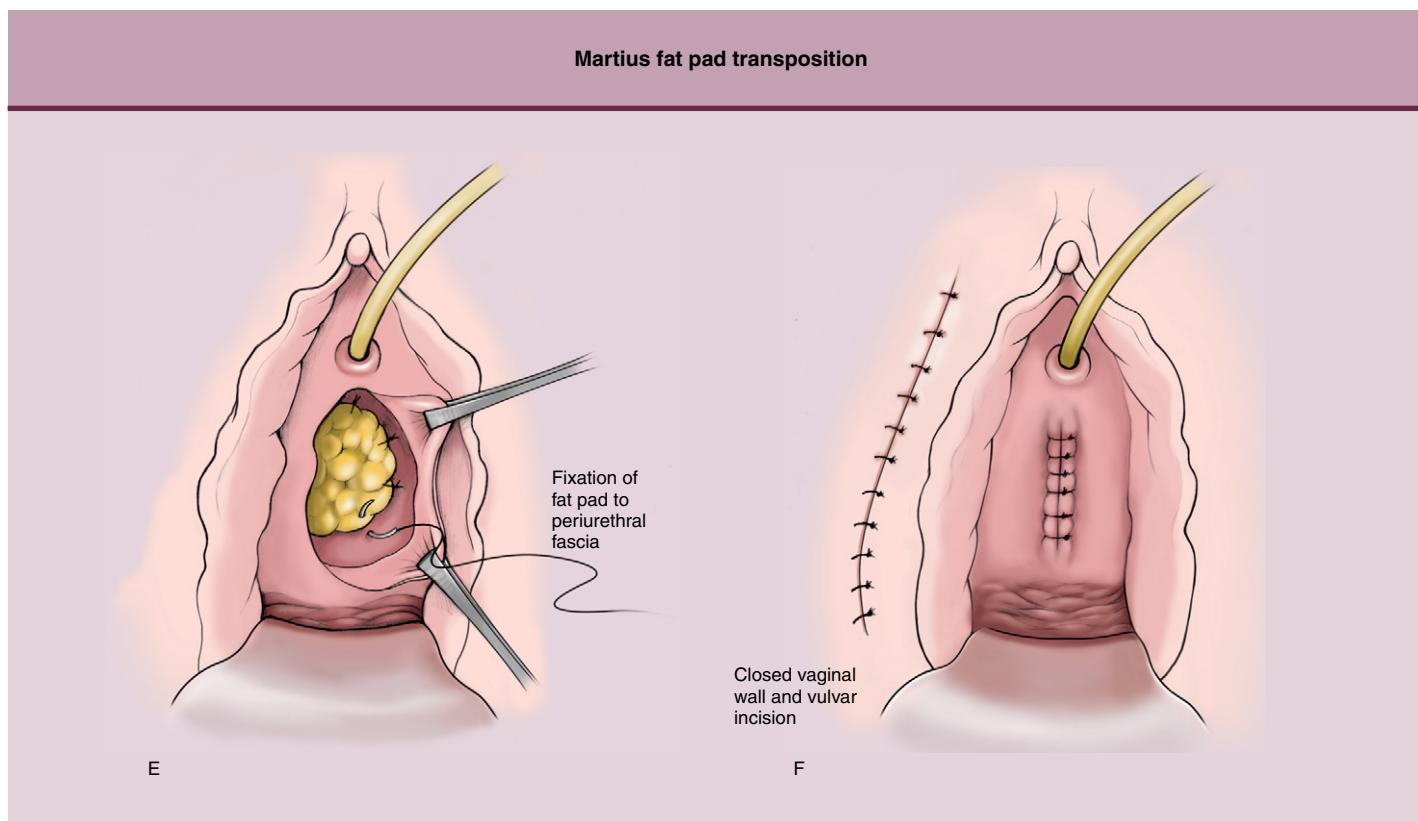

**Figure 29-5 Urethrovaginal fistula repair.** A, Note the initial circumferential incision with midline extension proximally and distally. B, Further lateral dissection exposes paraurethral tissue and allows for tension-free closure. C, The first layer is closed by interrupted fine, delayed-absorbable suture on a small tapered needle, avoiding intramucosal placement. D, The second is an interrupted imbricating layer. Martius fat pad transposition is highly recommended for these repairs.

**Figure 29-6 Martius (bulbocavernosus) fat pad transposition.** A, The labial fat pad is supplied anteriorly by branches of the external pudendal and obturator arteries, and posteriorly by branches of the internal pudendal artery. Although traditionally the posterior blood supply was thought to be of superior quality, the graft may be swung anteriorly or posteriorly depending on the need of the surgeon. B, An incision is made over the labial fat pad, and it is dissected bluntly and with electrocautery. C, Once it is detached, a submucosal tunnel is created and enlarged to ensure adequate blood flow to the graft. D, The graft is pulled through the tunnel to the area needed and sutured in place.

*Continued*

**Figure 29-6, cont'd** *E*, The graft is pulled through the tunnel to the area needed and sutured in place. *F*, Hemostasis of the donor site is verified, and the incisions are closed.

of the stent and is excised. Ureteral integrity is verified and continually monitored during the surgery. The vagina is closed transversely with interrupted delayed-absorbable suture with the knots within the vaginal lumen. A second layer of vagina is used to imbricate the first if sufficient tissue is found. The bladder is closed in two layers side to side (Fig. 29-8). Prior to complete closure of the bladder, a suprapubic catheter is placed through a separate stab incision. If an omental flap is deemed necessary, it is placed into the vesicovaginal space once the bladder sutures have been tied (Fig. 29-9). Cystoscopy is used to verify water-tight closure prior to wound closure.

When the fistula is adjacent to the ureteral orifice, uretero-neocystostomy must be performed at the time of fistula repair (Fig. 29-10). Once the dependent portion of the repair is complete, attention is turned to performing the uretero-neocystostomy (Fig. 29-11). The implantation site should be placed in the posterior aspect of the bladder but sufficiently distant from the repair site. A double-J stent is placed and left for 4 to 6 weeks (Fig. 29-12). The anastomosis site is drained with a Jackson-Pratt drain brought out through a separate stab incision.

#### Vesicouterine Fistula Repair

A transperitoneal approach is preferred for repair of vesicouterine fistulas. This may be done with or without hysterectomy, but should be delayed for 3 months if the inciting procedure was a cesarean section to allow for involution of the uterus. A vertical bladder incision is made and the fistula identified. If the

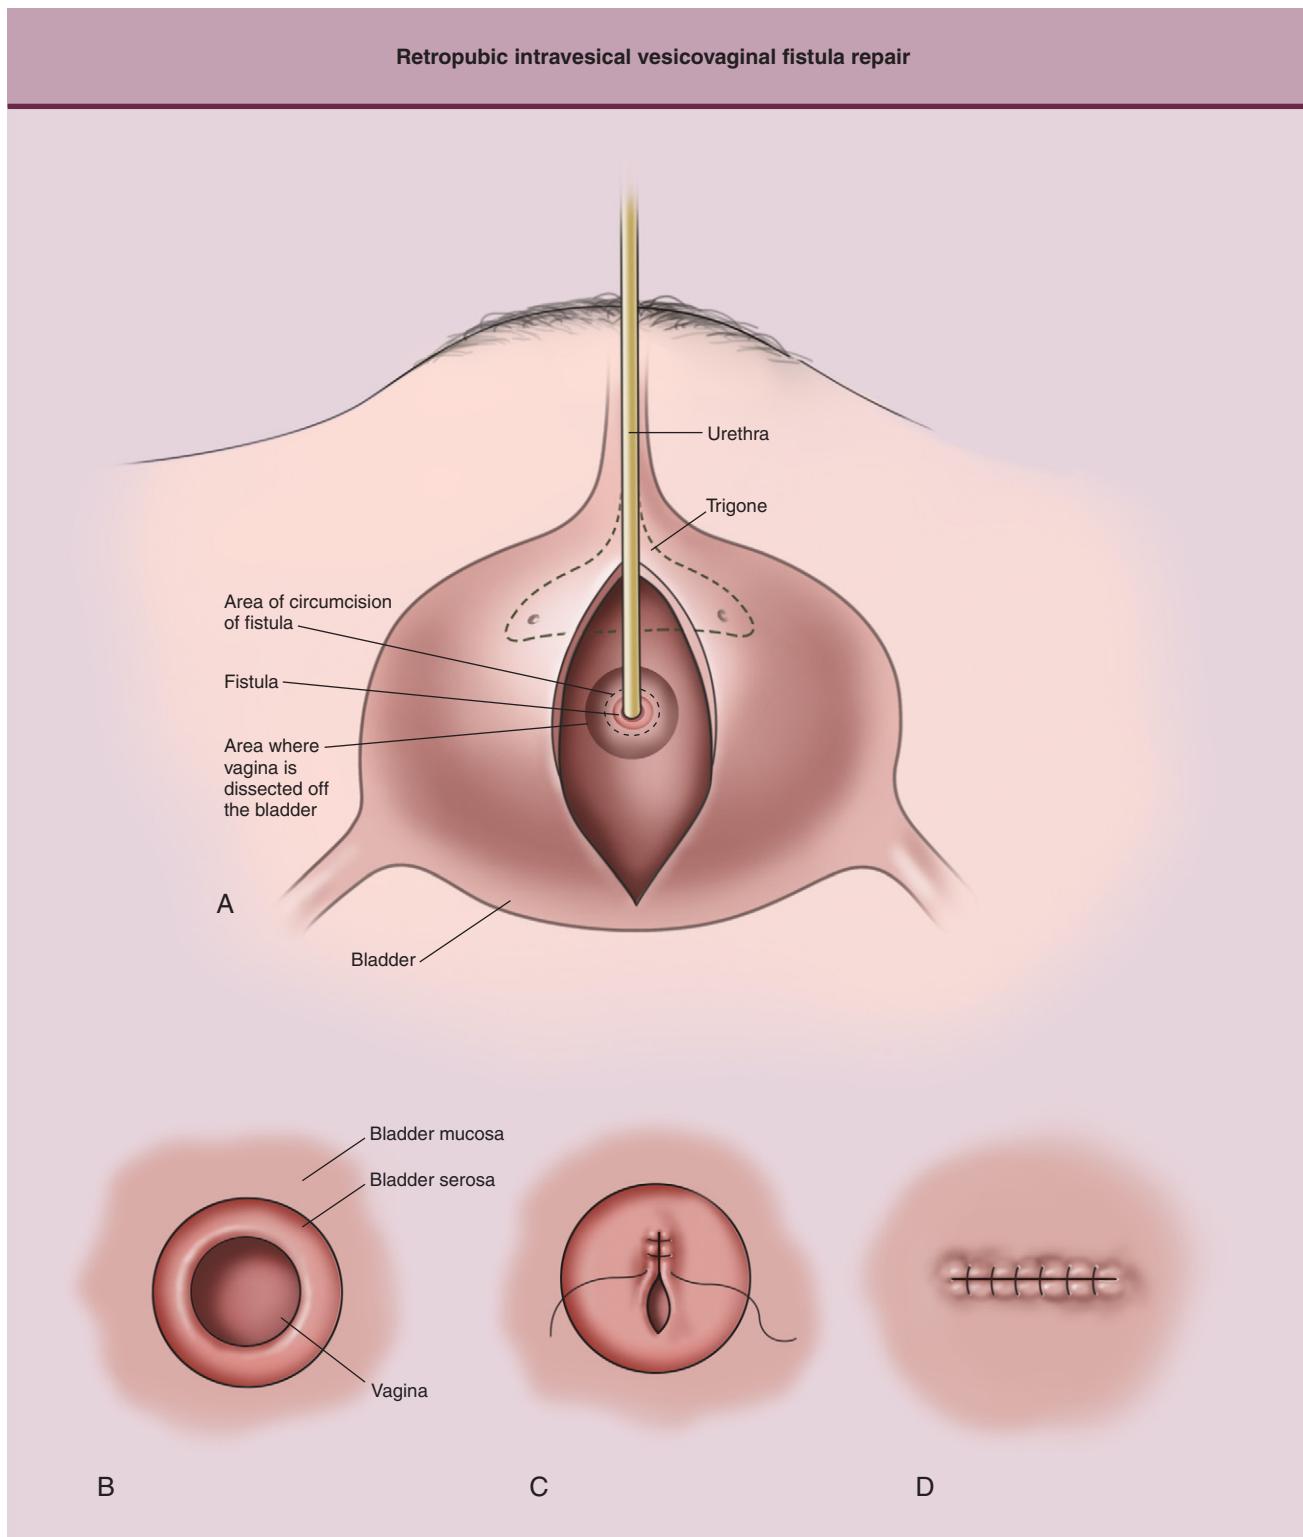

uterus is to be preserved, the vesicouterine space is developed sharply down to the fistula. At this point the vertical bladder incision is extended posteriorly to help with easy identification of the vesicouterine fistula. Once the planes have been appropriately dissected, layered, tension-free closure of the bladder is performed with uterine closure done separately. An omental flap may be placed and sutured into the space for interposition (Fig. 29-13). It should be kept in mind that such omental transposition will make any subsequent cesarean section more difficult. If repair is done along with a hysterectomy then it is performed in routine fashion with careful, sharp dissection of the bladder off the uterus, cervix, and vagina. The remaining vesical fistula is then excised and the defect closed in layers without tension.

#### Postoperative Care

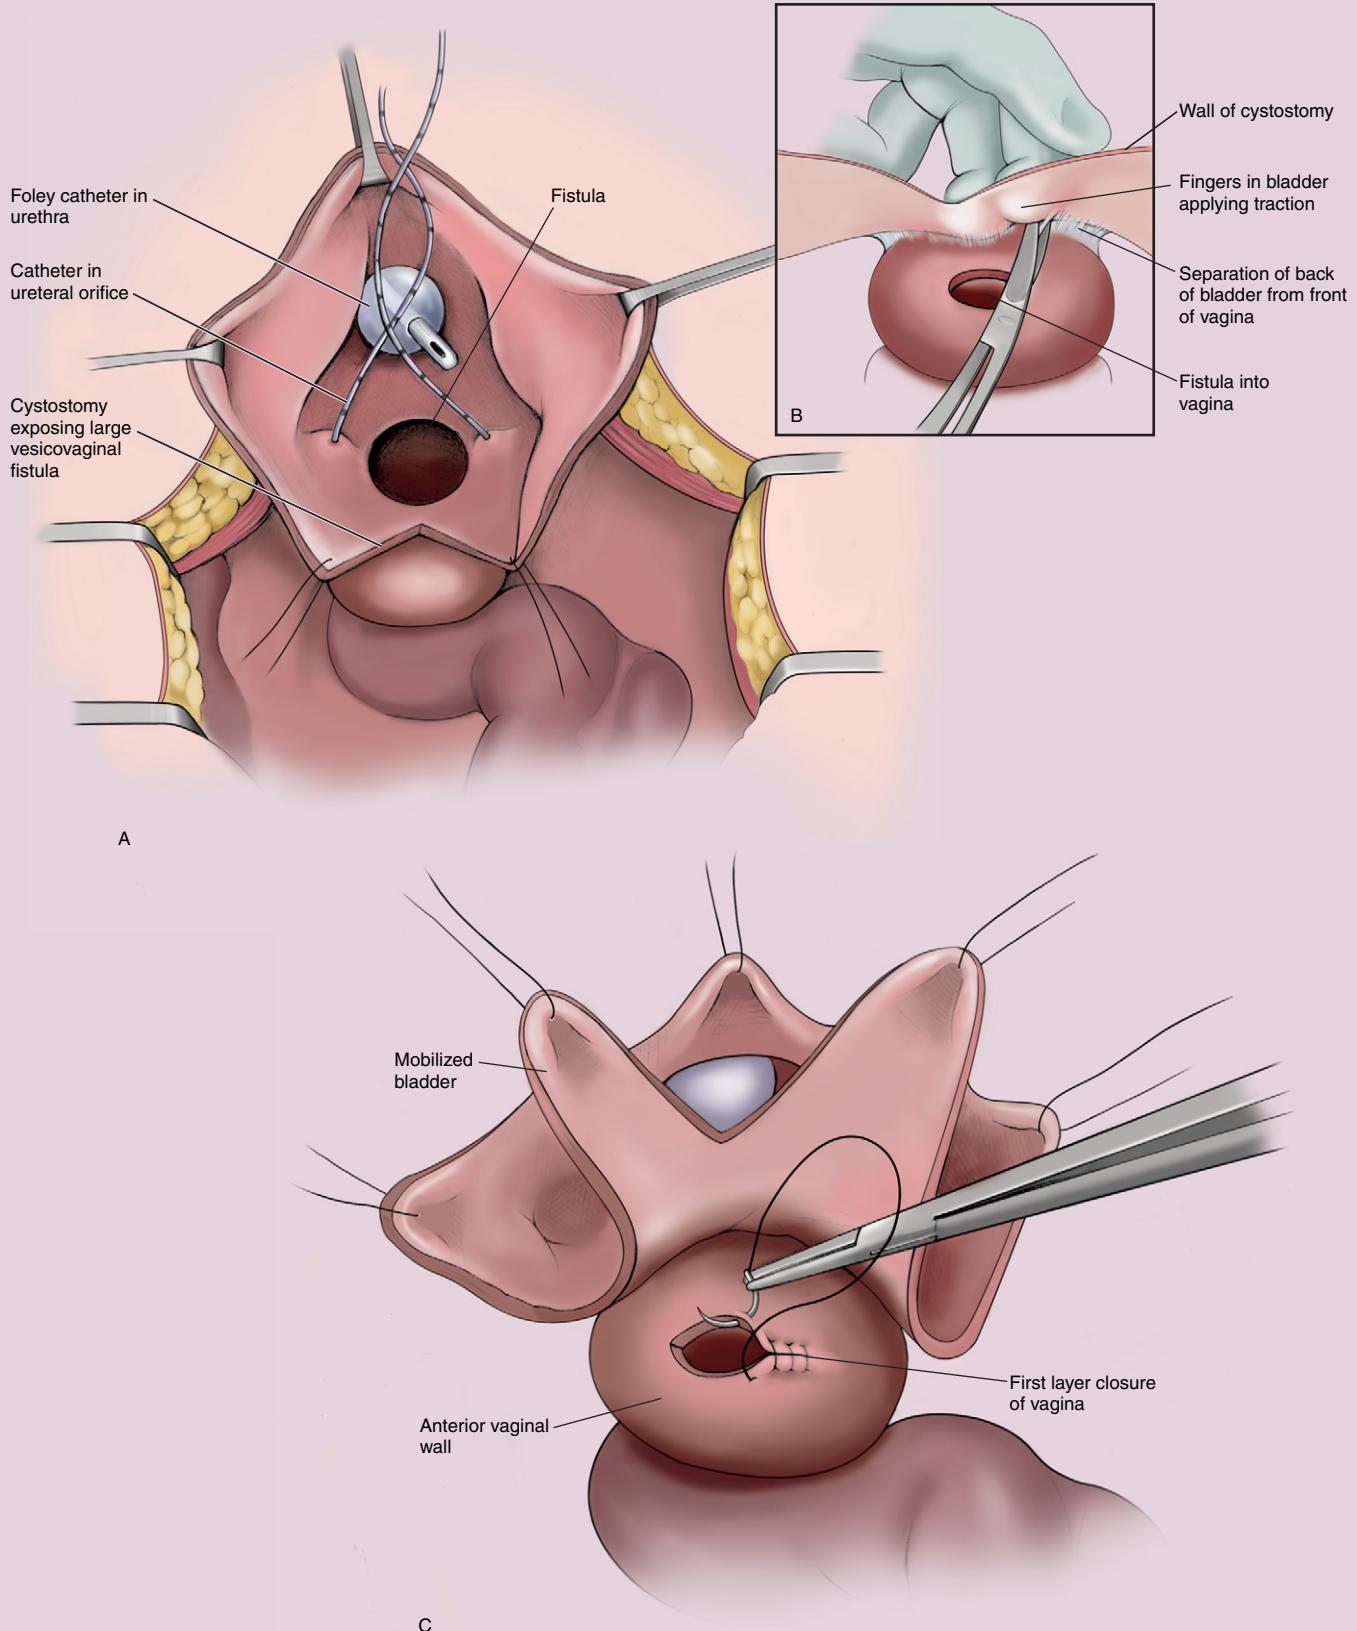

Ensuring proper bladder drainage is of utmost importance. The authors accomplish this in the early postoperative period with combined transurethral and suprapubic drainage. The transurethral catheter is removed once gross hematuria has cleared, usually a few days. This often takes longer with the transvesical-transperitoneal than with the vaginal approach. The suprapubic catheter is left for 2 to 3 weeks depending on the complexity of the repair. Some authors advocate routine evaluation with a cystogram prior to its removal, others do not.

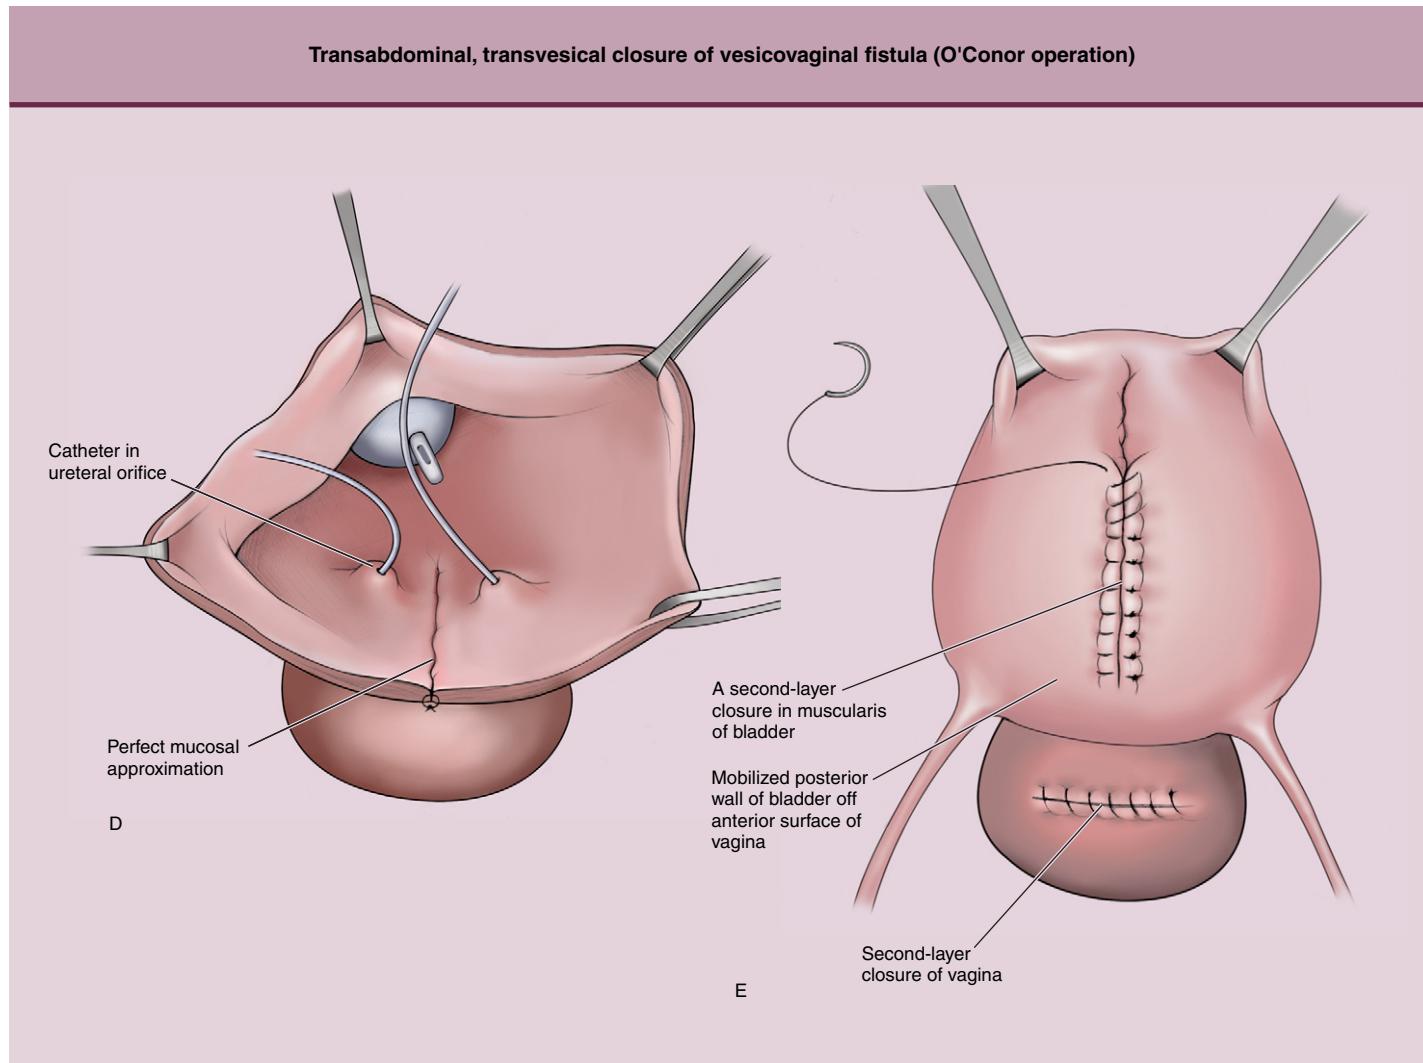

Avoiding bladder spasms is considered important in preventing recurrence, although this has not been well studied. Some

*Text continues on p. 431.*

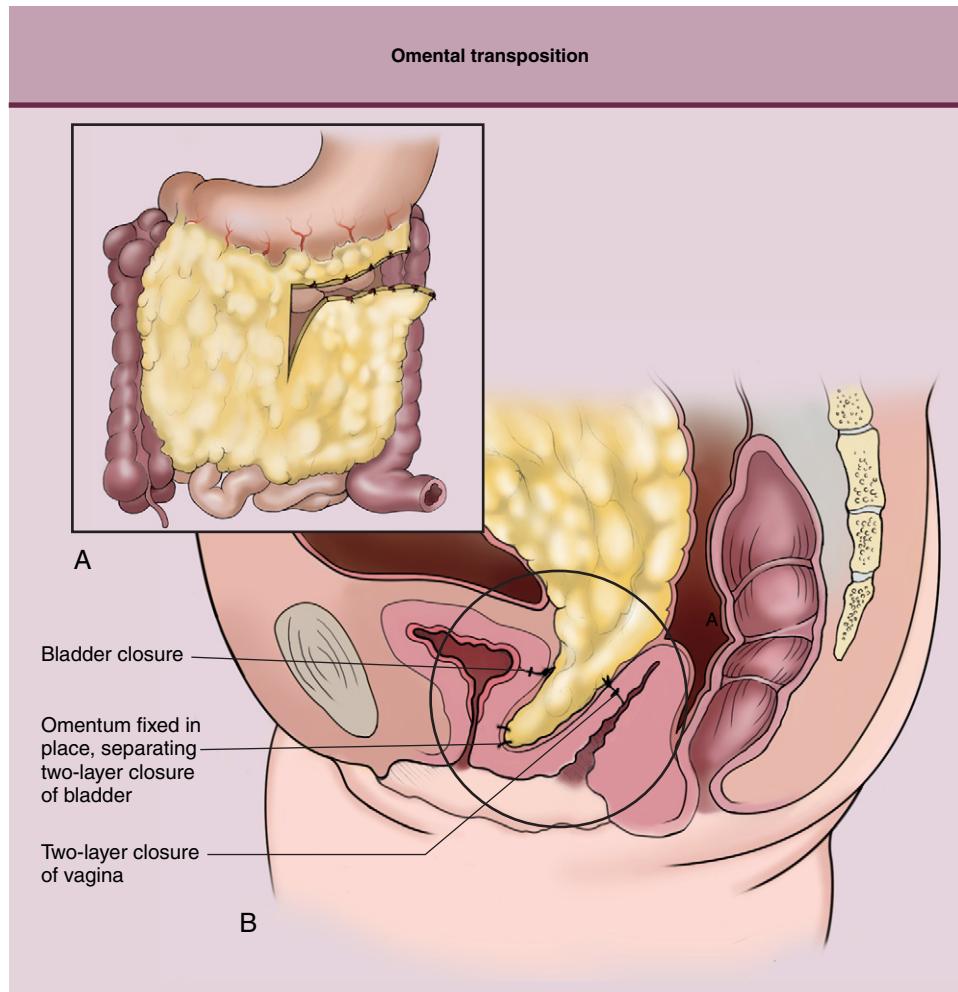

**Figure 29-7 Retropubic intravesical vesicovaginal repair.** A–D, The approach is retropubic, with retroperitoneal bladder incision. The fistula is identified and circumscribed, and the vesicovaginal space is dissected radially. The fistula is excised, and repair is accomplished in layers with interrupted delayed-absorbable suture on a small tapered or U-shaped needle. Staggering of the sutures is depicted for security of the closure.

**Transabdominal, transvesical closure of vesicovaginal fistula (O'Conor operation)****Figure 29-8** For legend, see opposite page.

**Figure 29-8 Transperitoneal-transvesical vesicovaginal fistula repair.** A, The bladder is incised midline from its anterior portion back posteriorly until the fistula is reached; the fistula is excised, and the ureters are protected. B, Dissection is continued in the vesicovaginal space distal to the fistula to allow tension-free closure in layers. C, The vagina is closed with interrupted delayed absorbable suture with the knots located inside the vagina. D, The dependent portion of the bladder is closed with interrupted double-layer closure on the bladder and single-layer vaginal closure. E, The rest of the bladder incision is closed with running suture in two layers.

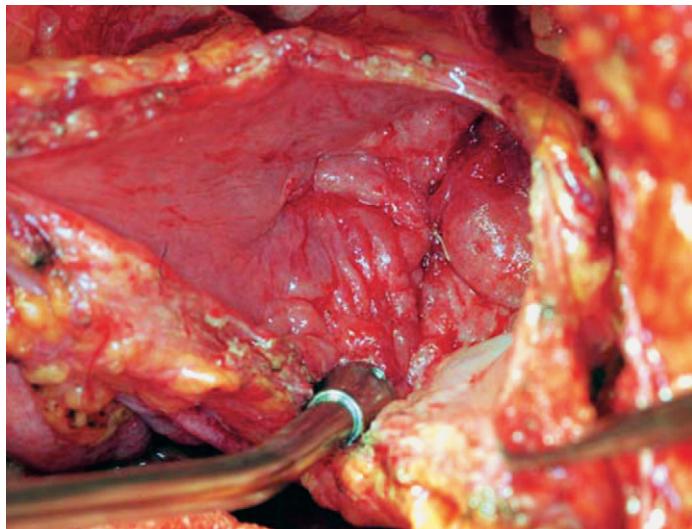

**Figure 29-9 Omental transposition.** A, The omentum is detached by severing its vasculature on the left along the greater curvature of the stomach. B, This results in extra length so the flap will reach between the vagina and bladder, anchored by absorbable suture.

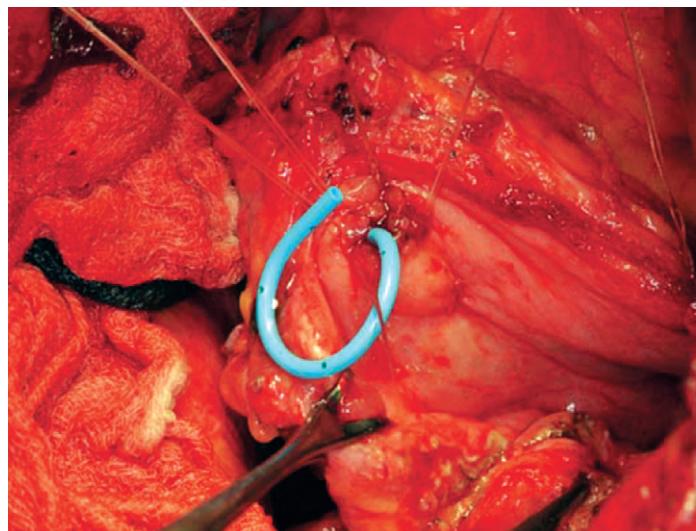

**Figure 29-10** This cystoscopic view shows a guide wire placed through the fistula into the vagina, and the left ureteral orifice is seen just above it. This patient underwent a transvesical-transperitoneal fistula repair with left ureteroneocystostomy.

patients have severe pain associated with bladder spasms, and these may require belladonna and opioid (B&O) suppositories. For most patients, standard anticholinergic medication is sufficient to prevent these spasms.

Single-dose antibiotic prophylaxis is given prophylactically with a first-generation cephalosporin as in many other gynecologic surgery cases. The authors do not routinely give oral antibiotic prophylaxis even in the presence of bladder catheterization,

**Figure 29-11** This intravesical view shows the completed repair of the most dependent portion of the bladder. The right ureteral orifice is in view near the incision line but not involved in it. The left orifice is no longer seen owing to its association with the fistula. Prior to closure of the bladder, the left ureter was identified and dissected retroperitoneally, tied off distally, then cut at the level of the cardinal ligament as close to the bladder as possible, in preparation for reimplantation.

**Figure 29-12** This intravesical view directed at the left dome shows the completed ureteroneocystostomy with double-J stent in place.

especially with the liberal use of suprapubic catheters for these patients.

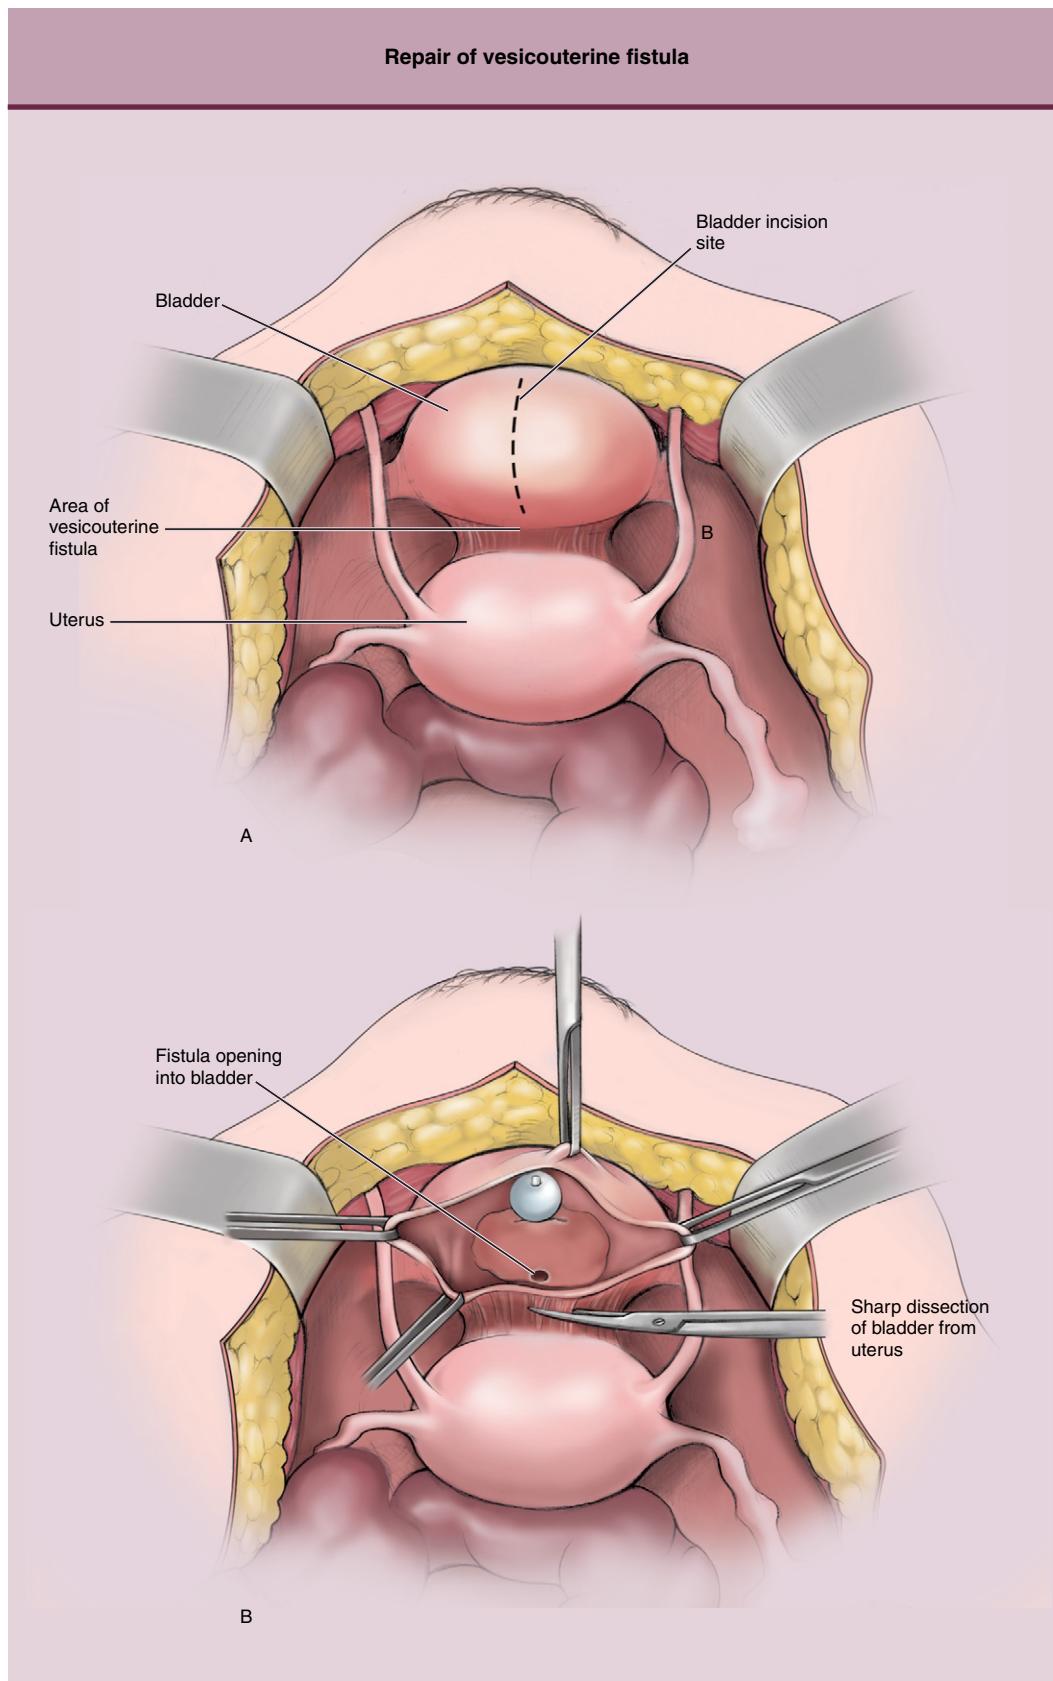

Vaginal packing rarely seems necessary following fistula surgery. Vaginal intercourse is prohibited for 2 to 3 months, to allow complete healing of the suture line. The use of vaginal estrogen cream is encouraged preoperatively and restarted 2 weeks following surgery to allow for re-epithelialization of the incision.

## RECTOVAGINAL FISTULAS

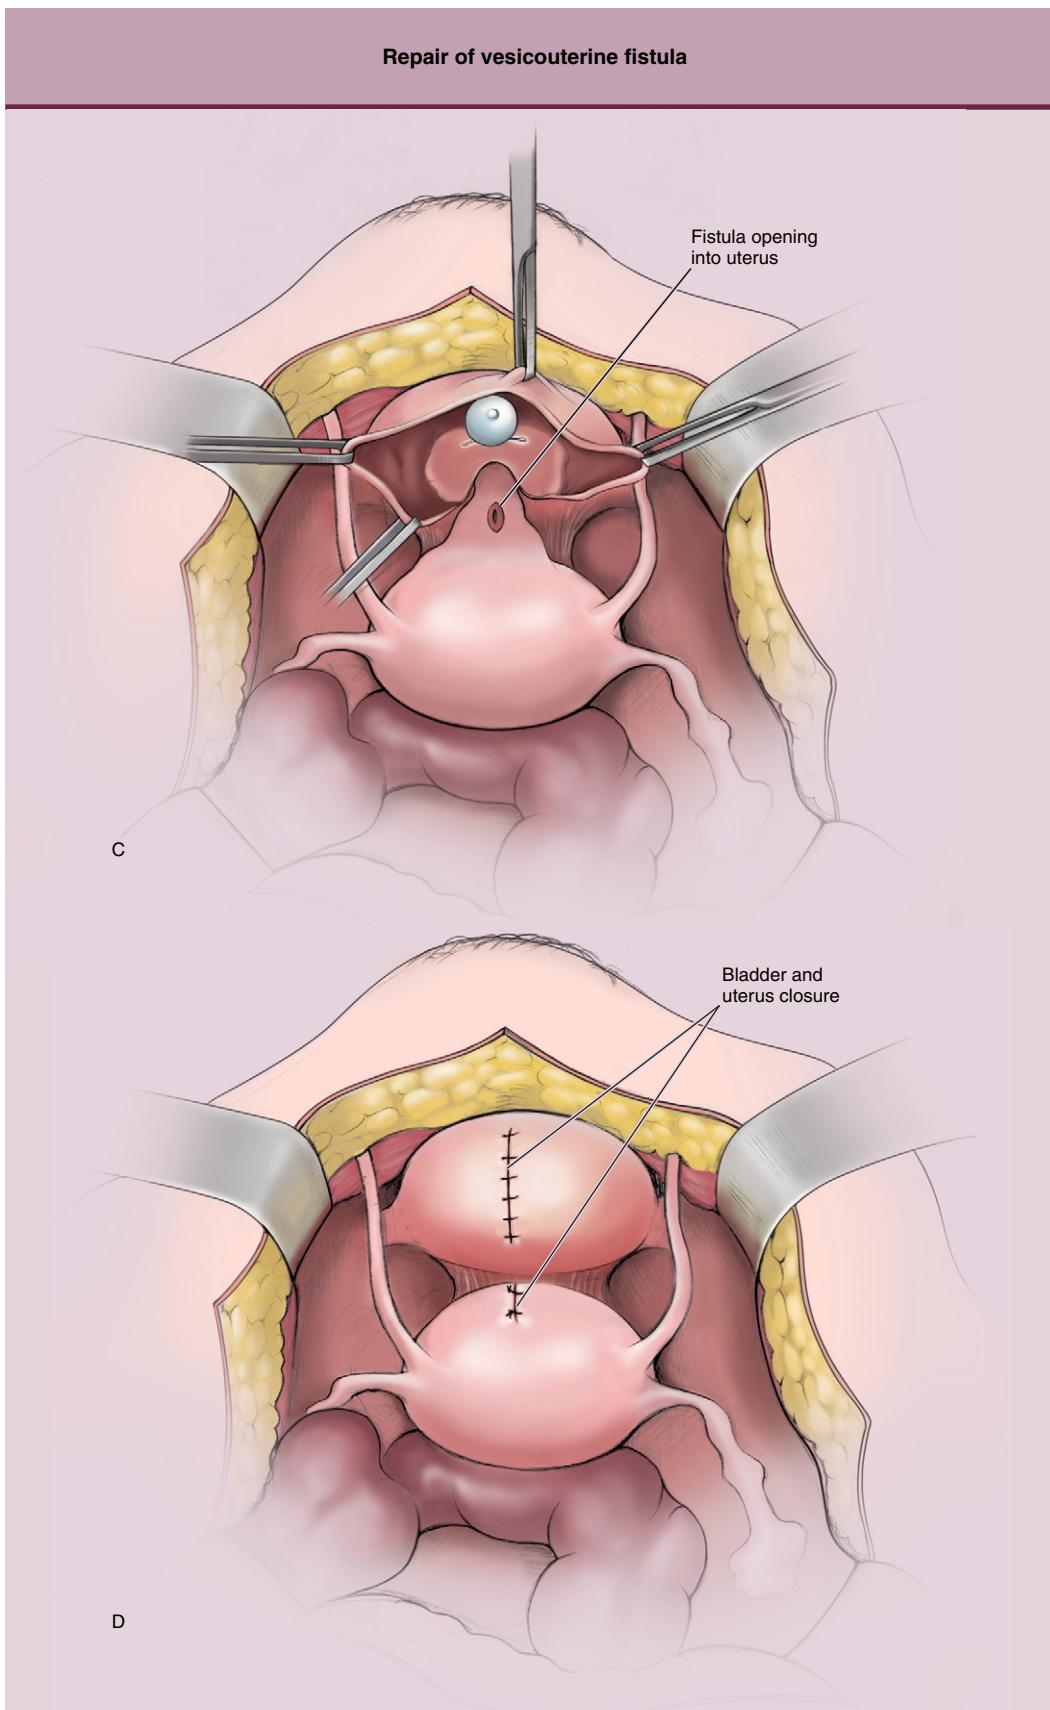

### Epidemiology and Risk Factors

Rectovaginal fistulas are uncommon, comprising less than 5% of all anorectal fistulas, but cause severe distress and discomfort to the patient and are a challenge for the operating gynecologist. They are classified on the basis of location, size, and etiology. Fistulas located between the lower third of the rectum and the lower half of the vagina are considered low, and those between the upper two thirds of the rectum and the upper vagina are considered high. Low rectovaginal fistulas are further characterized by whether they are associated with disruption of the anal sphincter or the perineum. They are, in most cases, less than one-half cm in diameter, although when they are caused by obstructive labor, they can involve loss of large areas of the rectovaginal septum.

Obstetric trauma such as perineal laceration or episiotomy, precipitous birth, forceps delivery, vacuum extraction, or unsuccessful attempts to repair 3rd or 4th degree tears may result in a low rectovaginal fistula. Prolonged labor may cause a wide area of ischemic injury of the rectovaginal septum with resulting large fistulas. Vaginal or rectal operative procedures such as hysterectomy, rectocele repair, hemorrhoidectomy, excision of rectal tumors, and low anterior resection can also result in rectovaginal fistulas. Perirectal abscesses when drained spontaneously or surgically may result in fistulas that open into

**Figure 29-13 Vesicouterine fistula repair.** Similar to the transperitoneal-transvesical approach depicted in Figure 29-8, except the fistula is located somewhat higher. A-C, The bladder is incised in the midline, the fistula is identified, and the vesicouterine space is developed until the fistula is excised.

**Figure 29-13, cont'd** A-C, The bladder is incised in the midline, the fistula is identified, and the vesicouterine space is developed until the fistula is excised. D, The uterine defect is closed with interrupted suture in one layer, and the bladder is closed in two layers similarly to the depiction in Figure 29-8.

## Urogynecology

the vagina or perineum. Traumatic penetrating or blunt trauma including forced coitus may also be responsible for development of rectovaginal fistulas.

Inflammatory bowel disease such as Crohn's or, much less commonly, ulcerative colitis is associated with rectovaginal fistula formation and should be strongly considered in any case of failed primary repair. A variety of infections including diverticulitis, Bartholin's gland abscess, lymphogranuloma venereum, tuberculosis, or human immunodeficiency virus (HIV) may be the underlying etiology.

Regressing or recurrent cervical, rectal, vaginal, or vulvar carcinoma or the neoadjuvant radiation therapy prescribed for these conditions may result in high rectovaginal fistulas. Radiation fistulas from external beam or intracavitary therapy may occur with risk being dependent on the dose and method of application. Fistulas noted in these settings must be carefully evaluated for cancer recurrence and always treated as complex fistulas, with a propensity for failure.

Obstetric injury is the most common etiology in the developing world, but many rectovaginal series in the western hemisphere also cite obstetric causes high in the list of etiologies. Although vesicovaginal fistula is the most frequent complication of obstructed labor in the developing world, rectovaginal fistulas have been seen in 17.4% of obstetric fistula patients.<sup>9</sup> In developed countries, rectovaginal fistulas after vaginal delivery are uncommon. A review of 20,500 vaginal deliveries in Arizona found only 25 patients (0.1%) who developed a rectovaginal fistula requiring surgical correction.<sup>97</sup>

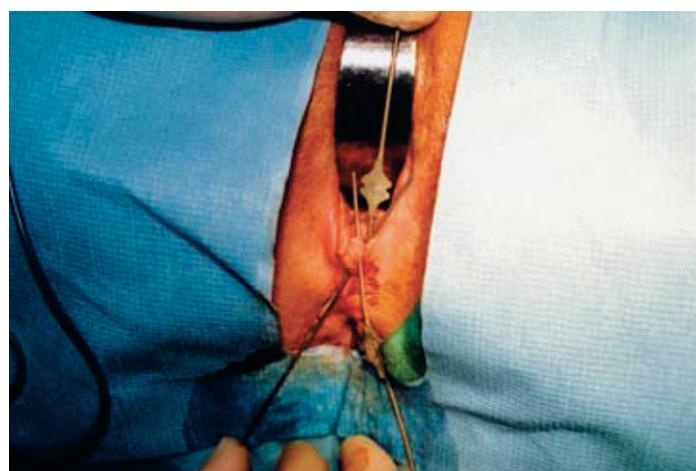

### Clinical Features

Small rectovaginal fistulas may be entirely asymptomatic or intermittently so, often depending on stool consistency. When the fistulas are somewhat larger, escape of gas may be the only complaint, or a slight fecal odor can be detected in the vaginal discharge. When the fistula is large, the entire bowel content is evacuated through the vagina. Recurrent bouts of vaginitis and cystitis are common. When inflammatory bowel disease is the underlying etiology, bloody mucus and diarrhea are frequently noted.

The time from the initial insult to clinical presentation depends on the etiology of the fistula and the circumstances. Vaginal wall lacerations associated with unrecognized obstetric or operative injury typically present in the first 24 hours of the trauma. In the case of an apparently normal 4th degree laceration repair, infection or breakdown of the wound may occur within 7 to 10 days and result in formation of a rectovaginal fistula. In contrast, irradiation-induced fistulas are slowly progressive, and necrosis due to devascularization may become symptomatic a few months or even years after the original insult.

### Diagnosis

The diagnosis of simple rectovaginal fistulas usually can be accomplished by digital or anoscopic examination. In many instances merely spreading the labia and inspecting the posterior vagina and perineum may reveal the fistulous tract. A speculum can be used and rotated 90 degrees to show a more proximal fistula. The darker rectal mucosa can often be seen at the fistulous opening in contrast to the pink vaginal mucosa when the fistula is large. A pit or depression is palpable both rectally

**Figure 29-14** Multiple rectovaginal and rectoperineal fistulas are identified in a patient referred for two previously failed attempts at repair. This patient also required anal sphincteroplasty, perineorrhaphy, and reattachment of the distal rectovaginal fascia following excision of all the fistulous tracts.

and vaginally on rectovaginal or rectoperineal examination. After prior unsuccessful repair, multiple fistula tracts can often be identified by careful evaluation (Fig. 29-14). In cases in which there is difficulty in identifying the site of a small fistula despite strong clinical suspicion, filling the vagina with water and the rectum with air through a proctoscope will demonstrate bubbles rising from the fistula. If the fistula is still not demonstrated, a 20-minute ambulatory tampon test with methylene blue instilled into the rectum may help localize the fistula. If these diagnostic maneuvers are not successful, the fistula may be higher in the vagina and radiologic contrast studies are needed. This may include vaginography, barium enema, or CT scan with contrast. Proctosigmoidoscopy with biopsy should be used to exclude any underlying disease process whenever there is doubt regarding the specific etiology of a rectovaginal fistula.

Additional testing with endoanal ultrasound, anorectal manometry, and neurophysiologic studies may be useful in selected cases. It has been recommended that patients with rectovaginal fistulas secondary to obstetric injury be evaluated for occult sphincter defects, since they influence the outcome of repair as well as the type of repair used.<sup>98</sup> Improving and maintaining continence is just as important as healing the fistula in achieving a satisfactory outcome in the treatment of rectovaginal fistulas. The assessment for occult sphincter defects may be done by endoanal ultrasound and/or anorectal manometry. Most low rectovaginal fistulas of obstetric origin involve the anal sphincter, and success rates seem to be improved when concomitant anal sphincteroplasty is performed.<sup>98–100</sup> Conversely, abnormal neurophysiologic testing does not preclude surgical repair for a rectovaginal fistula with or without sphincteroplasty and is therefore not routinely used in this context.

### Management

Conservative management may be attempted in the hope of allowing spontaneous healing following a small rectovaginal

fistula of obstetric etiology; most, however, require surgical intervention. The timing of repair depends on the integrity and health of the surrounding tissues. All infections must be treated by appropriate drainage and antibiotics. Traditionally, postobstetric fistulas required a waiting period of 3 to 6 months. However, earlier intervention is successful as long as the tissues remain soft, pliable, and adequately vascularized with no evidence of inflammation or infection. Vaginal estrogen cream and a bowel regimen including fiber supplementation to improve bowel transit and consistency may be used in preparation for surgery. It is not necessary, however, to unduly delay repair of a severely symptomatic patient as long as the tissues appear healthy. In contrast, attempted repair of irradiation-induced fistulas may require up to a 1-year delay to ensure maximal resolution of tissue necrosis. Rectovaginal fistulas associated with Crohn's disease should be surgically repaired only after adequate therapy and remission have been achieved.

The patient is carefully counseled prior to surgery regarding the route, success rate, and any associated procedures. Pre-operative standard mechanical bowel preparation is used, and prophylactic antibiotics are given intravenously 30 minutes prior to the procedure.

### Surgical Therapy

The type of surgical repair depends on the size, location, and etiology of the rectovaginal fistula as well as surgeon preference and training. In the case of a simple low fistula, transperineal, transvaginal, or transanal advancement flap closure may be selected. The transabdominal route of closure is often preferred for high rectovaginal fistulas. No adequately designed studies confirm that any of the approaches is superior to the others.

Transperineal and transvaginal approaches have good success rates ranging from 85% to 100%.<sup>101,102</sup> In general, the transperineal approach is performed when the anal sphincters are involved and repair is necessary, or when the perineal body is deficient and a perineorrhaphy is planned. This approach may be started with a curvilinear incision along the anterior anal sphincteric border with dissection continuing cephalad to the level of the fistula and above. Alternatively, a transverse incision at the level of the posterior fourchette or dissecting off a triangular wedge of perineal skin may be used when deeper dissection is needed.

A fistulotomy involves cutting the entire bridge of perineal tissue superficial to the fistula. This rarely is necessary, except when the rectoperineal fistula is very distal and superficial, thereby cutting only perineal skin.

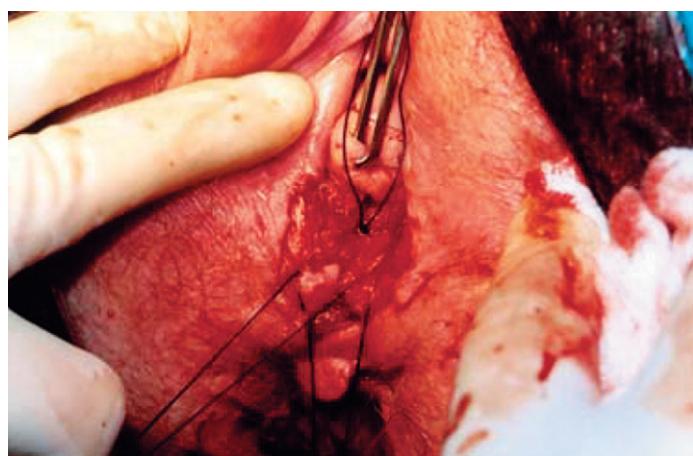

Regardless of the incision used, the principles of repair are similar for all transperineal approaches. Wide dissection of the rectovaginal space is achieved sharply distal, proximal, and lateral to the fistula, the fistula is excised and hemostasis achieved with suture ligature and light electrocautery as long as it is away from the incision's edge. Closure of the wound starts with the rectal mucosa using fine, delayed-absorbable suture and avoiding the bowel lumen. Then the bowel serosa is imbricated on the first layer, incorporating internal anal sphincter if it is disrupted with a slightly larger caliber suture. This is followed by end-to-end repair of the external anal sphincter throughout its 4- to 5-cm length, nearing the level of the levator ani muscle without

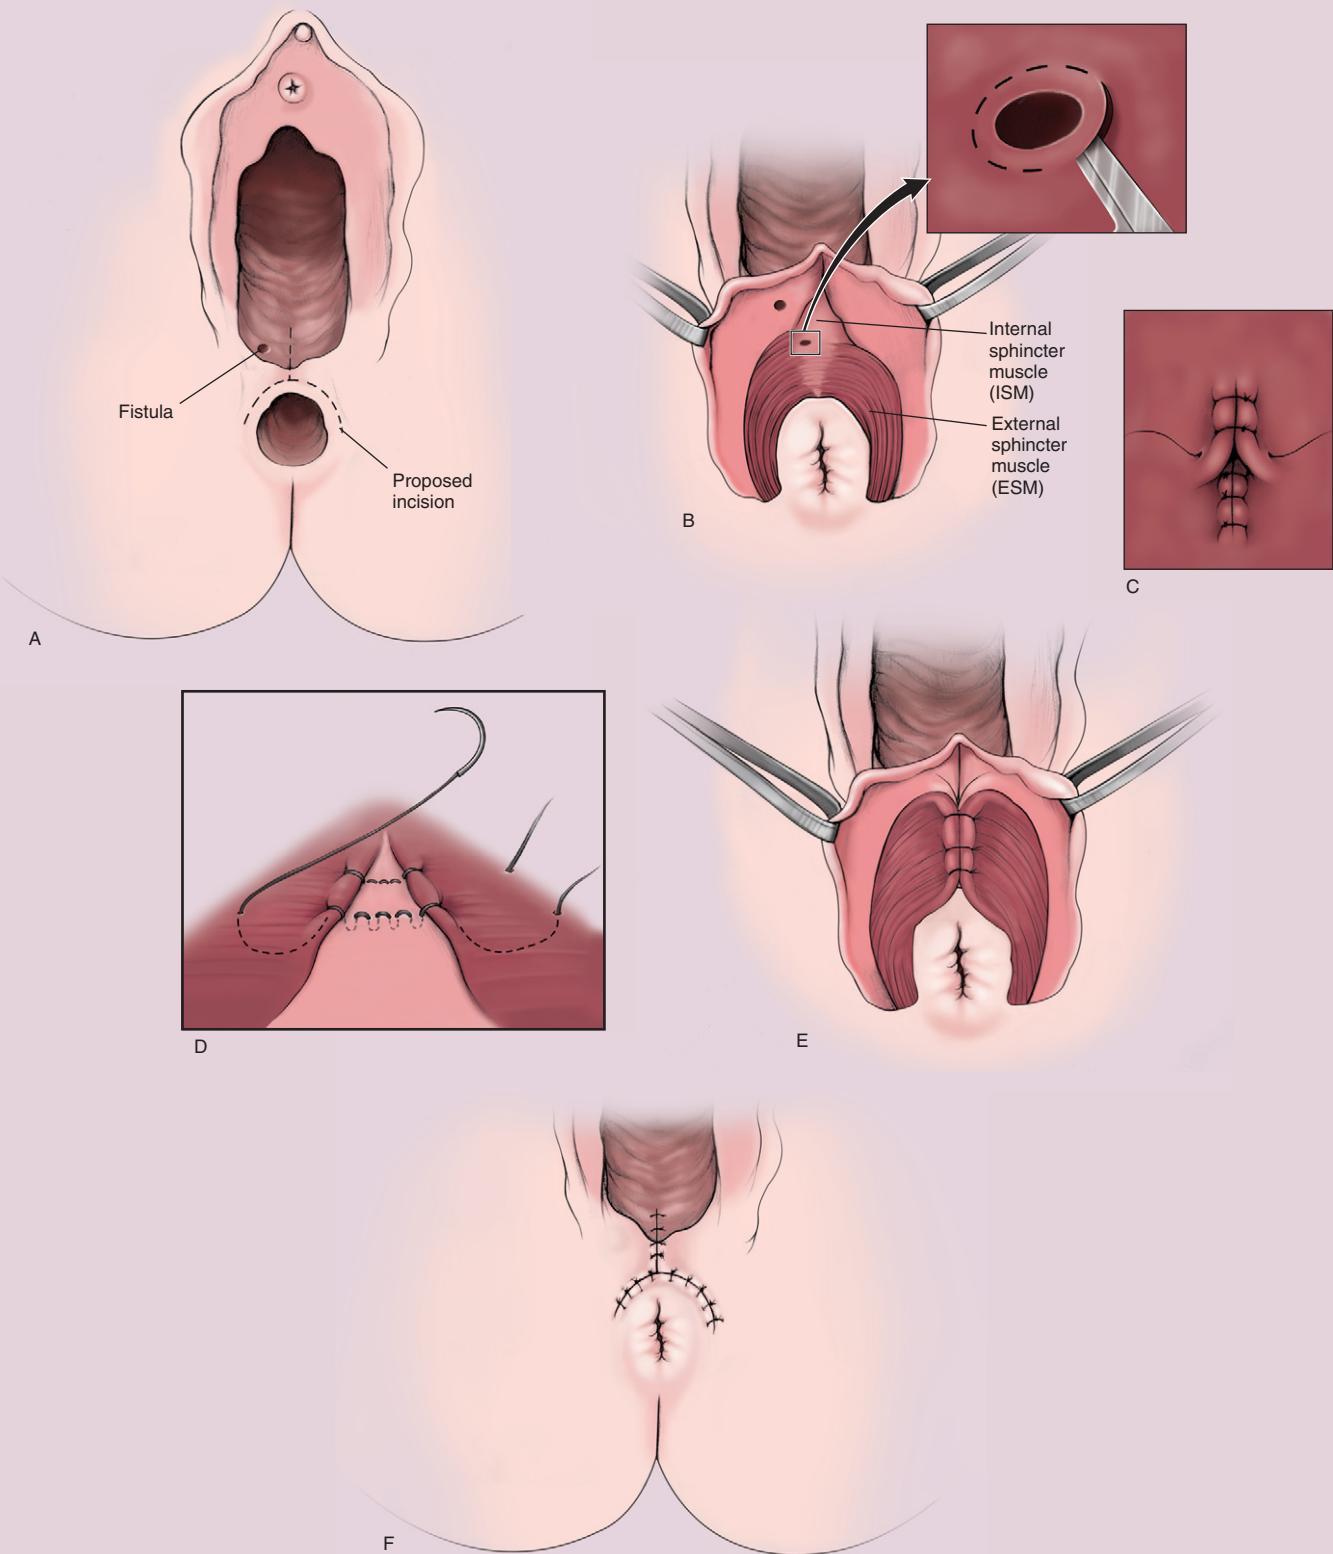

**Figure 29-15 A rectovaginal fistula involving the anal sphincters, with an attenuated perineal body.** This fistula was repaired via a transperineal approach, the rectovaginal space was dissected, and the fistula was excised.

plicating it (Figs. 29-15 and 29-16). Some authors prefer sphincteroplasty by an overlapping technique. If perineorrhaphy is needed, it is performed by plicating the posterior bulbocavernosus muscles in the usual fashion. The newly rebuilt perineal body is used to anchor the distal torn end of the rectovaginal fascia by means of proximal to distal stitches to avoid stenosis at the introitus. The vaginal mucosa is trimmed only enough to provide fresh edges for reapproximation. All stitches are interrupted to allow for careful apposition of surfaces with minimal distortion (Fig. 29-17).

A transvaginal approach is preferable for low fistulas that are proximal to the anal sphincters, or mid-vaginal fistulas, when no sphincteroplasty or perineorrhaphy is required. In all cases excision of the fistulous tract is advised with appropriate layered repair using interrupted delayed-absorbable sutures, avoiding

**Figure 29-16 Closure of the external anal sphincter muscle, after closure of the rectal mucosal layer, and the internal sphincter.** The authors prefer end-to-end repair including the entire 4 to 5 cm of its length. The uppermost suture in the photograph depicts the most proximal suture used; it is placed near the level of the levator ani.

**Repair of distal rectovaginal fistula involving the anal sphincter**

sutures within the bowel lumen, followed by interrupted imbricating stitches (Fig. 29-18).

A Martius flap may be considered if it is a repeat repair and the tissue appears scarred, or in the case of a radiation fistula. Strong consideration for fecal diversion with colostomy should be given for patients with multiple recurrent and otherwise more complex rectovaginal fistulas.

Transanal advancement flaps are preferred by colorectal surgeons and have considerably varied success rates ranging from 41% to 100% when performed following obstetric injury.<sup>99,103</sup> When done in conjunction with sphincteroplasty, success rates approach about 95%.<sup>100</sup> Addition of a labial fat pad transposition did not appear to improve the results of transanal advancement flap repair in a report in the colorectal literature.<sup>104</sup>

Postoperatively, a liquid diet is recommended for several days. Pain control is administered by intravenous patient-controlled narcotics or epidural anesthesia. A Foley catheter is left in place for several days, and a low-residue diet prescribed with addition of stool softeners.

Small series of simple and recurrent rectovaginal fistulas have been treated with fibrin glue. In one report, 6 of 8 patients with recurrent rectovaginal fistulas were successfully treated.<sup>105</sup> This technique has not gained widespread popularity.

#### **Complicated Rectovaginal Fistulas**

High rectovaginal fistulas and those resulting from recurrent persisting causes, radiation injury, or inflammatory bowel disease frequently require a transabdominal approach. Depending on the quality and blood supply of the tissue around the fistulous tract and the condition of the surrounding tissue, the repair may or may not require bowel resection. When the surrounding tissue is pliable without severe inflammation or scarring, the rectovaginal septum is dissected, the fistulous tract is divided and

excised, and the rectal and the vaginal openings are closed primarily in layers. Interposition of an omental flap adds needed good vascularity to the area of the repair, and it will separate and support the suture lines. When the bowel is severely diseased, the involved segment has to be resected. Coloanal reconstruction with or without fashioning of a colonic reservoir pouch is preferred, often with temporary fecal diversion by a loop ileostomy.

Rectovaginal fistula associated with Crohn's disease is a difficult management problem. About 9% of the fistulas occurring in Crohn's disease are rectovaginal. The first line of treatment is medical, with surgical treatment being reserved for patients with persistent troublesome symptoms.

Irradiation-induced rectovaginal fistulas also present the surgeon with a difficult challenge. Adequate blood supply must be ensured, which is supplied by interposition of skeletal muscle with its blood and nerve supplies intact. Prior to any attempted repair, the presence of recurrent cancer must be excluded. It is important to document adequate sphincter function and absence of rectal stricture. Frequently, laparotomy is needed to expose the fistula and accomplish adequate dissection, although transvaginal repair has also reportedly been successful. The fibrotic margins of the fistulas are excised, and the vagina and bowel wall are separated. Subsequently, the freed rectal mucosa and submucosa around the fistula opening is closed transversely. Bulbo-cavernosus or gracilis muscle is mobilized on its vascular pedicle with preservation of nerve supply and swung to the fistula site through a subcutaneous tunnel under the labia and vaginal mucosa and sutured adjacent to the repaired fistula.<sup>106–108</sup> Transabdominally, an omental flap can serve as a source of a new blood supply and is often used for supporting the repair. A diverting colostomy is used to protect the surgical site. It can be reversed in 3 to 6 months.

**Figure 29-17** (facing page) **Low rectovaginal fistula involving the anal sphincter.** *A*, A transperitoneal approach is depicted that starts with an anterior perianal curvilinear incision, with midline extension. *B*, Dissection is carried up to the fistula, which is excised, and the vagina is further mobilized off the rectum proximally, medially, and laterally. Closure of the rectal defect is accomplished with interrupted delayed-absorbable suture, ensuring lack of tension on the suture line. *C*, The second layer should incorporate the internal anal sphincter and is closed with interrupted delayed absorbable suture. *D*, The external anal sphincter closure begins proximally near the levator ani incorporating internal sphincter muscle when possible. *E*, The interrupted sphincter closure stitches are tied. *F*, Perineorrhaphy, if needed, is achieved by unification of the posterior-most aspect of the bulbocavernosus muscle in the midline to rebuild an attenuated perineal body. Following vaginal mucosal trimming, closure completes the repair, ensuring that introital narrowing has not occurred.

## Repair of low rectovaginal fistula with intact perineum

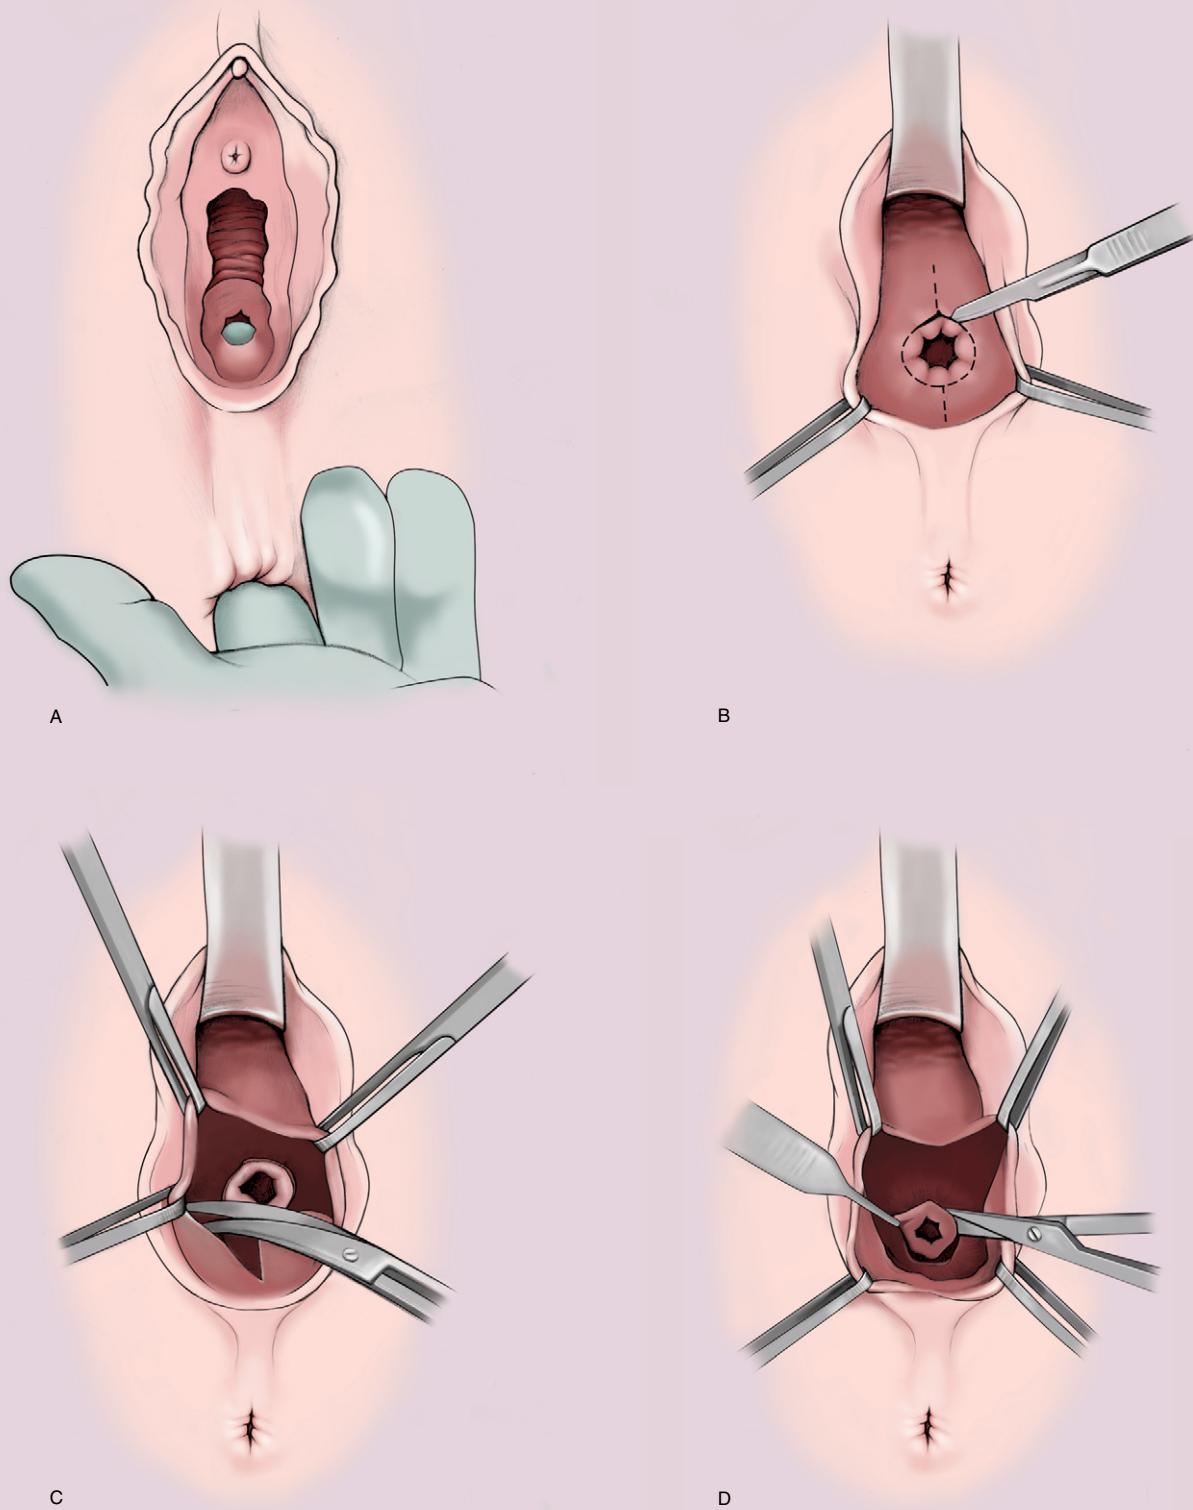

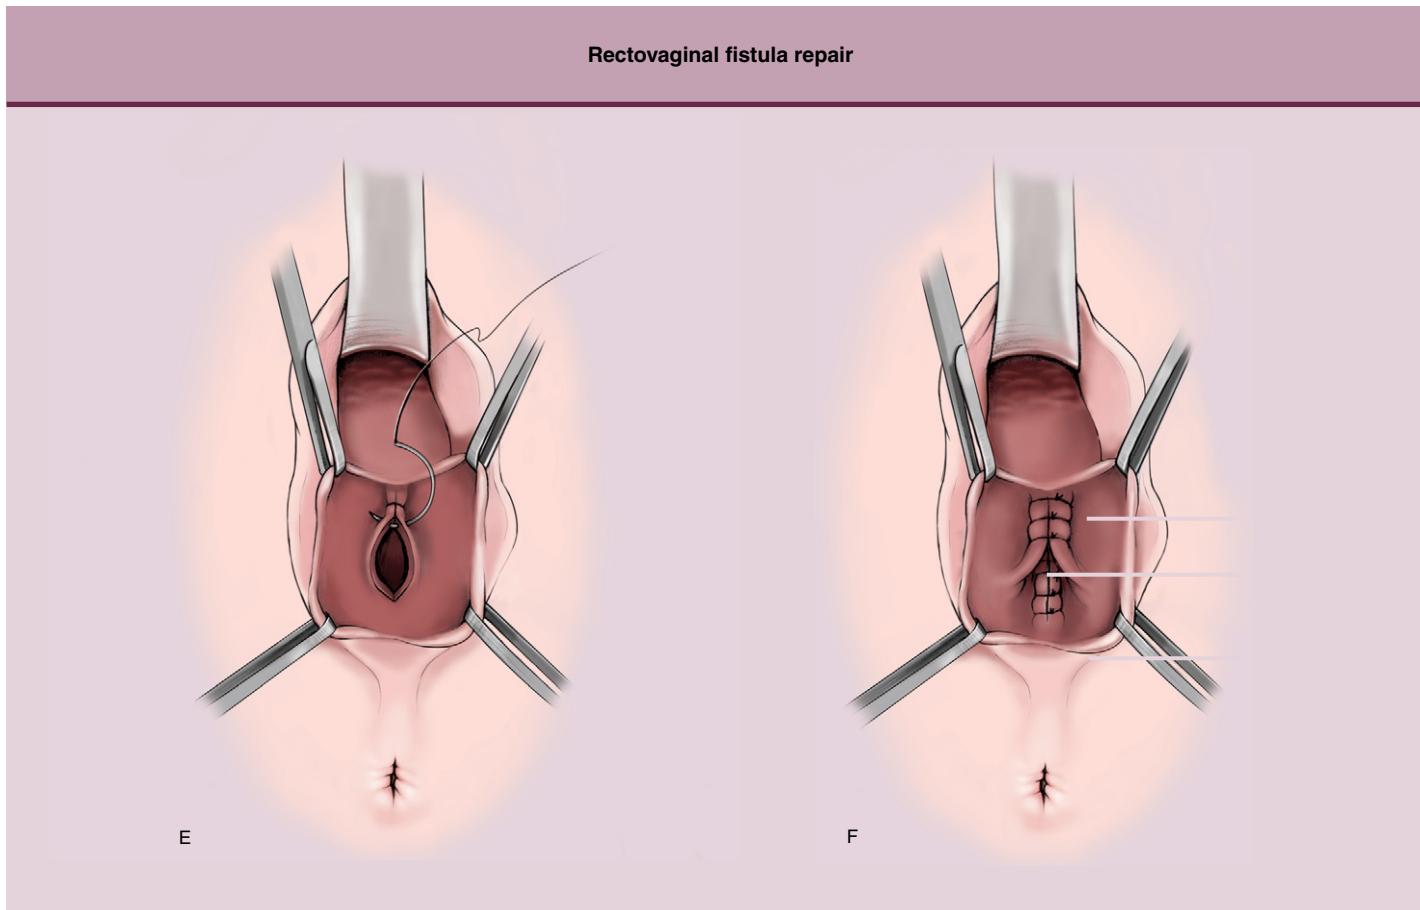

Figure 29-18 For legend, see opposite page.

**Figure 29-18 A low rectovaginal fistula, but proximal to the anal sphincter and with an intact perineal body.**

A, Some authors consider this a mid-vaginal fistula. Repair involves circumcisión of the fistulous tract (B), dissection of the vagina off the rectum (C), excision of the fistula (D), and closure of the rectal defect in two layers (E), followed by vaginal mucosal closure (F).

## Section 5 Pediatric and Adolescent Gynecology

### Chapter 30

# Puberty and Precocious Puberty

Alexandra S. Carey, MD, and Pamela J. Murray, MD, MPH

#### KEY POINTS

- The sequence and duration of pubertal events is relatively predictable, but there is a wide range of ages at which puberty begins.
- The decline in the age of menarche has stabilized, but there is an observable trend toward an earlier onset of puberty in American girls.
- African American girls are observed to begin puberty earlier than white girls. The significance of this trend is controversial.
- Multiple factors play a role in the timing of puberty. Genetics is still thought to have a substantial influence in the timing of normal puberty.
- It may be difficult to distinguish normal early puberty from precocious puberty.
- True precocious puberty is usually idiopathic in girls, but it is considered a diagnosis of exclusion. In boys, underlying CNS or other pathology must always be considered.
- Isolated premature pubarche is associated with an increased future risk of polycystic ovary syndrome, hyperandrogenism, and insulin resistance.

#### INTRODUCTION

Puberty is a dramatic transition in a child's life, marking the change from childhood to adulthood. The changes that take place during puberty are physical, emotional, and physiological. These changes begin across a broad range of ages, with clearly recognized differences between the sexes. Although the timing of pubertal events varies, the stages of puberty occur in a predictable pattern and the overall length of pubertal development is constant (about 3 to 5 years). An understanding of normal pubertal development is required to diagnose and manage related disorders, particularly precocious puberty, delayed puberty, and other growth and maturational problems.

Precocious puberty is the onset of one or more pubertal signs, including secondary sex traits and accelerated growth, before the age that is 2 standard deviations below the mean age for the onset of puberty (Fig. 30-1).<sup>1</sup> In recent years the determination of when puberty is "precocious" in girls has been challenged. The mean age of the signs most associated with pubertal onset—breast development and pubic hair growth—has decreased. Complete data are still lacking on the age range of the onset of normal puberty. The majority of girls who develop signs of

puberty at an early age have no underlying disease, but determining what is "normal" early puberty versus "precocious" early puberty is not always straightforward. The diagnosis of precocious puberty is challenging and currently controversial. As appropriate, analogous states in males are presented.

The terminology used to describe precocious puberty varies, particularly when differentiating gonadotropin-releasing hormone (GnRH)-dependent, or "true," precocious puberty from other classifications of early or precocious puberty (GnRH-independent). See list of Key Terms used to describe puberty and precocious puberty. When interpreting relevant literature and communicating information, the use of specific and correct terminology is critical.

#### Historical Definition

The reference standard of the normal onset and stages of puberty is based on older studies. The data collection and the resultant constructs of Tanner were revolutionary at the time. The 1969 article by Marshall and Tanner that launched "Tanner staging" included 192 white British girls from a single socio-economic class.<sup>2</sup> The standard definition of precocious puberty uses Tanner staging as a clinical metric and is defined as secondary sexual development in females less than 8 years of age and secondary sexual development in males less than 9. Menarche at less than 10 is also considered precocious. This historical definition also assumes accelerated linear growth and bone maturation accompanying the changes in breasts, pubic hair, and genitals.

#### Historical Trends

The factors that eventually lead to the onset of puberty are still incompletely understood. Menarche is an objective marker of puberty. Mean age of menarche has decreased over the past century. Better socioeconomic conditions and improved nutrition and general health have been associated with a secular trend toward earlier puberty. The average age of menarche has slowly decreased by 2 to 3 months per decade in industrialized European countries over the past 150 years up until the late 1970s (Fig. 30-2). In the mid-19th century the average age of menarche was 17 years in the United States, 15 years in France, and 17 years in Scandinavia.<sup>3</sup>

This trend to an earlier age of menarche has since abated. A decrease of about 2.5 to 4 months in age of menarche has been found over a 25-year period, which has also paralleled an increase in body mass index (BMI), although no direct relationship between menarche and BMI has been found.<sup>4,5</sup> African American females, on average, attain menarche earlier than white

- Ethnicity
- Genetics, e.g., maternal history, congenital pathology
- Leptin
- Nutrition

females, but this recent trend is not consistently associated with an increase in weight in African American females (Table 30-1).

In spite of relatively stable economic conditions in the United States and a relatively constant mean age of menarche, a trend toward an earlier onset of puberty in American girls has been reported.<sup>6</sup> This trend toward an earlier onset of puberty raises questions regarding the interplay of known and unknown factors that contribute to pubertal timing. The factors that are thought to play a role in the timing of the onset of puberty are listed in Table 30-2.

### Current Observed Trends

The overall duration of puberty is related to its age of onset. Girls with a later onset have a slightly shorter duration of puberty and girls with an earlier onset have a longer duration.<sup>7</sup> Apter, from a study of a cohort of Scandinavian women, concludes that the earlier the age of menarche, the shorter the interval to regular ovulation.<sup>8</sup> The “earlier maturers” with menarche before 11 years have 50% of their cycles ovulatory in 6 months, “average maturers” reach this in 2 years, and “late maturers” (14+ years) take an average of 4.5 years until 50% of their cycles are ovulatory. Another contemporary trend is the correlation between earlier onset of puberty and ethnicity, with African American girls and other populations observed to start puberty at an earlier age than white American girls. This trend is likely related to genetics and lifestyle differences between these groups. The major lifestyle changes that affect growth and pubertal development are diet and exercise, with other environmental factors (food additives and topical personal care products) potentially involved but less well understood. The causes of the epidemic of childhood obesity in America contribute to earlier onset of puberty, and African American girls are more overweight and exercise less than white American girls.<sup>9</sup> This observation that obesity correlates with earlier onset of puberty has led to multiple hypotheses and studies regarding the role and interplay of obesity, ethnicity, genetics, and puberty.

### Contemporary Studies and Reevaluation of the Definition of Precocious Puberty

The classic definition of when puberty is early or precocious was challenged by the 1997 Herman-Giddens study through the American Academy of Pediatrics (AAP) Pediatric Research in Office Settings (PROS) Study. The PROS study was a large cross-sectional study involving 65 pediatric practices across the country with a total of 17,077 female patients included in the final study and data analysis. Only white and African American

girls were included because other races made up only 2.8% of the group. The age range was 3 to 12 years and included 9.6% African Americans and 90.4% white females, all undergoing complete physical examinations. Hispanic girls were included in both the African American and the white groups. Breast development was recorded by inspection in the majority of participants, but 39% of the sample also had their breast Tanner staging performed by inspection and palpation.<sup>10</sup> The study concluded that the mean age at which African American girls were exhibiting signs of puberty was 8.87 years for breast development and 8.78 years for pubic hair growth, whereas the mean age at which white American girls were starting puberty was 9.96 years for breast development and 10.51 years for pubic hair growth. Therefore, a substantial number of girls are starting puberty even earlier than these means. The study found the age of menarche to be stable compared with earlier population studies of the 1970s (National Health Examination [NHE] and others). Table 30-3 lists the significant findings from this study.

The Herman-Giddens study, with a large cohort, suggests that an earlier onset of pubertal signs is occurring but has some notable limitations. The age of menarche has not changed significantly in the past 50 years, although there is a difference between the average age of menarche in white girls and African American girls, as noted in the National Health and Nutrition Examination Study (NHANES) III study and reproduced in the PROS study. The PROS study has led to a great deal of debate on what the diagnostic guidelines should be for defining when and why precocious or early puberty occurs. The pros and cons of the PROS study are outlined in Table 30-4.

Based on the PROS study, the Lawson Wilkins Pediatric Endocrine Society proposed new guidelines for differentiating the signs of early puberty from the diagnosis of precocious puberty. The pediatric endocrine society performed a comprehensive review of the data on which the existing definitions were based and critically examined the data from the PROS study. The recommendation with the most clinical impact was that the age at which the signs of puberty would be considered precocious would be lowered to less than 6 years in African American females and less than 7 years in white females in otherwise healthy children. A summary of their findings is listed in Table 30-5.

There has been ongoing controversy over these new guidelines, and some endocrinologists have issued statements challenging

**Table 30-3**  
**Significant Racial Differences in Puberty, from PROS Study**

	<b>Black Girls</b>	<b>White Girls</b>
Mean age of onset of any development	8.11 years	9.71 years
Mean age of menarche	12.11 years	12.88 years
Breast development at 7 years	15.44%	4.97%
Breast development at 8 years	37.76%	10.5%
Pubic hair growth at 7 years	17.65%	2.75%
Pubic hair growth at 8 years	34.27%	7.67%

PROS, Pediatric Research in Office Settings (study by American Academy of Pediatrics).

**Table 30-4**  
Pros and Cons of PROS Study

Pro	Con
No other large-scale studies of racially diverse girls in the United States to assess changes over time in the age of pubertal onset	A selection bias may exist in that younger females with advanced development were more likely to come in for physical examinations
Addresses the need for current, demographically relevant standards for assessment of the onset of pubertal changes in females	No data included on endocrine evaluations pursued in early developers as young as age 3 years No information on possible pathologic conditions that may have been missed
Large number of subjects included and therefore may be more representative than current "norms"	Not a population-based sample, as girls were drawn only from pediatric practices over a limited period of time, making it a broad convenience, but not necessarily a representative sample
Impossible to assess secular trends from one generation to the next without such data	The study recognizes early pubertal signs, but it does not follow the progression through the final stages of puberty and does not include data on more advanced stages of puberty
Clinicians have relied on Marshall and Tanner's classic studies on pubertal changes in girls despite their limitations	Most breast examinations were by inspection without palpation. Subcutaneous fatty tissue may have been reported as breast buds
The trends in pubarche parallel thelarche	

PROS, Pediatric Research in Office Settings (study by American Academy of Pediatrics).

them.<sup>11,12</sup> The traditional older age limits for defining precocious puberty are still used in Europe.

A subsequent study by endocrinologists (Midyett et al) contests the Lawson Wilkins guidelines. Midyett maintains that if the new guidelines are followed, there will be underdiagnosis of serious endocrine conditions.<sup>13</sup> This was a retrospective chart review of 223 patients referred for sexual precocity occurring between 7 and 8 years in white females and 6 and 8 years

**Table 30-5**  
Primary Conclusions of Lawson-Wilkins Pediatric Endocrine Society Regarding Precocious Puberty

1. The current recommendation that breast development at less than 8 years of age is precocious is based on outdated studies.
2. Stage 2 breast development and pubic hair development is being attained 1 year earlier in white females and 2 years earlier in African American females than previous studies demonstrated.
3. The concern that females with moderate precocious puberty will be significantly shorter adults is overstated. The majority will have final height that is within normal limits.
4. In most females with onset of puberty between 6 and 8 years, GnRH agonist therapy will not have a significant effect on adult height.
5. Females with breast development or pubic hair should be evaluated if this is occurring before age 7 years in white females and before age 6 years in African American females.

**Table 30-6**  
Findings of Midyett Chart Review<sup>13</sup> Regarding Precocious Puberty

1. 12.3% of patients referred to Midyett et al endocrine clinic with signs of precocious puberty had underlying pathologic conditions.
2. The pathologic conditions that were diagnosed did not include idiopathic precocious puberty.
3. One third of the girls with two signs of precocious puberty (breast and pubic hair development) had a bone age more than three standard deviations above the mean.
4. A subset of girls with isolated breast development were found to have advanced bone age.
5. Although weight and body mass index (BMI) correlate positively with benign earlier sexual development, a substantial number of girls with serious endocrine conditions were obese.
6. The authors conclude that all girls less than 8 years of age with secondary sexual development (one or more signs) deserve at least a bone age measurement and close longitudinal follow-up.

in black females. The major findings of the study are listed in Table 30-6.

In view of this recent conflicting data, primary practitioners need to be cautious in their approach to the early occurring signs of puberty. The defining age of sexual precocity does not have an absolute or universally accepted answer. Therefore, the approach to early developers cannot be guided by age alone, except in the more extreme cases of girls 6 years of age or younger and boys less than 9 years old, where prompt evaluation by a pediatric endocrinologist is the standard of care.

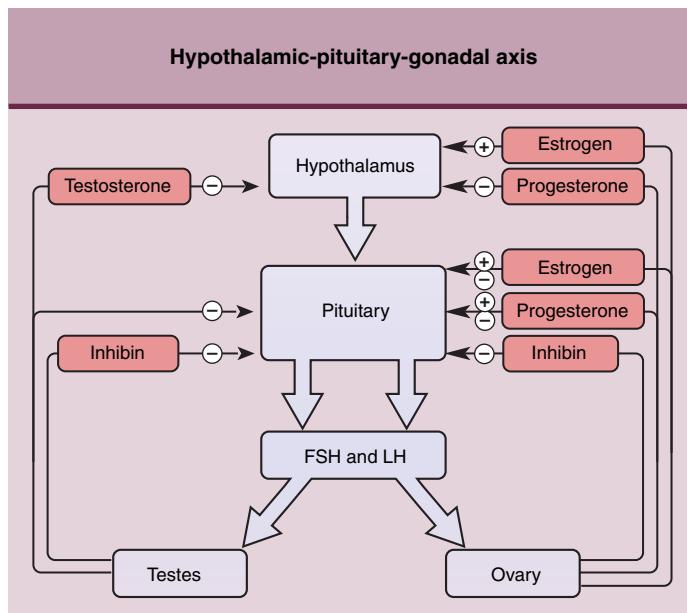

## NORMAL PUBERTY

During puberty the central nervous system (CNS) and peripheral endocrine organs interact to initiate and sustain a reproducible series of endocrine changes. These changes occur in three endocrine axes: the adrenal glands (adrenarche), the gonads (gonadarche), and the growth hormone–insulin-like growth factor axis, “somatarche.” The gonadal and growth hormone system are integrated with one another and the hypothalamic-pituitary-gonadal (HPG) axis. Adrenarche appears to be an independent process. These changes result in the acquisition of secondary sexual traits, a marked increase in growth and change in body composition, as well as psychological changes. They mark the physical and psychological transition from childhood to adulthood, with the physiologic endpoint of reproductive ability.

## Fetal, Infant, and Childhood Pubertal Endocrinology

Normal development at puberty requires a functioning hypothalamic-pituitary-gonadal axis (Fig. 30-3). GnRH is present in the hypothalamus by 14 weeks' gestation and functionally active by 20 weeks' gestation, stimulating follicle-stimulating hormone (FSH) and luteinizing hormone (LH) production. FSH and LH concentrations attain adult levels at midgestation and then fall secondary to negative feedback from pregnancy steroids. By 20 weeks' gestation the pituitary is sensitive to the negative feedback of sex steroids on FSH and LH production.

“In utero” the sex steroids and gonadotropins stimulate germ cell division and follicular development, so that by midgestation the primordial ovarian follicles reach their maximum number

**Figure 30-3 The hypothalamic-pituitary-gonadal (HPG) axis and the feedback effect of gonadal hormones.** (From Blair JC, Savage MO: Normal and abnormal puberty. In Besser GM, Thorner MO [eds]: Comprehensive Clinical Endocrinology, 3rd ed. Spain, Mosby, 2002, p 319.)

and then decrease logarithmically throughout life until menopause, when they are depleted.

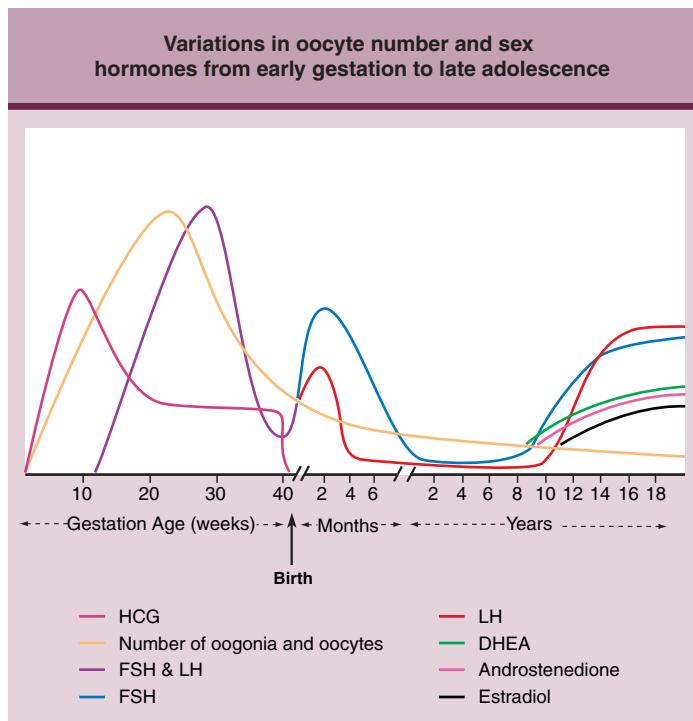

At birth, sex steroids, LH, and FSH are elevated but decrease postpartum. The gonadotropins and sex steroids peak in the first few months of life and then drop to low levels until puberty, although FSH levels may not be suppressed maximally until 1 to 4 years. Gonadotropin levels are lowest during mid-childhood (until 6 to 8 years). Prepubertal girls typically have lower LH to FSH ratios. Figure 30-4 depicts the changing serum concentrations of sex hormones from gestation through 18 years. The suppression of gonadotropins during childhood is dependent on a sensitive negative feedback mechanism of low level estrogen on the hypothalamus and pituitary, and there appears to be an intrinsic central inhibitory influence on GnRH.

### Hormonal Changes at Puberty

The hormonal changes that occur at puberty are due to a complex interplay of the HPG axis, with the adrenal gland functioning independently of the HPG axis. The initial pubertal changes of the hypothalamus and pituitary involve an increase in GnRH, LH, and FSH secretion in a distinctive pulsatile pattern. These hormonal changes of puberty, in general, begin 2 years before the onset of physical changes.

### GnRH and Gonadotropins

The pulsatile secretion of GnRH by the hypothalamus, released from its inhibition by the central CNS influence, is the initiator of puberty, although a decrease in the sensitivity to the negative feedback of estrogen also plays a role. GnRH is a decapeptide and is released in a pulsatile fashion. There are multiple influences on GnRH synthesis, including higher cortical centers, the limbic system, neurotransmitters, sex steroids, and gonadal peptides. GnRH binds to receptors in the anterior pituitary that synthesize

**Figure 30-4 Serum concentrations of sex hormones and oocytes over time.** (From Speroff L, Glass RH, Kase NG [eds]: Clinical Gynecologic Endocrinology and Infertility, 6th ed. Baltimore, Lippincott Williams & Wilkins, 1999, p 382.)

and store FSH and LH. FSH and LH are glycoproteins. Each is composed of two dissimilar peptide subunits, the alpha and beta chains. The  $\alpha$  chains are similar in structure, but the  $\beta$  subunit is unique and gives specificity from one hormone to the other.

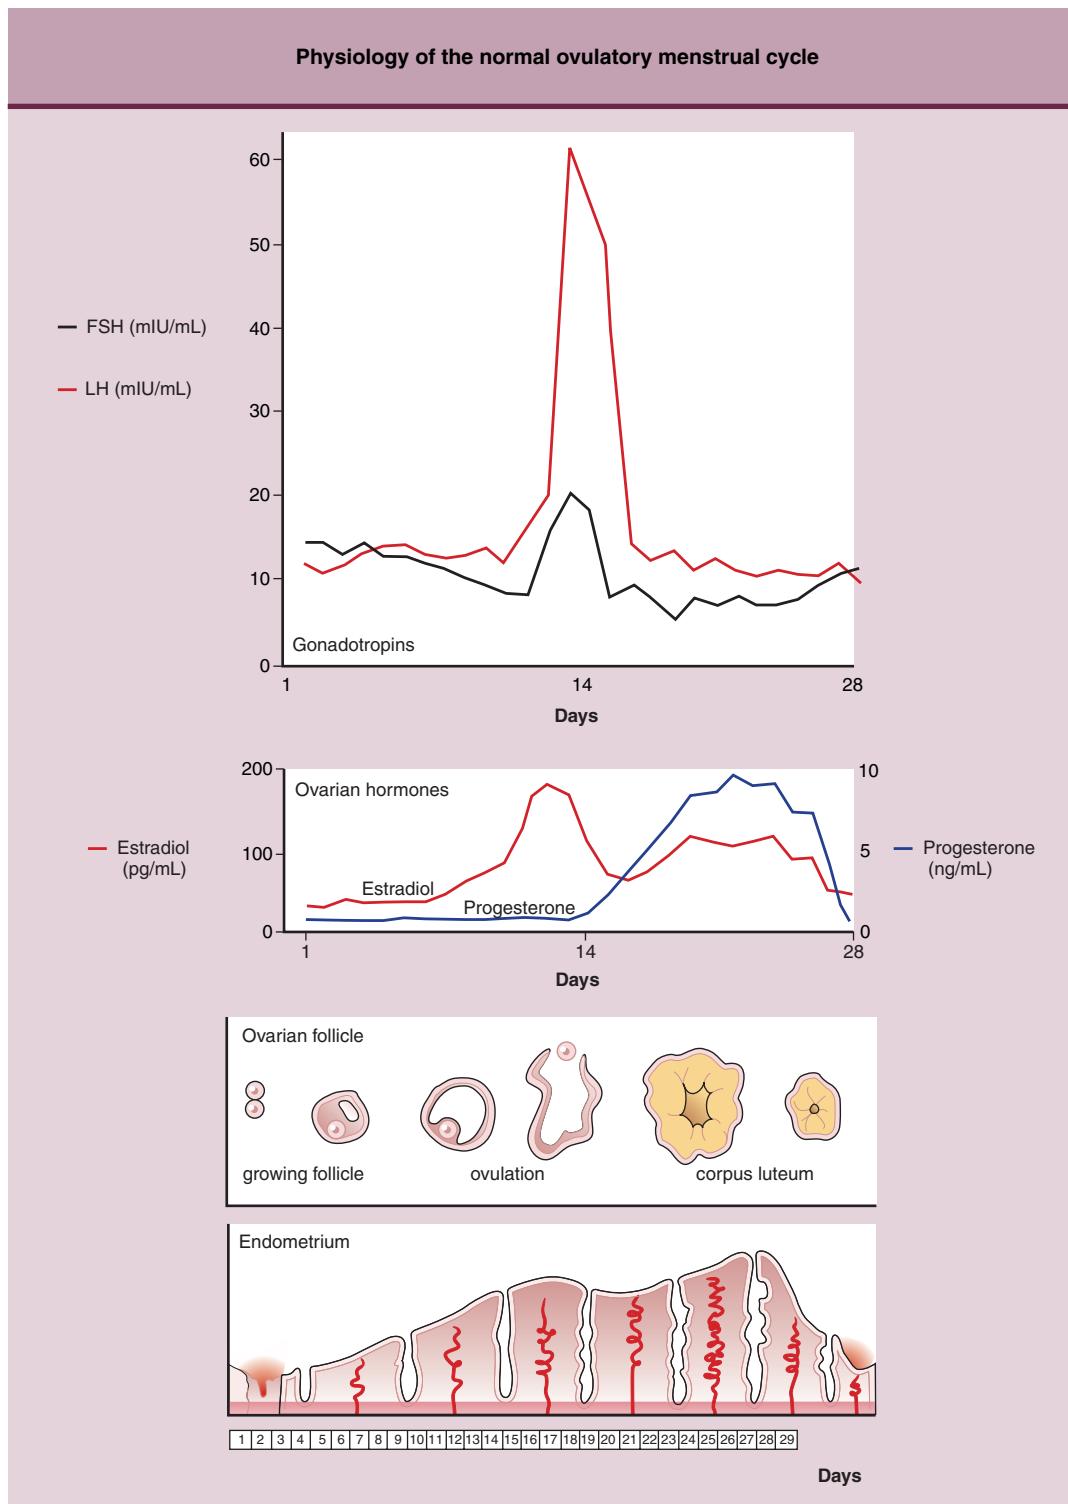

GnRH gradually increases in amplitude and frequency as puberty progresses. Renewed GnRH secretion first occurs during sleep and leads to reactivation of gonadotropin synthesis and secretion. At the onset of puberty, GnRH has a priming influence on the pituitary, leading to progressive increase in LH and FSH, as well as an increase in GnRH receptors in the pituitary.

### Gonadotropins and Gonadarche

The increase in gonadotropins and sex steroids from the gonad and adrenal cortex occurs before the clinical onset of puberty. At the beginning of puberty, there is an increase in pulsatile FSH and LH secretion during sleep. As puberty progresses, this reverts to an absolute increase in daytime secretion and a relative decrease in nighttime secretion. The change is more marked for LH than for FSH, with LH levels continuing to rise as puberty progresses. The steady rise of LH secretion is marked by an increase in both pulse frequency and amplitude, especially pulse amplitude. FSH increases in amplitude but not in frequency early in puberty. A rise in FSH levels is observed before a rise in LH in females, and FSH secretion in females is greater than in males throughout puberty. Similar patterns may also be found in the reactivation of the HPG axis after suppression by disease, starvation, stress, and anorexia nervosa.

### Ovarian Maturation

FSH stimulates follicular growth of the ovary, starting at the onset of puberty. FSH stimulation and secretion lead to ovarian

**Figure 30-5 Physiology of the normal ovulatory cycle.** (From Laufer MR: The physiology of puberty. In Emans SJ, Laufer MR, Goldstein DP [eds]: Pediatric and Adolescent Gynecology, 5th ed. Philadelphia, Lippincott-Raven, 2005, p 145.)

aromatase conversion of androgens to estrogens. Progesterone secretion increases with pubertal progression and leads to mitosis and maturation of follicular development. Mitosis leads to an increase in the layers of granulosa cells and to an increase in intercellular fluid rich in inhibin B and FSH. LH receptors increase as cell numbers increase and the ovary becomes more sensitive to LH stimulation. LH, in turn, increases the production of progesterone and androgens.

Estrogen levels rise as puberty progresses and eventually act on the hypothalamus to increase GnRH pulse amplitude. Estrogen production induces a positive feedback loop, leading to an increase in the gonadotropin surge and higher LH levels. At the same time that estrogen is enhancing the LH response, inhibin inhibits the FSH response. As LH reaches its peak levels by mid to late puberty, associated with episodic peaks of estradiol, menarche occurs. Ovulatory cycles start after a positive feedback loop is firmly established when increasing levels of estrogen trigger a midcycle LH surge. The timing at which ovulatory cycles begin to occur regularly is, on average, 2 years after menarche, but this varies considerably. The physiology of the normal ovulatory menstrual cycle is shown in Figure 30-5.

#### **Inhibin, Activin, and Follistatin**

Inhibin, activin, and follistatin are polypeptide hormones that are synthesized in various body tissues, including the gonads, where they are secreted at their highest levels. These hormones have different local action in different tissues. Each acts to either increase (activin) or decrease (inhibin and follistatin) FSH synthesis at the pituitary level. They have been found to play a role in pubertal development, including modulation of steroid secretion in the ovary and adrenal gland. The extent of their role in puberty and reproduction is being actively investigated.<sup>14</sup>

#### **Sex Hormone-Binding Globulin**

Sex hormone-binding globulin (SHBG) is a  $\beta$ -globulin protein that binds and transports sex steroids in plasma. Before puberty the levels of SHBG are about equal in males and females, and most estradiol and testosterone molecules are bound to SHBG reversibly. SHBG begins to decrease as pubertal age advances, and there is a consequent increase in the free or active hormones. By the end of puberty, males have one half the concentration of SHBG as females. SHBG levels may be included or implied in the battery of tests performed in obtaining a free testosterone level. Testosterone and elevated insulin levels are known to decrease SHBG levels, and estrogen increases SHBG production.

#### **Adrenarche**

**Adrenarche** is defined endocrinologically by the increase in adrenal androgens that begins 2 years before and continues during puberty. Increased secretion of adrenal androgens occurs, including dehydroepiandrosterone (DHEA), its sulfated product (DHEAS), and androstenedione (AND). Clinically the term is also used to describe the development of pubic and axillary hair that occurs at puberty. Pubarche specifically refers to the growth of pubic hair; however, it is often used interchangeably with adrenarche to include other clinical manifestations of androgen-stimulated maturation, including acne and other skin changes, body odor, and axillary hair growth. Increases in adrenal androgen

#### **Hypothalamic-Pituitary-Gonadal (HPG) axis**

Increase in GnRH frequency and amplitude  
Increase in basal luteinizing hormone (LH) and follicle-stimulating hormone (FSH) concentrations  
Increase in LH/FSH ratio  
Increase in estradiol and testosterone  
Increase in growth hormone (GH) and insulin-like growth factor 1 (IGF-1)

secretion precede the rise in gonadotropins and subsequent activation of the HPG axis, but they can overlap. Adrenarche is not under direct control of the HPG axis, and it can progress without gonadarche, as is seen in Turner's syndrome, congenital adrenal hyperplasia (CAH), and adrenal hyperandrogenism. The chronologic sequence of the hormonal events of puberty is presented in Table 30-7.

### **CLINICAL SIGNS OF PUBERTY**

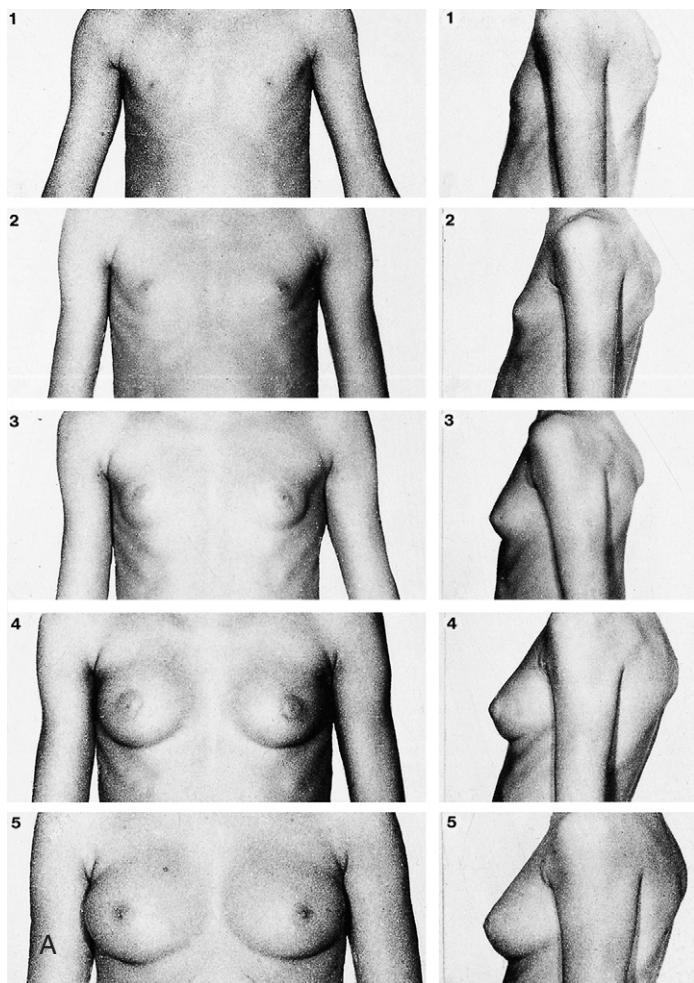

The clinical signs of puberty occur in a generally predictable pattern in both males and females; however, there is significant variation in the onset and duration of puberty for both sexes. The first signs of puberty occur between 8 and 13 years in the majority of females and between 9.8 and 14.2 years in most males.

#### **Females**

Usually the first sign of puberty is accelerated growth after a decrease in height velocity that precedes puberty. This is usually followed by thelarche, but either may be the cardinal sign. The sequence of pubertal events in females is listed in Table 30-8. Thelarche occurs in response to estrogen, which stimulates

**Table 30-8**  
**Sequence of Pubertal Development in Females**

- Increase in growth velocity—usually the first event but can overlap with breast budding; evident by rapid change in shoe size
- Adrenarche—development of body odor and skin changes; overlaps with increase in growth velocity and thelarche
- Thelarche (or breast buds)—occurs within 1 year of the growth spurt
- Pubarche—occurs within 6 months of breast budding; the two may overlap
- Peak height velocity—occurs within 1 to 2 years of breast budding, usually at Tanner stage 2–3
- Axillary hair growth—usually occurs 1 to 2 years after pubarche
- Physiologic leukorrhea (estrogen-stimulated clear, milky vaginal discharge)—occurs 6 or more months before menarche
- Menarche—occurs within 2 years of breast budding in the majority; usually occurs within 1 year after peak height velocity, at Tanner stage 3–4
- Ovulation—can begin episodically at any time around menarche; regular ovulation can occur within 6 months of menarche and as late as 5 years after menarche, but the majority of cycles are ovulatory within 5 years of menarche

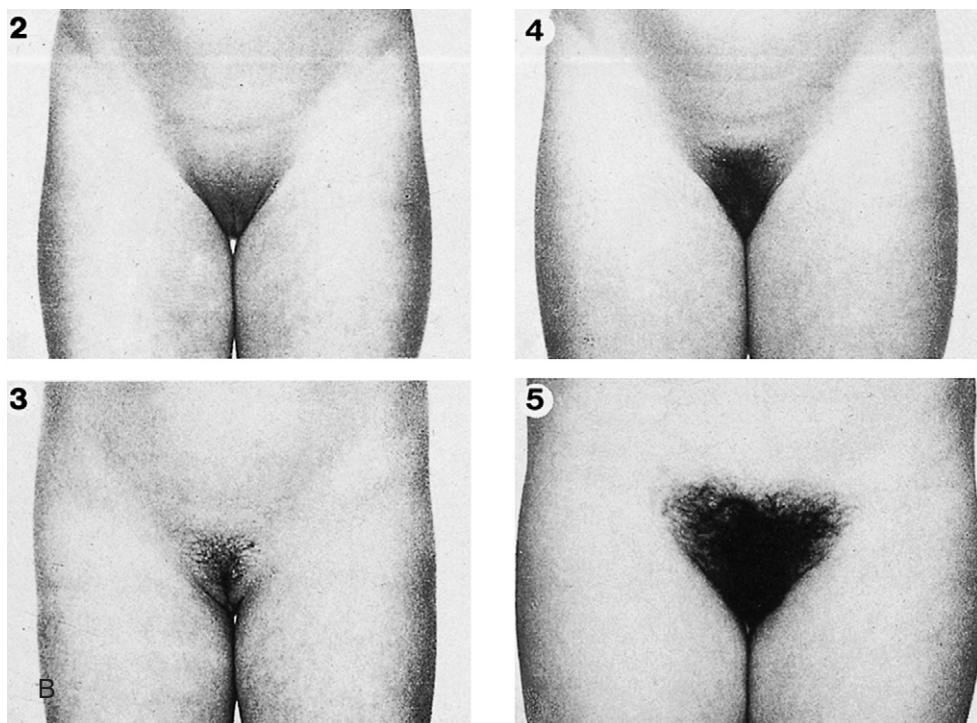

growth of the breast ductal system and the accumulation of fat. Together these produce changes in the contour of the breast. Initial breast development can be unilateral or bilateral, and this asymmetry is often more marked in premenarchal girls, often causing concern in patients and their parents. Breast tenderness in early puberty is common. There are variations in the progression of breast development. Some girls progress from Tanner stage 3 directly to Tanner stage 5 breast development, whereas others stay at Tanner stage 4 without progression to Tanner stage 5. Female Tanner staging is demonstrated in Figure 30-6.

In about 20% of girls, pubarche is the first sign of puberty, but through most of puberty the stage of breast development coincides with that of pubic hair development. Pubarche in females is dependent on adrenal androgens; however, pubic hair will not usually advance beyond Tanner stage 3 in the absence of gonadal sex steroids. Pubic hair is initially fine and sparse, and changes in quality to become coarser, curlier, and denser as puberty progresses. It expands in distribution, and should be detectable even in the presence of shaving or other hair removal techniques.

The peak height velocity usually occurs 1 to 2 years after the first appearance of breast buds, at Tanner breast stage 2–3 and precedes menarche by up to 1 year. After menarche growth rate decelerates and most girls do not grow much more than 5–6 cm thereafter. Puberty that begins earlier generally has a slightly longer duration.

Menarche is a later pubertal event, usually occurring 2 years after thelarche. This timing may vary, and menarche can occur from 1 to 5 years after thelarche, although a 5-year interval is unusual and warrants close surveillance. Menarche occurs at Tanner breast stage 3–4 in at least 75% of pubertal girls. The mean age for the onset of menstruation is 12.8 years in white American females and 12.2 in African American females.

**Figure 30-6 Female Tanner stages.**

A, Breasts. B, Pubic hair. (From Marshall WA, Tanner JM: Variations in pattern of pubertal changes in girls. Arch Dis Child 1969;44:291–301. Reprinted by permission from the BMJ Publishing Group.)

The great majority of American girls (94%) have obtained menarche by 14 years. The first menstrual cycles are typically anovulatory.

### Vaginal, Uterine, and Ovarian Changes

Estrogen produces changes in vaginal contour, color, mucosa, and pH. Dulling of the vaginal mucosa occurs because of the cornification of epithelial cells. Before menarche, a clear, white vaginal discharge is noted, which is termed *leukorrhea*. Leukorrhea is desquamated epithelial cells and mucous from estrogenized mucosa. It can begin before thelarche. Unopposed estrogen exposure can cause profuse vaginal secretions with a problematic discharge that may decrease with maturity and concomitant progesterone secretion. It can be quite bothersome to the patient. As puberty progresses the vaginal pH decreases. There is also thickening of the labia majora, labia minora, and hymen. The decrease in vaginal pH allows for yeast colonization with consequent potential for infections that are microbiologically different from the typical infections of prepuberty

(with gram-positive cocci and gram-negative rods) that cause vulvovaginitis.

The vagina also grows in size. The ovaries and uterus undergo substantial changes with the progression of puberty. In the years preceding puberty and as puberty progresses, the ovaries increase in size and volume and show evidence of active follicular growth and atresia. Small "cysts" are common in prepubertal ovaries (5 to 7 mm), and are usually asymptomatic. They can be an incidental finding on ultrasound. Follicular activity may be noted on ultrasound in mid to late puberty. Initially small and then larger follicular cysts appear and regress. It is common to see multiple small ovarian cysts or follicles on pelvic ultrasound during late puberty. The uterus increases in size and volume and changes shape from tubular to bulbous. These changes in the female genital tract are described in more detail in Table 30-9.

### Males

The first sign of puberty in males is testicular enlargement, with a volume of 4 mL corresponding with the onset of puberty. The

**Table 30-9**  
Changes in Gynecologic Anatomy and Physiology from Birth to Postmenarche

	Newborn	Early Childhood	Peripuberty (8–13 yr)	Postmenarche (>13 yr)

**Table 30-10**  
**Sequence of Pubertal Development in Males**

- Testicular enlargement (>2.5 mm) and thinning of scrotal skin
- Pubic hair growth—usually occurs 6 months after testicular enlargement is first noted
- Penile growth—occurs around the same time as pubic hair growth (the two may overlap); growth initially occurs in length and then in width
- Transient gynecomastia (symmetric or asymmetric)—usually seen at Tanner stage 2–3; occurs secondary to estrogen stimulation and is benign in the majority of cases
- Axillary hair growth—occurs about 1 year after pubic hair growth
- Peak height velocity—occurs at Tanner stage 3–4, at a mean age of 14 years
- Fertility—usually occurs at Tanner stage 4 but may occur earlier
- Facial and body hair, voice change—may begin at Tanner stage 3–5 but progresses for several years after puberty is complete

sequence of pubertal events in males is listed in Table 30-10. The scrotum becomes darker in color and more lax. With the progression of puberty the testicular enlargement continues. At the same time, under the influence of androgens, penile growth occurs first in length and then in width. The glans develops toward the end of puberty, as adult size and shape are reached. Pubic hair usually precedes axillary hair by 1 year (both are

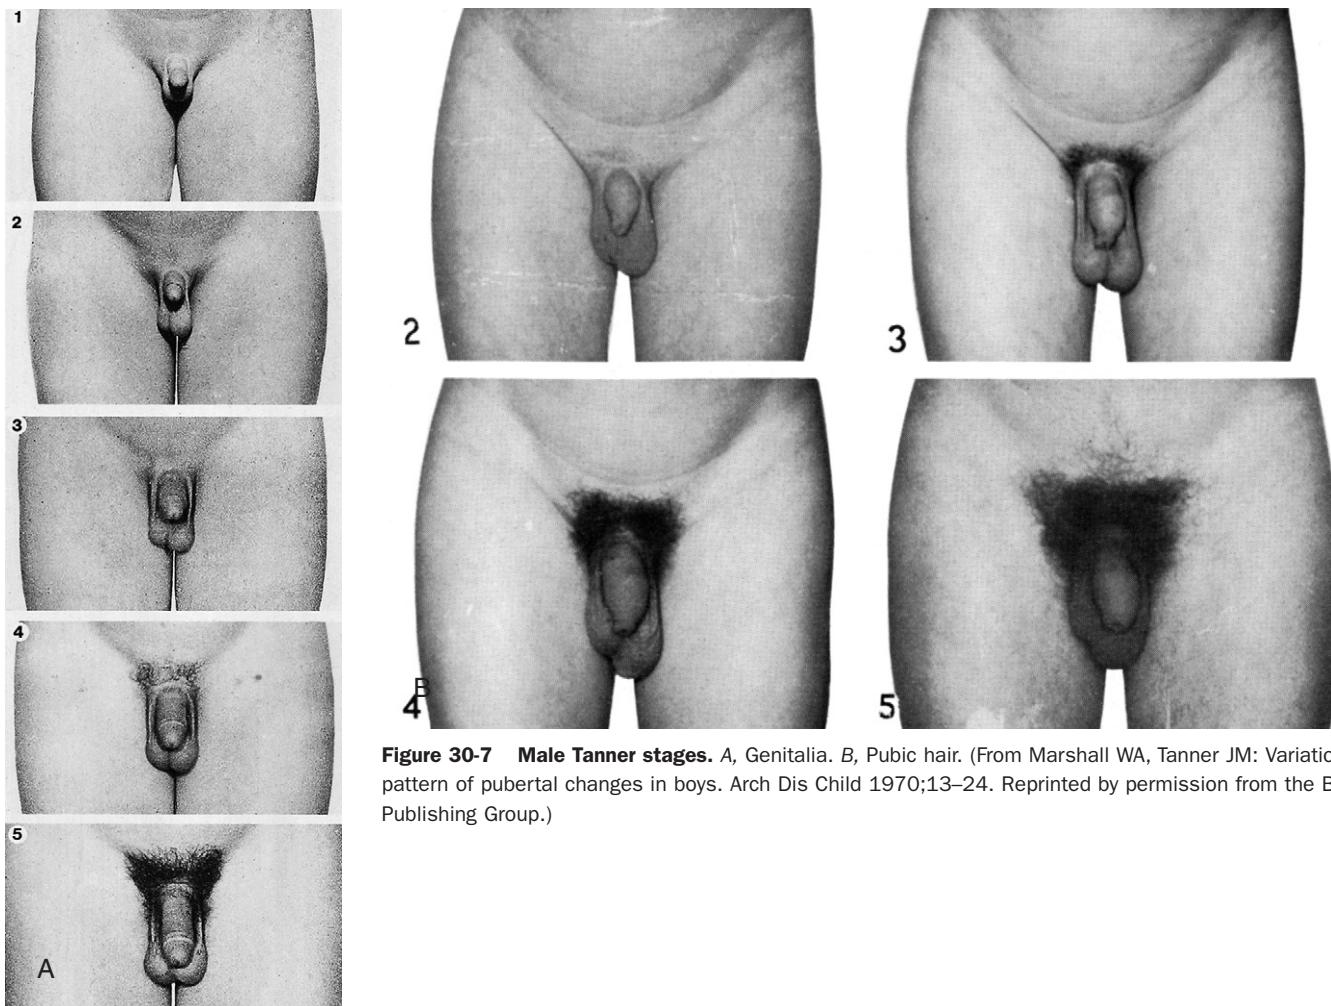

stimulated by androgen) and is usually seen after testicular enlargement. Pubarche in males is dependent on testicular androgens. Pubic hair is usually noted after testicular enlargement, and it is initially fine, straight, and sparse and is located at the base of the penis. It first changes in quality to become coarser and curlier and then expands in distribution, as noted in Tanner staging.

Peak height velocity occurs at a later chronologic age and Tanner stage in males than in females. It is seen, on average, at 14 years of age, when boys are between Tanner stage 3 and 4 pubertal development. Pubertal development in males progresses at a slower pace through Tanner stage 3 genital development and accelerates thereafter. The time frame from Tanner stage 2 to Tanner stage 4 in males is typically 4 years, whereas in females it is shorter. Tanner staging of genital and pubic hair development is shown in Figure 30-7.

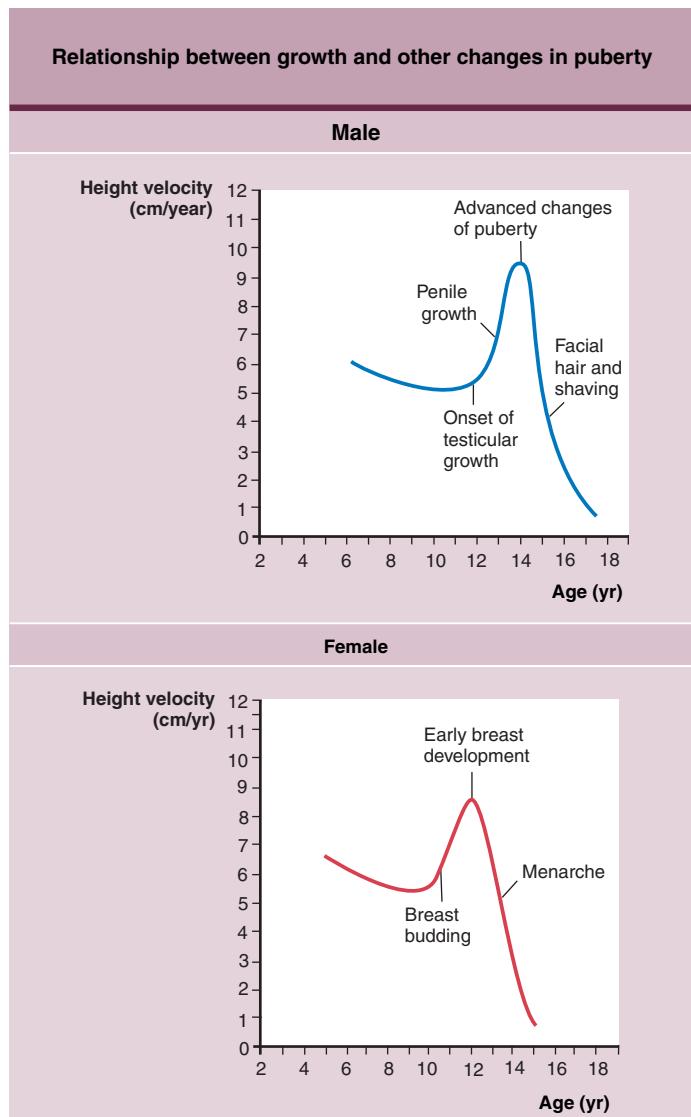

### Somatic Growth in Puberty

#### Clinical Events

The rate of linear growth during puberty is greater than at any other time except infancy. The pattern and rate of growth in males and females is similar until the onset of puberty. The pubertal growth spurt occurs about 2 years earlier in girls than in boys. Boys have a longer prepubertal growth period as well as

**Figure 30-7 Male Tanner stages.** A, Genitalia. B, Pubic hair. (From Marshall WA, Tanner JM: Variations in pattern of pubertal changes in boys. Arch Dis Child 1970;13–24. Reprinted by permission from the BMJ Publishing Group.)

**Figure 30-8 Comparative growth curves for males and females and their relationship to other changes in puberty.** (From Blair JC, Savage MO: Normal and abnormal puberty. In Besser GM, Thorner MO [eds]: Comprehensive Clinical Endocrinology, 3rd ed. Spain, Mosby, 2002, p 326.)

a longer growth spurt and a greater peak height velocity, and thus attain taller adult heights. Figure 30-8 demonstrates the difference in growth curve and timing of pubertal changes between boys and girls.

#### Hormonal Events

The major hormones that play a role in the growth spurt at puberty are estrogen, insulin-like growth factor 1 (IGF-1), and growth hormone (GH). Normal growth at puberty depends on the concerted action of all three. Other hormones are thought to also play minor roles, albeit less well defined. An increase in sex steroids, predominantly estrogen, stimulates the secretion of GH, which then stimulates IGF-1 production. Sex steroids, especially estrogen, seem to have the central role in pubertal growth for both girls and boys. The amount of estrogen required to stimulate long-bone growth is very small, which correlates

with the fact that girls achieve peak height velocity early in puberty at a time when serum estradiol levels are quite low (20 pg/mL). Estrogen at high levels, as seen toward the end of puberty, decreases GH and IGF-1 levels. Finally, the sex steroids are responsible for the termination of growth. They stimulate epiphyseal fusion and result in closure of the growth plates.

GH is secreted in pulses with a circadian pattern. For this reason, random sampling is not helpful. Before puberty, GH production is independent of the sex steroids, but during puberty its secretion is crucially dependent on the sex steroids. GH synthesis doubles during puberty, increasing in pulse amplitude, not pulse frequency. Maximal growth hormone production occurs at maximal height velocity in both sexes. Basal levels of GH are higher in girls than boys throughout puberty, reaching their maximum at Tanner stage 4. The basal level of GH secretion in boys is constant throughout puberty. By the end of puberty, GH decreases in both boys and girls regardless of continued exposure to sex steroids.

#### Changes in Body Composition at Puberty

Body composition is similar between the sexes at the onset of puberty when girls and boys have the same percentage of body fat. By the end of puberty females have 2 times the body fat as males and males have 1.5 times the lean body mass and skeletal mass as females. Body proportions also change during puberty. In early puberty growth is greatest in the limbs, but at peak height velocity growth in the trunk is greater. Growth in truncal width is different between males and females—in males the maximum growth is across the shoulders (biacromial diameter) and in females the maximum growth is across the pelvis (biliac diameter).

#### Bone Density and Puberty

The major changes in bone mineral density occur during the first 3 years of life and then again during puberty, especially during peak height velocity and just after menarche in females. Estrogen is primarily responsible for the attainment of adult bone mineral density. Calcium intake has been shown to play an important role in increasing bone density in adolescent females, and supplementation is recommended in adolescent females who are ingesting suboptimal amounts of calcium (80% of the recommended daily allowance in their diet).<sup>15</sup> Vitamin D intake may be critical where sun exposure is limited, especially in winter. The increase in bone density during puberty ranges from 10% to 20%, which provides up to 20 years of protection against the later normal age-related loss of skeletal mass. The critical role of estrogen on bone mass accumulation is emphasized by the observation that nearly all of the bone mass in the hip and vertebral bodies is accumulated in females by late adolescence (18 years of age), mostly during the postmenarchal period. The increase in vertebral bone density is greater in African American females, as compared with white females, partly explaining why later in life osteoporosis and vertebral fractures are less common in black women than white women.<sup>16</sup> Deficiencies of pubertal development have been shown to adversely affect bone density in males and females, mostly due to estrogen deficiency. Children with precocious puberty have an increased bone mineral density consistent for their bone age, but treatment with GnRH analogs and antagonists reversibly decreases bone mineral density.

**Table 30-11****Medical Conditions Associated with Early or Precocious Puberty**

- Congenital adrenal hyperplasia (CAH)
- McCune-Albright syndrome
- Neurofibromatosis 1
- Spina bifida
- Testotoxicosis
- Tuberous sclerosis
- Williams syndrome

**Determinants of the Timing of Puberty****Genetic**

The strongest factor regulating puberty and its timing is genetic. The variance in pubertal onset can be predicted genetically 50% to 80% of the time. As discussed earlier, puberty begins with the reactivation of GnRH secretion after its suppression in mid-childhood. The mechanisms that cause this suppression and then reactivation are not clearly understood, but they help explain some of the genetic contributions to puberty. Precocious puberty is seen in several genetic disorders (Table 30-11).

The influence of genetics on puberty is demonstrated in the long-standing correlation between mothers, daughters, and sisters with timing of pubertal onset and menarche. As discussed, studies have shown that puberty varies among racial groups. It has been postulated that the genetic control of the variance in pubertal timing is linked to a complex polygenic trait or to multiple genes and that individual variation in pubertal timing involves familial, ethnic, gender, and environmental factors. Twin studies have shown a greater concordance between monozygotic than dizygotic twins in timing of skeletal maturation, age of growth spurt, age of menarche, and Tanner staging in puberty.

**General Health and Nutrition**

Improved health and nutrition play an important role in the onset of puberty. Young women who have anorexia nervosa and intense exercisers with low weight and low percentage of body fat have delayed menarche or amenorrhea. This delay in menarche is more pronounced when training starts prepubertally. One theory supports that a low percentage of body fat generates less estrogen, since some estrogens are produced in adipose tissue by the aromatization of androgens. Inconsistent with a simple relationship between age of menarche and body weight is the observation that some morbidly obese girls have delayed menarche. This may be influenced by a combination of hormonal changes that are associated with extreme obesity. Variations in the timing of puberty have been observed in developing countries based on socioeconomic status, other social stressors, and demographic factors, including urban versus rural living.

Nutritional components in the diet may also play a role, although this is less well defined. It is clear that nutritional factors play a role in the age of pubertal onset through their effects on the accumulation of adipose tissue. Phytoestrogens are naturally occurring plant estrogens, and are abundant in certain food products, including soybean, clover, alfalfa, peanut, and flaxseed. Studies of phytoestrogens in the diet have demonstrated this effect of diet on puberty as well, as they have been found to interact with estrogen receptors, having either agonistic or antagonistic effects. An association between diets high in animal protein in early life compared with a diet high in vegetable

protein has been associated with earlier menarche.<sup>17</sup> Finally, a diet high in animal fat, dairy products, refined sugars and low in complex carbohydrates, fiber, and whole-grain is associated with higher plasma sex hormones and higher urinary and fecal excretion of estrogens, as well as higher cholesterol and insulin levels.<sup>18</sup>

**Leptin**

Leptin is a hormone produced in adipose tissue. Leptin acts on CNS neurons to regulate eating behavior and energy balance. It is thought to play a role in the stimulation and maintenance of puberty, but its exact role is still unclear. In the leptin-deficient mouse, sexual maturation and fertility are restored with leptin, and in the normal female mouse administration of leptin accelerates the onset of puberty. There seem to be sex differences in leptin concentration, with higher levels found in girls throughout life. Finally, there are low levels of leptin in athletes and patients with anorexia nervosa or delayed puberty, whereas girls with idiopathic precocious puberty have been found to have increased levels of leptin.<sup>19</sup> The current thinking with regard to leptin is that it plays a role in the regulation of puberty but is not the initiating hormone for the onset of puberty.

**Obesity**

An association has been observed between female obesity and earlier onset of puberty, but a causal direction of this relationship has not been clearly determined. Kaplowitz et al re-evaluated the PROS population and found a positive relationship between earlier pubertal signs and obesity.<sup>20</sup>

A more recent longitudinal study looked at 183 white girls from age 5 to 9 years and found a significant relationship between higher percentage of body fat, greater BMI, and larger waist circumference and earlier pubertal timing in females.<sup>21</sup> The authors proposed factors that are thought to contribute to this positive association of obesity and earlier pubertal onset, as listed in Table 30-12.

Currently in the United States, the association of higher socioeconomic status with higher weight is no longer true. This confounds the interpretation of the association of earlier onset of puberty and obesity with the historical trend of improved socioeconomic conditions and earlier puberty.

**Biochemical Exposures**

Endocrine-disrupting chemicals (EDCs) are synthetic substances such as dichlorodiphenyltrichloroethane (DDT) that can negatively influence the endocrine system.<sup>22</sup> Some of these compounds can act as estrogen analogs although they are structurally quite

**Table 30-12**  
**Factors Contributing to Earlier Puberty in Girls with Greater BMI**

- Genetic factors
- Increased levels of estrogen from adipose tissue
- Greater stores of body fat secondary to a process of accelerated growth that starts early in development and affects both BMI and timing of puberty
- Leptin is associated with an increase in the percentage of body fat and is thought to play a permissive role in puberty

BMI, Body mass index.

different. Multiple compounds are often mixed in a suspect agent, making it challenging to sort out the effects of individual agents.

Some cosmetics also contain estrogens, and the Food and Drug Administration (FDA) does not regulate those with less than 10,000 IU of estrogen per ounce. The use of hormone-containing hair products in two case studies was associated with early puberty that regressed with discontinuation of use. The individuals using these products were African American women and girls.<sup>23</sup> This reinforces that sex steroids are well absorbed through the skin.

#### Other Factors

One factor that is thought to play an indirect role in the timing of puberty is stress, a component of the influence of acute or chronic illness, and psychological or physical adversity. The correlation between child sexual abuse and later neurobiological consequences has been demonstrated, with adverse effects on the hypothalamic-pituitary-adrenal axis.<sup>24</sup>

Another factor that may play a role in pubertal timing is in utero environment, particularly low birth weight. Infants born with intrauterine growth retardation (IUGR) have been observed to be at increased risk for precocious pubarche in childhood.<sup>25</sup>

## PRECOCIOUS PUBERTY

Precocious puberty is, importantly, different from “early puberty” (see Key Terms). When true precocious puberty is present, there is typically substantial acceleration of linear growth and bone maturation, which can lead to early epiphyseal fusion and shorter adult height. For this reason some pediatric endocrinologists do not consider early pubertal development without growth acceleration as precocious puberty, but rather “pseudoprecocious” puberty. True precocious puberty is 20 times more common in girls than in boys.

It is prudent for primary care physicians to approach the diagnosis of precocious puberty cautiously, since it can be difficult to differentiate “normal” early developers from those with underlying disorders. Understanding the etiology and predicting the rate of progress of puberty and growth are critical in determining the urgency and aggressiveness of the workup and possible treatment options. When a girl at 6 years or less has pubertal signs or when pubertal changes are more advanced or quickly progressing, or when a boy is less than 9 years old, the approach is clear. Prompt consultation with and referral to a pediatric endocrinologist are required. In the 6- to 8-year-old female being evaluated for pubertal signs, the clinical presentation, rate of progression of changes, and level of patient and parental concern influence the clinician’s approach.

The evaluation is individualized. At a minimum, a careful history and thorough physical examination, radiographic bone age, and plan for close follow-up are recommended. An initial follow-up visit provides the opportunity to review the findings and identify rapid changes. A subsequent visit 3 to 4 months later will provide documentation of progression. In addition, puberty beginning “on time” but progressing too quickly, slowly, or discordantly warrants the attention and evaluation of a pediatric endocrinologist. Continuity of care and meticulous follow-up is the way to ensure detection of slowly developing lesions of the brain, ovary, or adrenal gland or, by ongoing observation, to confirm the overall benign nature of early puberty.

**Table 30-13**  
**Classification of Precocious Puberty**

GnRH-dependent
Central precocious puberty (CPP) or “true” or complete precocious puberty—always implies a hypothalamic source
GnRH-independent
Peripheral precocious puberty (PPP) or pseudoprecocious or incomplete precocious puberty—hormonal drive originating from exogenous, gonadal, adrenal, or other hormone-secreting tissue
Isolated precocious puberty or incomplete precocious puberty
Isolated menstruation or premature menarche

#### Etiology and Pathophysiology

The typical etiologic classification scheme is given in Table 30-13 (see Key Terms for definitions). Classification by etiology helps as a general guide to the differential diagnosis, but there is overlap between categories in both etiology and presentation.

#### Central Precocious Puberty

Central precocious puberty (CPP) is chronologically early pubertal development that is GnRH stimulated, as is normal puberty. In females breast development or an increase in growth appears first, and in males testicular enlargement is the first sign of puberty. Pubic hair growth follows, although all three changes can occur at the same time. There are often changes in behavior caused by sex steroid influences. The pathogenesis of CPP is not fully understood, but it has been hypothesized that it occurs secondary to suppression of or injury to the neural source of negative feedback inhibition at the level of the hypothalamus. It is much more common in females in whom it is idiopathic (95% of the time) and thought to be secondary to premature activation of the hypothalamic GnRH pulses.

Although CPP is idiopathic in the majority of cases, it is a diagnosis of exclusion, requiring a thorough investigation for other causes. Particularly, the possibility of serious CNS or peripheral endocrine pathology needs to be explored. CPP may be the only presenting sign of a hypothalamic tumor. In females below age 4, a CNS lesion is often the cause. Girls older than 4 years are more likely to have idiopathic precocious puberty. An underlying CNS pathology is highly probable in males with true precocious puberty regardless of age; they should be investigated aggressively.

#### Differential Diagnosis of Central Precocious Puberty

In approaching the diagnosis of CPP all etiologic categories of precocious puberty deserve consideration. Table 30-14 illustrates the differential diagnosis of precocious puberty.

Many CNS tumors cause CPP (see Table 30-14). All these tumors are typically near the hypothalamus. Hypothalamic hamartoma, the most common CNS tumor manifesting as CPP, is a congenital malformation that contains GnRH-secreting neurons. It often presents at age 2 or less, and precocious puberty progresses quickly. The hamartoma is usually attached to or suspended from the floor of the third ventricle and is then termed *parahypothalamic*, which is more often associated with precocious puberty. The tumor can also be intrahypothalamic,

**Table 30-14**  
**Differential Diagnosis of Precocious Puberty**

I. Central precocious puberty	III. Isolated precocious puberty
A. Idiopathic	A. Premature thelarche
B. CNS pathology	1. Premature thelarche
1. Hypothalamic hamartoma	2. Exogenous steroid
2. CNS tumor—craniopharyngioma, astrocytoma, glioma, optic glioma (associated with neurofibromatosis), ependymoma, suprasellar teratoma, pineal tumor—boys only	3. Ovarian cyst
3. Hydrocephalus	a. Isolated
4. Infiltrative disease (sarcoidosis, storage disease)	b. Secondary to endocrine disorder (McCune-Albright syndrome, hypothyroidism)
5. Infectious/postinfectious—meningitis, encephalitis, brain abscess	4. Early central precocious puberty
6. Genetic syndrome—neurofibromatosis, tuberous sclerosis, Williams syndrome	B. Premature pubarche
7. Postsurgical or irradiation injury	1. Premature pubarche
8. Trauma	2. Androgen-secreting tumor
9. Space-occupying lesion—arachnoid cyst or suprasellar cyst	3. CAH
10. Congenital defect—septo-optic dysplasia (associated with panhypopituitarism), spina bifida/myelomeningocele	4. Exogenous steroid
11. Skull abnormality—rickets	IV. Isolated vaginal bleeding: first confirm that there is true blood (e.g., heme test)
C.* Excessive sex steroid exposure leading to activation of the HPG axis— androgen-secreting tumor, McCune-Albright syndrome, congenital adrenal hyperplasia (CAH), testotoxicosis, exogenous steroid use, hypothyroidism	A. Vulvovaginitis
II. Peripheral precocious puberty	B. Trauma
A. Gonadal tumor	C. Abuse
1. Ovarian tumor—granulosa cell, theca cell, mixed cell, germ cell, cystadenoma, gonadoblastoma, lipid cell tumor, teratoma, choriocarcinoma, arrhenoblastoma, benign ovarian cyst	D. Foreign body
2. Testicular tumor—Sertoli cell (seen in Peutz-Jeghers syndrome), Leydig cell, mixed cell, gonadoblastoma, rhabdomyosarcoma, lymphoma, neuroblastoma, leukemia	E. Ovarian cyst
3. β-hCG-producing tumor—germ cell tumor, hepatoblastoma, choriocarcinoma	1. Isolated
B. Adrenal tumor—adenoma, carcinoma	2. Secondary to endocrine disorder (McCune-Albright syndrome, hypothyroidism)
C. Congenital adrenal hyperplasia (CAH)	F. Hypothyroidism
D. Hypothyroidism	G. McCune-Albright syndrome
E. McCune-Albright syndrome	H. Exogenous estrogen or estrogen withdrawal
F. Testotoxicosis (male-limited precocious puberty)	I. Hemorrhagic cystitis
G. Ovarian cyst	J. Urethral prolapse
H. Exogenous sex steroid (oral, cutaneous intravaginal, injectable)	K. Constipation
	L. Lichen sclerosis
	M. Local tumor—rhabdomyosarcoma, endodermal carcinoma, clear cell adenocarcinoma, mesonephric carcinoma
	N. Other infection— <i>Shigella</i> , <i>Streptococcus pyogenes</i>

\*These diagnoses can overlap in all categories of precocious puberty.

Parts I and II adapted from Tomboc M, Witchel SF, Lee PA: Precocious puberty. In Sanfilippo JS, Muram D, Dewhurst J (eds): Pediatric and Adolescent Gynecology, 2nd ed. Philadelphia, WB Saunders, 2001, p 60.

which indicates that it is enveloped by the hypothalamus, causing distortion of the third ventricle. Intrahypothalamic hamartomas are more often associated with seizures and other neurologic problems than with precocious puberty. The seizures are typically gelastic seizures, which are characterized by brief stereotyped attacks of laughter, but there are often other types of seizures as well. Hypothalamic hamartomas are generally benign and do not progress over time, but they can cause growth acceleration and bone age advancement. Over recent years a greater number of cases of precocious puberty have been attributed to hypothalamic hamartoma secondary to better identification and radiographic imaging technology.

Genetic diseases that manifest as CPP are neurofibromatosis, tuberous sclerosis, Williams syndrome, McCune-Albright syndrome, and testotoxicosis. The last two disorders typically present as peripheral precocious puberty or isolated precocious puberty because the onset of puberty is due to a GnRH-independent sex steroid source, but they have the ability to trigger the HPG axis.

Other less common causes of CPP are CNS irradiation and post-traumatic damage. These patients may have simultaneous growth hormone deficiency that is masked by the exaggerated effect on growth that precocious puberty causes. Many CNS diseases, including spina bifida, are associated with earlier puberty, in contrast to most other chronic diseases that, for a variety of reasons, are often associated with delayed puberty. Finally, secondary CPP can arise from any source causing prolonged exposure to sex steroids that leads to accelerated skeletal maturation and sexual development.

### Peripheral Precocious Puberty

Peripheral precocious puberty (PPP) is the earlier onset of puberty instigated by a hormone other than GnRH. As defined in Key Terms, PPP is also referred to as pseudoprecocious and incomplete precocious puberty. It usually develops secondary to autonomous sex steroid secretion of gonadal, adrenal, or ectopic origin. It can also occur owing to an exogenous sex steroid source. Its presentation varies, and it is possible to observe some

or all of the changes of CPP. Importantly, in PPP, LH and FSH levels are low or prepubertal secondary to sex steroid suppression. Finally, there is often some growth acceleration and advanced bone age, but to a lesser degree than in CPP.

#### Differential Diagnosis of Peripheral Precocious Puberty

The differential diagnosis of PPP includes adrenal and gonadal tumors, genetic disorders, other endocrine disorders, and benign ovarian cysts (see Table 30-14). Androgen-secreting adrenal and gonadal tumors can all cause isolated premature pubarche, and they usually function autonomously. Androgen-producing tumors cause progressive and rapid androgen excess and usually cause virilization in females and precocious puberty in males.

Ovarian tumors are relatively uncommon but occur in about 11% of girls with precocious puberty. Granulosa cell tumors constitute 60% of ovarian tumors causing precocious puberty. Other ovarian tumor types are listed in Table 30-14. There is often a palpable abdominal mass along with an estrogen effect, since all these tumors can produce estrogen and androgens autonomously, with consequent breast and pubic hair development. Imaging studies play an important diagnostic role, including ultrasound, computed tomography (CT), and magnetic resonance imaging (MRI). Depending on the suspected lesion, different studies may offer different diagnostic information. Consultation with a pediatric radiologist is advised, and care should be taken to minimize exposure of the gonads to irradiation.

Testicular tumors in males can produce increased androgens and cause precocious puberty. The testis affected is usually larger and firmer and has an irregular consistency. These tumors are typically painless. Testicular tumors presenting as PPP are included in Table 30-14.

Human chorionic gonadotrophin (hCG)-secreting tumors are more common in males and can be associated with the 47,XXY karyotype. Germinomas occurring in the hypothalamus, pineal gland, and mediastinum can secrete hCG and thus stimulate Leydig cell secretion of testosterone in boys, independent of GnRH and LH. hCG-producing tumors can also be present in other tissues, including hepatoblastoma, hepatoma, teratoma, and chorioepithelioma. hCG induces precocious puberty in males by activating LH receptors. However, in females these tumors do not usually cause precocious puberty because LH receptor expression requires FSH stimulation.

Adrenal adenomas and carcinomas can secrete estrogens, androgens, or both. They may also secrete other adrenal hormones, such as glucocorticoids, so that Cushing's syndrome may be part of the presentation. Adrenal tumors are not usually suppressed by dexamethasone, which differentiates them from congenital adrenal hyperplasia (CAH). CAH is an endocrine disorder that occurs secondary to enzyme deficiencies in steroidogenesis. The two variants that typically present as precocious puberty or virilization in adolescents are 21-hydroxylase deficiency and 11 $\beta$ -hydroxylase deficiency. These are autosomal recessive disorders, although a heterozygous state has been described. In males, excessive secretion of testosterone causes precocious puberty, and in females an accumulation of adrenal androgens causes virilization and/or precocious pubarche. In females, some breast development can be seen with virilization. Late-onset CAH accounts for 1% to 5% of the cases that present as androgen excess in females.

**Table 30-15**  
**Clinical Characteristics of McCune-Albright Syndrome**

- Café-au-lait spots (irregular, large macules that do not cross the midline)
- Osteitis fibrosa or cystic bone lesions
- Endocrine abnormalities
  - Precocious puberty
  - Multinodular goiter and other thyroid disorders
  - Pituitary gigantism
  - Amenorrhea-galactorrhea
  - Cushing's syndrome

McCune-Albright syndrome is a heterogeneous entity, predominantly found in females, which is diagnosed clinically and confirmed with imaging studies. The clinical characteristics of the disorder are listed in Table 30-15. When it presents as precocious puberty, it may begin with cyclic vaginal bleeding or as breast development secondary to the presence of large, hormone-secreting ovarian cysts. Precocious puberty usually occurs secondary to autonomous gonadal steroidogenesis, but it can be centrally mediated. The pathophysiology is explained by the autonomous function of tissues in which productivity is regulated by cyclic adenosine monophosphate (cAMP), as a result of a germ line mutation. A subunit of the G protein, linked to the LH receptor, becomes active, and stimulates Leydig cell production of testosterone or granulosa cell production of estradiol. Since McCune-Albright syndrome is the result of a mosaic mutation, its presentation is varied and its transmission sporadic. Precocious puberty can occur at any time from infancy to late childhood. Fertility is typically unaffected, but adult height may be compromised depending on the degree of bone age advancement.

Testotoxicosis, or familial male precocious puberty, occurs in males secondary to a germ line mutation that causes a defect in the transmembrane LH receptor, which triggers cAMP-dependent steroidogenesis. The testes secrete testosterone autonomously, usually beginning in infancy. It usually presents with virilization in preschool-aged or younger boys. There is increased testicular volume and penile and pubic hair growth. Advanced bone age and height velocity can also be seen. Testotoxicosis is inherited in an autosomal dominant pattern, but can also be inherited sporadically.

Ovarian cysts that function autonomously can occur in prepubertal females and cause precocious puberty. These follicular cysts are recurrent in nature. They are frequently associated with McCune-Albright syndrome. The ovarian cysts seen in PPP are usually unilateral, sometimes palpable on examination, and notably larger than 9 mm on ultrasound. This is in contrast to multiple, smaller cysts or follicles found in normal puberty and in GnRH-stimulated CPP. Ovarian cysts can present with early breast development or vaginal bleeding. Estradiol levels are elevated secondary to autonomous ovarian function, but GnRH and gonadotropins are prepubertal, as is bone age and height velocity. With rupture and dissolution of an estrogen-secreting cyst, there is estrogen withdrawal and bleeding.

With profound hypothyroidism, high concentrations of TSH act through the FSH and LH receptors and cause gonadal stimulation because of the similarity in structure of these

## Pediatric and Adolescent Gynecology

pituitary glycoproteins. In females, thelarche or uterine bleeding can be seen. Multiple, large cysts can occur in primary hypothyroidism. In males, macroorchidism is seen without excessive phallic or pubic hair growth. In VanWyck and Grumbach syndrome, hypothyroidism can also be associated with precocious puberty and hyperprolactinemia with secondary galactorrhea in both sexes. Notably, the symptoms of precocious puberty in hypothyroidism occur in the absence of growth acceleration. Skeletal age is typically delayed which differentiates it from true precocious puberty.

Exogenous steroid exposure is another reversible cause of early signs of puberty. The prolonged use of estrogen creams for labial adhesions can sometimes lead to premature breast development. The role of estrogens in the diet has been postulated to play a role in earlier puberty, but this has not been validated. The same is true for estrogen in cosmetics, hair products, and EDCs in the environment.

### **Isolated Precocious Puberty or Incomplete Precocious Puberty**

Incomplete precocious puberty is the isolated appearance of one secondary sex trait. These conditions are typically slowly progressive and benign. They must be followed closely, since they can be the presenting sign of a potentially accelerating process, such as CPP, or early evidence of a CNS or other tumor.

#### **Premature Thelarche**

Premature thelarche is the premature onset of breast development before age 8 years. It can be unilateral or bilateral, and usually there is no darkening or widening of the areola. It is most commonly seen in girls less than 5 years old and predominantly in those less than 2. Breast buds are 2 to 4 cm. Breast tissue can be mildly tender and granular in texture, rather than smooth. Estrogen may be elevated, but gonadotropin response to GnRH is prepubertal, which differentiates it from CPP. The uterus and ovaries are prepubertal, as is the vaginal mucosa. Height velocity is typically normal, bone age is not substantially advanced, and there is no compromise in final adult height.

It is usually transient, but 10% of cases progress to CPP, especially when the age of onset is over 2 years. Evaluation includes careful questions about sources of exogenous estrogen, including pills, patches, or other medications in the household. Initial evaluation includes a bone age and plan for follow-up. Often no intervention is needed. It has been postulated that premature thelarche is caused by a derangement in the maturation of the HPG axis with higher than normal FSH secretion and increased sensitivity peripherally to sex hormones. It is crucial to keep in mind that patients with isolated premature thelarche cannot be differentiated at presentation from those with progressive precocious puberty, and therefore they require close and regular follow-up. These patients may not need referral to a pediatric endocrinologist unless there is advanced radiologic bone age or other signs of more rapidly advancing puberty.

#### **Premature Pubarche (or Premature Adrenarche)**

Premature pubarche is defined as the onset of pubic hair growth before 8 years in girls and 9 years in boys without any other signs of puberty. It is more frequent in girls and it is usually slowly progressive. Premature pubarche is often used interchangeably

with premature adrenarche, which includes other signs of increased androgens: body odor, acne, skin changes, axillary hair, and penile or clitoral enlargement. Pubic hair growth is typically limited to the labia majora or base of the penis and there is only slight, if any, penile or clitoral enlargement. Hormonal changes associated with adrenarche are also found including a slight increase in DHEA, DHEAS, and AND. These are relatively weak androgens, but they are peripherally converted to testosterone. There is no corresponding activation of the HPG axis, and the gonadotropin response to GnRH is prepubertal. There is minimal or no breast or testicular development, but there may be modest accelerated growth and bone age. Prolonged exposure of the CNS to androgens infrequently activates the HPG axis and leads to CPP.

Premature pubarche was originally thought to be a benign condition, but the differential diagnosis includes some of the causes of PPP, including CAH and androgen-secreting tumors of the adrenals or gonads. Recent studies suggest that individuals with isolated premature pubarche have an increased risk of later endocrine pathology. This encompasses the spectrum of hyperandrogenism, including functional ovarian hyperandrogenism, polycystic ovary syndrome (PCOS), and an increased risk of insulin resistance. Ovarian hyperandrogenism is characterized by signs and symptoms of androgen excess and by an exaggerated ovarian 17-hydroxyprogesterone (17-OHP) response to GnRH agonist challenge. A study by Ibanez et al found that girls with premature pubarche are at increased risk for anovulation from late adolescence onward.<sup>26</sup>

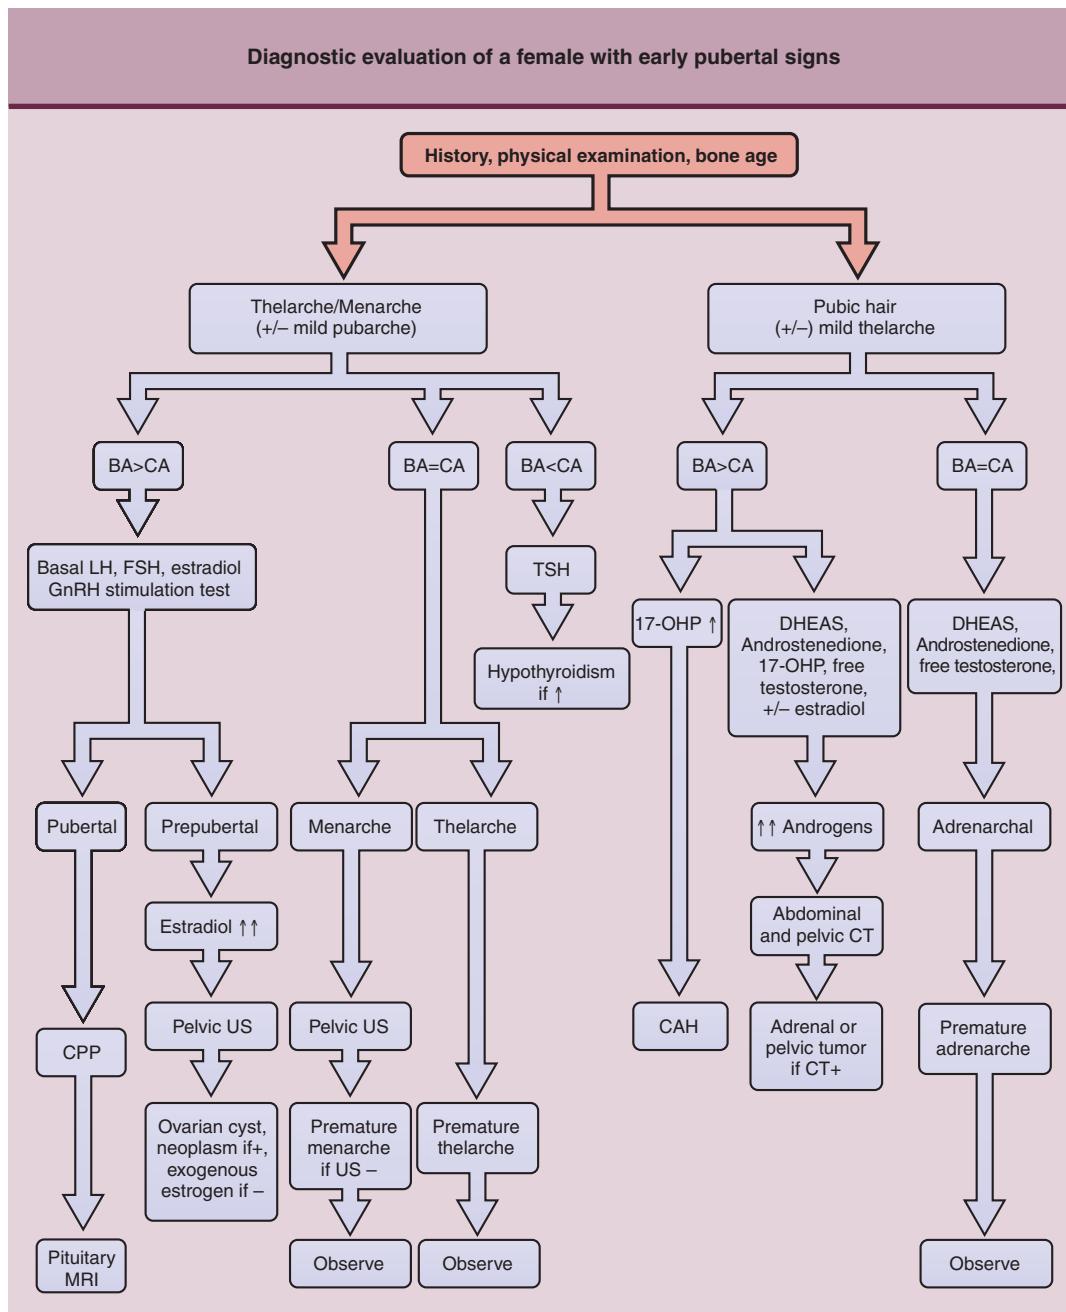

Certain populations appear to be at higher risk for premature pubarche and subsequent endocrine problems, including African American, Caribbean, South American, Native American, and Mediterranean populations and babies born with low birth weight. Hyperandrogenism is seen in a greater proportion of African American and Caribbean Hispanic girls with premature pubarche.<sup>27</sup> A link between fetal growth and adrenarche has been suggested with prenatal growth restriction associated with more pronounced adrenarche.<sup>28</sup>

Thus, premature pubarche in certain cases may be a precursor of insulin resistance, PCOS, and related endocrine abnormalities. The primary care provider's or gynecologist's approach to diagnostic evaluation of these patients, before consultation with a pediatric endocrinologist, includes history, physical examination, bone age, and baseline laboratory testing if the bone age is advanced. A diagnostic flowchart is depicted in Figure 30-9. These patients need to be observed closely in future years and may need referral to pediatric endocrinology and reproductive endocrinology in the future.

#### **Premature Menarche**

Premature menarche in isolation is a rare presentation of precocious puberty that may indicate PPP or isolated precocious puberty. In the prepubertal setting, the new onset of vaginal bleeding is worrisome to the patient and family. It is helpful to determine first whether there is truly blood, and if so, the source of the blood. Many conditions, including those arising from the urethra, skin, and rectum can present with "vaginal bleeding." See Table 30-14 for the differential diagnosis.

True "vaginal" or menstrual bleeding occurs secondary to estrogen stimulation. There are typically other signs of estrogen stimulation, such as breast development and vaginal epithelial

**Figure 30-9 Diagnostic flowchart for girls in the workup of precocious puberty.** Androgens, DHEAS, androstenedione, testosterone; BA, bone age; CA, chronologic age; CAH, congenital adrenal hyperplasia (nonclassical form); CPP, central precocious puberty; CT, computed tomography; DHEAS, dehydroepiandrosterone sulfate; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone; MRI, magnetic resonance imaging; 17OHP, 17 $\alpha$ -hydroxyprogesterone; US, ultrasonography. (Adapted from Root A: Precocious puberty. Pediatr Rev 2000;21:16.)

changes. Less common causes of isolated vaginal bleeding, which are associated with precocious puberty, include ovarian cysts, McCune-Albright syndrome (polyostotic fibrous dysplasia), hypothyroidism, and exogenous estrogen exposure. Ovarian cysts usually occur in isolation but can be associated with McCune-Albright syndrome or hypothyroidism. Following "premature menarche," growth and fertility are usually unimpaired. Most cases of premature menarche require at least one consultation with a pediatric endocrinologist. However, vaginal bleeding

secondary to ovarian cysts can be followed by the primary care provider, with serial ultrasound evaluations every 3 months, and referral if the problem persists.

#### Diagnosis and Evaluation of Precocious Puberty

The initial evaluation of the signs of precocious puberty should take into account the possibility of CNS pathology or hormone-secreting tumors. These warrant immediate referral and evaluation by pediatric subspecialists, possibly including

## Pediatric and Adolescent Gynecology

endocrinologists, neurosurgeons, oncologists, and general surgeons among others.

### History

A detailed history includes the age of onset of symptoms and progression of pubertal development and overall growth, and an in-depth review of any other potentially involved systems.

Past medical history includes any history of past CNS infection, trauma, irradiation, seizures, headaches, or visual changes. Other helpful questions include history of recent weight loss or excessive weight gain, recent history of more rapid or slower growth, changes in energy level or fatigue, recent history of exogenous steroid use, and finally any other symptoms related to hypothyroidism.

Family history should include history of early puberty or pubertal signs especially in the otherwise well child between 6 and 8 years of age. Family history is particularly important in constitutional early puberty, male-limited precocious puberty, CAH, and other inherited conditions, including neurofibromatosis (autosomal dominant, variable penetrance) and tuberous sclerosis (autosomal dominant).

In taking the history, consider that the sequence of development for CPP is similar to normal puberty, but it begins earlier. Therefore, it is helpful to ask about the expected events of normal puberty and the order in which they have occurred so far. Abrupt onset and rapid progression suggest a hormone-secreting lesion. If there is premature thelarche, ask whether neonatal breast development has persisted or regressed and then recurred. The latter indicates a new process.

If vaginal bleeding is the presenting complaint, elicit a detailed description of the bleeding. Bleeding is typically irregular and heavy with ovarian tumors or cysts and with early, anovulatory menstrual cycles. The bleeding may originate from the skin or mucosa, or a different orifice. Factitious bleeding may occur, and "blood" can be confirmed with a simple office test for blood.

Growth charts are central to the diagnosis of precocious puberty. Accelerated growth and advanced skeletal age differentiate CPP from more benign forms. The more rapid the growth rate, the more concerning and the more likely the condition is to be CPP, whereas the growth rate is steady or slow in GnRH-independent categories of precocious puberty. Increased appetite and emotional lability may be seen with an increased estrogen effect.

Questions about urinary symptoms, bowel symptoms, and abdominal pain are critical components of the history. It is important to question the parent or guardian and the child alone about the possibility of sexual abuse in the setting of prepubertal vaginal bleeding. It is common to find that vulvovaginal complaints, including bleeding and discharge, have been treated by providers without an examination of the child. This is not an acceptable practice, and findings need to be evaluated firsthand by a provider.

### Physical Examination

Normal growth parameters, such as height, weight, and BMI, along with percentiles for height, weight, and BMI, are crucial in assessing a child with early onset of puberty. Look at the patient's growth chart and document changes in height, clothes, shoe and hand size as reported by patients and their families. In

younger children, an increase in head circumference can indicate hydrocephalus or other CNS anomalies.

Vital signs can pinpoint particular sources of pathology. An elevated blood pressure may be seen in certain forms of CAH, and heart-rate alterations are observed in a variety of illnesses, such as a decreased resting heart rate in hypothyroidism. Vital signs change through each stage of puberty and adult values are substantially different from prepubertal values.

Examination of the skin offers diagnostic clues. Skin changes to evaluate include acne, oiliness, odor, hair (pubic, axillary, and other), and café-au-lait marks. In neurofibromatosis café-au-lait marks are brown with smooth edges ("coast of California") and typically multiple in number (6 or more). In contrast, café-au-lait spots in McCune-Albright syndrome are larger in size, with irregular borders ("coast of Maine"), and fewer in number (1 or 2).

An eye examination is critical to visualize the optic discs and to evaluate visual fields in assessing for CNS pathology and possible mass effect. With any suspicion of abnormalities in the region of the pituitary or hypothalamus, a sophisticated electronic mapping of visual fields is required. In addition to a comprehensive eye examination, a neurologic examination is important to assess for any CNS abnormalities.

A thorough examination of the thyroid gland is essential. The thyroid is palpated for fullness and nodules. The thyroid becomes transiently fuller during puberty, and it can resemble a truly enlarged gland. Other physical findings related to thyroid disorders are sought, including hair and skin changes, changes in heart rate, and deep tendon reflexes.

The importance of Tanner staging of breasts was discussed earlier, and a complete examination, including palpation, is necessary to differentiate between the irregular, dense consistency of ductal breast tissue and the smoother consistency of subcutaneous fat. Dark pigmentation of the areolae and nipples can suggest ingestion of synthetic estrogens in various forms, such as oral contraceptive pills (OCPs), creams for hair or face, and anabolic steroids. Milky or other secretions from the nipples should be noted as well.

Inspection of external genitalia is equally important to staging of breast development. In females, the clinician assesses if there is an estrogen effect (enlargement of labia minora, thickening of mucosa, dull pink color to vaginal mucosa, and a clear or whitish discharge) and the degree of that effect. In males, measurements of phallic and testicular sizes can be compared to norms. Initially, testicular volume is disproportionately larger than phallic size in normal puberty and CPP; however, in PPP or premature pubarche, phallic size may be greater and testes may be prepubertal in size. If the testes are asymmetrically enlarged, a neoplasm, such as a Leydig cell tumor, is considered.

A vaginal bimanual or speculum examination is often unnecessary and traumatic. An ultrasound examination is more sensitive for assessment of pubertal ovarian pathology, although a small, prepubertal ovary may reveal limited detail. An abdominal examination often identifies a mass, since a pelvic or abdominal mass is palpable in a majority of ovarian tumors.

In cases of premature pubarche it is important to seek out signs of virilization, such as voice change, hirsutism, clitoromegaly or increased phallic size, and an increase in muscle mass. These findings may suggest CAH or an adrenal tumor. In the case of

isolated premature pubarche, confirm the absence of breast development and other signs of estrogen effect. Looking at photos or videos from the past may be an excellent way to compare present and past appearances and body type. Finally, orthopedic history and examination provide information about fractures seen in McCune-Albright syndrome.

### Laboratory Studies

The decision to pursue imaging and laboratory studies is determined by the physical findings and history. A diagnostic flowchart for females is given in Figure 30-9.

The most useful initial test is a radiograph for bone age, which is advised in all categories of precocious puberty, as a minimal diagnostic workup. Bone age can help determine how extensive and urgent further workup should be. There is no consensus on whether to obtain bone age in equivocal cases; however, it is a noninvasive tool with modest cost and minimal risk. It involves taking a left hand and wrist radiograph, which is compared with standard atlases. It is best that the radiologist interpreting a bone age film is trained in pediatric radiology. In the United States the most commonly used reference standard for bone age is the Greulich and Pyle atlas. In the majority of patients who have CPP, the bone age is more than 2 years ahead of the chronologic age, whereas in cases of isolated precocious puberty, the bone age is only slightly advanced. The degree of advanced bone age in the case of PPP depends on the etiology.

Vaginal smears can confirm estrogen stimulation. If a greater percentage of cells are superficial, then there is a greater estrogen effect. Findings of greater than 40% superficial epithelial cells should lead to suspicion of an estrogen-secreting tumor or other source of estrogen.

Other common initial tests may include LH, FSH, estradiol, progesterone, DHEA, DHEAS, thyroid-stimulating hormone (TSH), AND, and free testosterone. More specific tests, depending on the differential diagnostic considerations, include 17-hydroxyprogesterone, a 24-hour free cortisol (if Cushing's syndrome is suspected), an adrenocorticotrophic hormone (ACTH) stimulation test (if CAH is suspected), and a  $\beta$ -hCG (if an hCG-secreting tumor is suspected).

When CAH is strongly suspected, a 17-hydroxyprogesterone level should be obtained, which is best drawn between 7 and 8 AM because of diurnal variations. An ACTH stimulation test is then recommended for those patients with elevated 17-hydroxyprogesterone and adrenal androgens, as well as premature pubarche, with accelerated growth and advanced bone age. Patients with CAH caused by 21-hydroxylase deficiency have elevated 17-hydroxyprogesterone levels that decline with dexamethasone administration. The ACTH stimulation test involves measuring basal concentration and post-ACTH secretory response of the adrenal androgens, progesterone and cortisol. A bolus of 0.25 mg of ACTH is infused intravenously, and serum is sampled at baseline and at 30 or 60 minutes afterward.

Quantification of serum FSH and LH is important in the workup of precocious puberty, but it is not straightforward, as elucidated in Table 30-16. A single random sample is not always helpful.

Interpretation of estradiol, progesterone, and androgen levels also is problematic because of differences in quality control and different laboratory interpretations of normal levels. These

**Table 30-16**  
**Difficulties in Obtaining Random Serum LH and FSH Levels**

- FSH and LH are released in pulses
- Secretion is associated with sleep in early puberty
- Levels vary throughout normal menstrual cycles
- Levels are often prepubertal in the early stages of CPP
- FSH levels are less specific; they can be similar for CPP and isolated premature thelarche
- Assays and laboratories used vary in quality and normal values

CPP, Central precocious puberty; FSH, follicle-stimulating hormone; LH, luteinizing hormone.

levels also change throughout the day, menstrual cycle, and stage of puberty. Therefore, it is important to review normal levels for age and stage of puberty and to know the reference values at the laboratory being utilized. Table 30-17 reviews the normal hormonal levels for males and females through the different stages of puberty.<sup>29</sup>

If there is pubertal development with accelerated growth and advanced bone age, without pubertal FSH and LH levels, and without virilization, then there may be an ovarian source causing these symptoms. A patient with an estradiol level above 100 pg/mL, low gonadotropin levels, and a suppressed GnRH response requires evaluation for an estrogen-secreting tumor. An hCG-producing tumor should also be considered in the diagnosis. An hCG-producing tumor can be confirmed by a quantitative serum immunoassay specific for the  $\beta$  subunit of hCG. In CPP the basal serum concentrations of estradiol may be low (<10 pg/mL) or appropriate for Tanner stage of breast development.

Serum testosterone in males with CPP is appropriate for Tanner stage but is markedly elevated in those with testicular tumors. Testosterone can also be increased in adrenal tumors secondary to direct secretion by the tumor or peripheral conversion that manifests as signs of virilization. Patients with adrenal tumors have significantly elevated DHEA, DHEAS, and AND, which cannot be suppressed by dexamethasone. Feminizing adrenal tumors usually secrete adrenal androgens, with mildly increased estradiol and suppressed FSH and LH. In testotoxicosis, there is a positive family history and mildly enlarged testes on examination (5 to 6 mL), pubertal testosterone levels, and an increase in testosterone after hCG stimulation. GnRH agonist does not typically suppress LH, FSH, or testosterone secretion in testotoxicosis.

The patient's fertility does not need to be evaluated in the workup of precocious puberty since sexual development does not depend on nor does it imply ovulatory capability. Complete sexual precocity, however, can lead to earlier ovulation with potential fertility.

Other studies may include MRI of the brain to exclude CNS structural abnormalities in CPP when the source of hormonal stimulation is not found with other tests. Chalumeau et al have proposed a diagnostic tree to determine which girls with CPP require neuroimaging. They found that independent predictors of CNS pathology were age of onset of puberty less than 6 years and estradiol levels greater than 100 pmol/L.<sup>30</sup>

Pelvic and abdominal ultrasound examination provides a look at ovarian, uterine, and adrenal size, symmetry, and pathology.

**Table 30-17**  
Normal Female and Male Hormonal Levels Through the Stages of Puberty

Tanner Breast Stage	Female					
	LH (IU/L)		FSH (IU/L)		Testosterone (ng/dL)	DHEAS (μg/dL)
	Basal	Post-GnRH	Basal	Post GnRH		
I	0.03 ± 0.03	2.0 ± 1.5	2.16 ± 1.14	21 ± 5.5	0.8 (0.5–2.0)	40 (19–114)
II	0.71 ± 1.04	21 ± 17	3.44 ± 1.58	10 ± 5.0	1.6 (1.0–2.4)	72 (34–129)
III	2.10 ± 2.33		4.88 ± 2.11		2.5 (0.7–6.0)	88 (32–226)

DHEAS, dehydroepiandrosterone sulfate; FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone.

Data from Neely EK, Hintz RL, Wilson DM, et al: Normal ranges for immunochemiluminometric gonadotropin assays. *J Pediatr* 1995;127:40–46. The gonadotropin assays employed in this manuscript are ultrasensitive; the standards were human pituitary luteinizing hormone 80/522 and follicle-stimulating hormone 83/575.

Pelvic ultrasound or other sensitive imaging is needed when a peripheral sex hormonal source is suspected and in girls with vaginal bleeding that cannot be explained by physical examination, such as vaginal or uterine neoplasms. Ultrasound also provides evidence for estrogen effects on the size and maturity of pelvic organs. It is helpful in looking at or differentiating ovarian cysts or tumors. Pelvic ultrasound shows the size of the endometrial stripe or uterine lining and helps assess the risk of uterine bleeding. The uterus is enlarged for age in CPP but should be normal for the stage of puberty. Pelvic ultrasound in prepubertal and pubertal girls may be difficult to read depending on the resolution of the equipment and the skill and familiarity of the technician and radiologist. A bone scan or radiogram may be indicated when McCune-Albright syndrome is suspected.

The definitive diagnostic test for CPP, if suspected, is GnRH stimulation of gonadotropin response. Though the test is performed and interpreted by a pediatric endocrinologist, it is helpful to understand how it is done and when it is indicated (Table 30-18).

One way the test is performed is by administering 100 μg of GnRH subcutaneously and then measuring serum LH and FSH levels 40 minutes after injection. Figure 30-10 shows the serum LH and FSH levels after GnRH infusion. In cases of CPP, the LH rise will be 2 to 3 times higher than the prepubertal response and will greatly surpass the FSH response. Table 30-19 shows the LH/FSH ratio in response to GnRH. Prepubertal LH levels are consistent with PPP or isolated precocious puberty, but in

some cases of early CPP post-GnRH LH values are still in the prepubertal range, and so these lab values need to be interpreted cautiously relative to other clinical and laboratory findings.

### Management and Treatment of Precocious Puberty

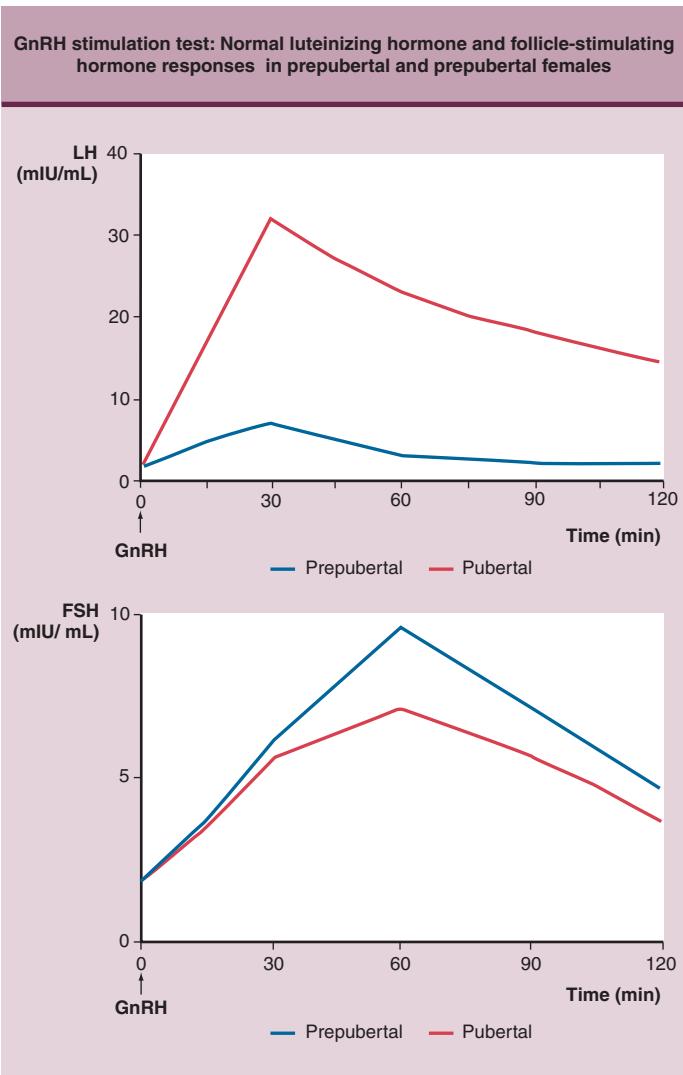

The management of precocious puberty depends on the etiology and diagnosis. Accurate identification of the cause and determination of its significance are crucial in managing precocious puberty of any etiology. In the cases of CPP, PPP, and often premature pubarche, the decisions will usually be made by the pediatric endocrinologist performing the diagnostic evaluation; however, it is helpful to anticipate the treatment options.

### Treatment of Idiopathic Central Precocious Puberty

True precocious puberty is characterized by the activation of the HPG axis, and standard treatment involves suppression of this axis with GnRH analog (GnRHa). Treatment goals include a decrease in the progression of pubertal changes, alleviation of associated behavioral problems, and an increase in linear growth

**Table 30-18**  
Determination of When to Administer a GnRH Stimulation Test

- Early pubertal symptoms consistent with central precocious puberty
- Increased height velocity for age
- Advanced bone age
- Elevated luteinizing hormone and follicle-stimulating hormone levels

**Figure 30-10 Serum LH and FSH levels after GnRH stimulation.**

(From Mansfield JF: Precocious puberty. In Emans SJ, Laufer MR, Goldstein DP [eds]: Pediatric and Adolescent Gynecology, 4th ed. Philadelphia, Lippincott-Raven, 1998, p 116.)

potential. The main long-term complication of idiopathic CPP is compromised final adult height. In deciding who to treat it is important to establish an estimate of a child's projected adult height based on the child's current height and comparing this to mean parental height (MPH). Determination of what a child's final height is likely to be based on MPH is shown in Table 30-20. It is also important to determine the degree of advancement in bone age.

**Table 30-19**  
**LH/FSH Response to GnRH Stimulation**

- Prepubertal: LH/FSH ratio less than 1
- Pubertal: LH/FSH ratio greater than 1

FSH, follicle-stimulating hormone; LH, luteinizing hormone.

**Table 30-20**  
**Calculation of a Child's Final Adult Height Based on Mean Parental Height at 50%**

**Girls**

$[(\text{Mother's} + \text{Father's height})/2] - 2.5 \text{ in. or } 6.5 \text{ cm}$

**Boys**

$[(\text{Mother's} + \text{Father's height})/2] + 2.5 \text{ in. or } 6.5 \text{ cm}$

**Determining Who to Treat**

The approach to treatment differs among pediatric endocrinologists. However, girls less than 7 years old, with secondary sexual development, markedly accelerated growth, and a bone age that is advanced by more than 2 standard deviations are usually treated. Most males with CPP are also treated, since they typically have a markedly advanced bone age and rapidly progressing pubertal development. Girls with less dramatic findings are not consistently treated but may be followed closely by a consulting pediatric endocrinologist. These are typically girls with more slowly advancing sexual maturation, only mildly advanced bone age, and a normal growth rate with good final height potential.

Klein et al found that GnRHa therapy improved the final height in children with rapidly progressing precocious puberty treated before 8 years of age in girls and 9 years in boys.<sup>31</sup> They found that GnRHa-treated girls between 6 and 8 years had a greater average adult height than their pretreatment-predicted height. Certain factors determine the degree of treatment success (Table 30-21).

A more recent study demonstrates that height velocity during GnRHa treatment is inversely related to the degree of prior estrogen exposure. The authors propose that this impaired growth is partly due to premature growth plate senescence caused by earlier estrogen exposure.<sup>32</sup> Other studies have demonstrated that intervening to improve final adult height is not always indicated because often the final effect on adult height is minimal and sometimes there is no difference.<sup>33</sup> However, in those girls who are not treated with GnRHa, close follow-up is critical because occasionally a child with seemingly slowly progressive precocious puberty may experience rapid acceleration of skeletal maturation and be a candidate for treatment. If such girls are not followed closely, the opportunity to treat may be minimized or lost. In 8- to 10-year-old girls with "advanced puberty" characterized by development of secondary sex characteristics, accelerated growth, and advanced bone age (not more than 1.5 years), GnRHa has not proved beneficial in altering final adult height.<sup>34</sup>

**Table 30-21**  
**Factors Determining GnRH-Agonist Treatment Success in Rapidly Progressing Precocious Puberty in Girls Less Than Age 8–9 years**

- Less delay in onset of treatment
- Longer duration of treatment
- Lower chronological age
- Less advanced bone age

Other reasons to treat central precocious puberty include psychosocial or behavioral problems in a younger child with the early development of secondary sexual characteristics. These children and their families may experience undue stress because of the earlier and more rapid rate of pubertal development, and treatment can be beneficial by slowing the pace of pubertal development.

#### Treatment of CPP with GnRHa

GnRHa works by initially stimulating gonadotropin release in the short term, which is then followed by desensitization and down-regulation of gonadotropin membrane GnRH receptors, ultimately leading to a marked decrease in gonadotropin and steroid production. Importantly, it is GnRH's pulsatile secretion that causes secretion of LH and FSH; however, when this pulsatile secretion is changed to a continuous infusion, LH and FSH secretion are suppressed. The same inhibition occurs when long-acting GnRHa is administered by intramuscular injection. As a result of a decline in gonadotropin and estrogen levels, most clinical characteristics of puberty, including accelerated growth and breast development, either regress or cease to progress. However, adrenarche progresses normally, since it is not under GnRH influence.

The treatment of choice, then, for central precocious puberty is GnRHa, and the most common form is depot leuprolide, which typically is administered as a subcutaneous sustained-release injection on a monthly basis. Other GnRH analogs approved for the treatment of CPP in the United States are histrelin and nafarelin. Shorter acting forms of GnRHa have been developed to be administered daily by subcutaneous injection or intranasal inhalation but are not as effective. Suppression of the HPG axis typically occurs 4 to 8 weeks after therapy is started in patients with central precocious puberty. In a few females vaginal bleeding may be seen in the first few weeks after initial treatment, but usually it does not persist.

The dose of GnRHa can be monitored by measuring estradiol levels in females (or testosterone levels in males), with the goal of keeping the sex hormone levels in the prepubertal range. Maintaining estradiol levels in the prepubertal range ensures efficacy of dose and treatment. A GnRH stimulation test and estradiol level is usually performed within the first 3 months after treatment has been started to confirm suppression. They can then be repeated every 6 months, along with bone age. Measurement of height, weight, and Tanner stage occurs regularly during treatment. Growth hormone treatment is sometimes added as supplemental treatment in patients with more substantial loss of growth potential and it has been found to significantly improve adult height in such cases. To date, there have been no reported adverse effects from simultaneous use of GH and GnRHa.<sup>35</sup>

Treatment is usually continued until girls are between 11 and 12 years of age and boys are between 12 and 13. Patients can then continue through puberty with their peers, and their growth potential is close to but does not exceed predicted height.

#### Post-GnRH Treatment Outcomes and Possible Side Effects

Height potential may be lost if therapy is stopped too early or too late, or if a patient only has incomplete suppression of estrogen. For the latter reason, these patients must be monitored regularly or the main purpose of treatment is defeated. After

treatment is stopped, the pubertal process quickly resumes and menstruation usually occurs within 6 to 18 months. Depot preparations of GnRHa therapy are convenient and safe with minor side effects. Hormonal suppression is reversible, with normal future reproductive function and often an improved final adult height. Rarely some patients develop sterile abscesses with IM depot leuprolide. The substitute treatment then becomes daily subcutaneous leuprolide injection.

Treatment with GnRHa has been associated with a decrease in bone mineral density (BMD), with patients treated with GnRHa having a lower BMD for bone age after 2 years of treatment although the BMD was normal for chronologic age.<sup>36</sup> Another study found that the bone age at discontinuation of GnRHa has an effect on final peak bone mass, in that the girls who stop therapy at a bone age of 11.5 have a markedly higher BMD than those who discontinue therapy at a bone age of 12.0 years ( $1.22 \text{ g/cm}^2 \pm 0.10$  and  $1.04 \text{ g/cm}^2 \pm 0.12$ ).<sup>37</sup>

An association has been observed between GnRHa treatment and an increase in BMI, whereas such an increase in BMI is not seen in controls. But this increase is reversible, with BMI equalizing between GnRH-treated and -untreated groups once final adult height is reached.

#### Treatment of Other Causes of Central Precocious Puberty

Determining the treatment of choice for nonidiopathic CPP or other causes of precocious puberty depends on the underlying cause (Table 30-22). Regardless of the cause of CPP, GnRHa may be a short-term treatment recommendation, even if it is given until a CNS lesion is removed. In the case of hypothalamic hamartoma, GnRHa is the therapy of choice.

When precocious puberty is due to testotoxicosis or McCune-Albright syndrome, the patient is referred to a pediatric endocrinologist. The therapeutic goal is to decrease androgen or estrogen production or to inhibit its peripheral effects. Estimation of final adult height is important in deciding treatment options. Various treatments have been tried in testotoxicosis, including cyproterone acetate, ketoconazole, medroxyprogesterone acetate, spironolactone, and aromatase inhibitors (testolactone). Medications used to treat McCune-Albright syndrome have included aromatase inhibitors, ketoconazole, and medroxyprogesterone, with varying rates of success. Most of these medications have helped alleviate vaginal bleeding but have had no affect on improving growth potential. Recently, the selective estrogen receptor modulator used in breast cancer treatment, tamoxifen, has been studied in the treatment of McCune-Albright syndrome with significant success. In one study, tamoxifen proved to be clinically effective in arresting vaginal bleeding, growth acceleration, and pubertal development.<sup>38</sup>

#### Prognosis for Precocious Puberty

The prognosis for precocious puberty depends on the underlying cause. The prognosis for idiopathic CPP is excellent overall. The main adverse outcome is compromised final adult height. The prognosis for the other etiologies of precocious puberty vary (Table 30-23).

#### Psychosocial Impact of Precocious Puberty

There has been no published demonstration to date that precocious puberty is associated with significant psychosocial

problems. Most children with precocious puberty have psychosexual, intellectual, and behavioral maturation in line with their chronological age. Unfortunately, parents, teachers, and peers can have unrealistic expectations of these mature-appearing children. It is therefore important to educate and provide counseling.

**Table 30-22**  
**Treatment of Precocious Puberty**

- I. Central precocious puberty (GnRH-dependent)
  - A. Idiopathic
    - 1. Rapidly progressing (bone age  $\geq 2$  SD above the mean)
      - a. Refer to pediatric endocrinology
      - b. Likely GnRHa analog (GnRHa) and counseling
    - 2. Slowly progressing (less advanced bone age)
      - a. Refer to pediatric endocrinology
      - b. Likely observation\* and counseling
  - B. Hypothalamic hamartoma
    - 1. Refer to neurosurgeon or pediatric neurologist for seizure management
    - 2. Also refer to pediatric endocrinologist if CPP present
      - a. Pedunculated (suspended from floor of third ventricle)—resect when possible
      - b. Not pedunculated
        - i. Treat symptoms
        - ii. GnRHa usually helpful
  - C. CNS pathology
    - 1. Tumor, congenital malformation, genetic, etc.
    - 2. Refer to specialist depending on MRI and laboratory test findings (neurosurgeon, oncologist, genetic specialist, etc.)
  - D. CPP secondary to prolonged elevation of peripheral steroid
    - 1. Refer to specialist depending on source
    - 2. Treat underlying cause
    - 3. Sometimes GnRHa is indicated
- II. Peripheral precocious puberty (GnRH-independent)
  - A. Gonadal tumor—refer to surgery, pediatric endocrinology, gynecology, or oncology
  - B. Adrenal tumor—Same as above
  - C. hCG-secreting tumor—Same as above
  - D. CAH
    - 1. Refer to pediatric endocrinology
    - 2. Possible glucocorticoid therapy and family evaluation
  - E. Ovarian cyst—observe\*
  - F. Testotoxicosis
    - 1. Refer to pediatric endocrinology
    - 2. Inhibit testosterone synthesis
  - G. McCune-Albright syndrome
    - 1. Refer to pediatric endocrinology
    - 2. Inhibit sex steroid synthesis
  - H. Hypothyroidism
    - 1. Refer to or consult with pediatric endocrinology
    - 2. Hormone replacement
  - I. Exogenous steroid source—discontinue exposure
- III. Isolated precocious puberty
  - A. Premature thelarche—observe\*
  - B. Premature adrenarche
    - 1. Observe\* and refer to pediatric endocrinology
    - 2. Long-term follow-up including evaluation of risk factors for future endocrine disease and other health risks
- IV. Premature menarche
  - A. Negative ultrasound (US)—observe\*
  - B. Positive US (cyst)—observe\*†
  - C. Positive US (tumor)—refer to surgery
  - D. Other cause of vaginal bleeding—treat or refer depending on suspected cause

\* Frequency depends on age and rapidity of onset and progression. Initial follow-up recommended in 3 months. If there is evidence of growth velocity acceleration, pediatric endocrine referral is required.

† Recurrence or complication is an indication for consultation.

**Table 30-23**  
**Prognosis for Precocious Puberty Based on Etiology**

- I. Central precocious puberty (GnRH-dependent)
  - A. Idiopathic—excellent prognosis
  - B. CNS lesion—good prognosis if resection is possible, but typically depends on tumor type and histologic features
    - 1. Craniopharyngioma—partial resection and radiation therapy leads to remission for many years in most cases
    - 2. Glioma—worst prognosis
    - 3. Hypothalamic hamartomas—good prognosis
      - a. Slowly growing; treat symptoms
      - b. Often need GnRHa or seizure prophylaxis
  - C. Genetic disorder (neurofibromatosis, etc.)
    - 1. Depends on other CNS or endocrine manifestations
    - 2. Growth potential and reproductive function generally normal
  - D. CPP secondary to a peripheral source—depends on the source
- II. Peripheral precocious puberty
  - A. Adrenal tumor—depends on tumor type
  - B. Ovarian (gonadal) tumor—depends on tumor type
  - C.  $\beta$ -hCG-secreting tumor—depends on type and location
  - D. CAH—good prognosis with glucocorticoid treatment but often adult short stature
  - E. Hypothyroidism
    - 1. Symptoms resolve once hormonal replacement started
    - 2. Good prognosis
  - F. Ovarian cyst—typically resolves on its own
  - G. McCune-Albright syndrome
    - 1. Dependent on other manifestations of the disorder
    - 2. Growth potential may be compromised
    - 3. Reproductive function generally normal
  - H. Testotoxicosis—good prognosis. Boys may be fertile earlier. Growth potential is variable.
  - I. Exogenous sex steroid exposure—symptoms resolve once source is removed
- III. Isolated precocious puberty
  - A. Premature thelarche—excellent prognosis but can evolve into CPP
  - B. Premature adrenarche—possibility of future endocrine disease
- IV. Premature menarche—typically excellent prognosis for normal development

when necessary, for these children and their parents. They need to be informed that they are early, yet normal, developers. Also, there has been little evidence to support an earlier onset of heterosexual activity in children with precocious puberty.

## SUMMARY AND CONTROVERSIES

Puberty is a complex hormonal process, occurring in a specific pattern and manifested by certain clinical, emotional, and developmental characteristics that ultimately result in a sexually mature individual with the ability to procreate. Though trends in the earlier onset of puberty have been informally acknowledged, the widely accepted age of onset of puberty in females has been 8 years old, and an earlier onset has been considered precocious puberty. In response to the large, cross-sectional, practice-based PROS study supported by the AAP, a controversy among endocrinologists and other clinicians has arisen regarding the age-limited definition of precocious puberty. The data from the PROS and NHANES III studies suggest that puberty is beginning earlier than previously thought with a notable difference between ethnic groups. The impact of this data on the diagnosis of precocious puberty is still unfolding. However, it is clear that girls with early signs of puberty may be at increased risk for later

## Pediatric and Adolescent Gynecology

endocrine disease. As a result, clinicians who are evaluating early signs of pubertal development in females should be wary of adhering to strict age limits in defining precocious puberty and approach each case individually.

It would be helpful for a large, prospective, population-based study to support the new guidelines for the evaluation of early pubertal onset. Until that time, the best approach to early or precocious puberty is a thorough history, complete physical examination, and a high level of concern, taking into account the many differential diagnostic possibilities. Utilizing subspecialty consultation is central to proper diagnosis and treatment in most cases. Pediatric endocrinologists are the most usual source of the required expertise. In some communities, specialists in adolescent medicine, pediatric gynecology, and neurosurgery may be available to assist with an initial diagnosis or some aspects of treatment.

### KEY TERMS

**Central precocious puberty (CPP) or true or complete precocious puberty:** early pubertal development that results from premature activation of the hypothalamic-pituitary-gonadal (HPG) axis and is GnRH-dependent.

**Constitutional early puberty:** early pubertal development that occurs in otherwise normal children who have a family history of early pubertal onset.

**Controsexual precocious puberty:** peripheral precocious puberty characterized by female virilization or male feminization.

**Early puberty:** pubertal development that occurs early in relation to traditional norms but is not considered precocious. May or may not occur in families.

**Isolated menstruation or premature menarche:** one or two episodes of isolated vaginal bleeding without other signs of puberty, usually occurring at the beginning of what will be normal pubertal development.

**Isolated precocious puberty or incomplete precocious puberty:** includes premature thelarche and premature pubarche. These are usually self-limited signs, without marked growth acceleration. Isolated precocious puberty can overlap in classification schemes with PPP or be an early sign of CPP.

**Isosexual precocious puberty:** peripheral precocious puberty, which is characterized by sex-concordant secondary sexual development.

**Peripheral precocious puberty (PPP) or pseudoprecocious or incomplete precocious puberty:** early pubertal development that occurs secondary to gonadotropin and/or sex steroid secretion occurring independently of GnRH. PPP can be isosexual or contrasexual.

**Precocious puberty:** a more general term describing early pubertal development that may be an aberration from normal. The term frequently is used before the etiology is determined. It can be GnRH-independent or -dependent.

**Slowly progressive or nonprogressive precocious puberty:** term used by some authors that describes the course of most cases of isolated precocious puberty. The term also overlaps with early puberty and constitutional early puberty. It is usually used to describe a normal variant.

## KEY POINTS

- Delayed puberty is defined as the lack of breast development by the chronologic age of 13 years in girls. Primary amenorrhea is defined as the absence of menses by 15 years of age.
- Girls who enter puberty later than the usual chronologic age most often have constitutional delay of growth and development, and the prognosis is excellent for normal stature and secondary sexual development.
- Constitutional delay of puberty is a benign variation of normal but can be mimicked by chronic disease and difficult to distinguish from causes of primary amenorrhea.
- After a thorough history and physical examination, the next step in the endocrine workup of a teenager with delayed puberty or amenorrhea is determination of gonadotropin, estradiol, and prolactin levels and bone age. Highly sensitive (third-generation) assays must be used for gonadotropin and estradiol determinations.
- Determining the stage of breast development (delayed or immature versus mature) is important in the algorithmic approach to the differential diagnosis and management of delayed puberty and primary amenorrhea.

Breast development (thelarche) is the first sign of true puberty in the vast majority of girls. In approximately 10% of girls, pubic hair development may occur first. The presence of pubic hair without breast development is *not* a sign of true puberty. This situation arises because adrenarche, which contributes to the onset of pubic hair development (pubarche), is an incomplete pseudo-puberty of the adrenal gland, which is gonadotropin-independent. The stages of breast and pubic hair development are shown in Figure 31-1.<sup>1</sup> Tanner stage I is prepubertal. Breast development stage II (B2) is the presence of a palpable subareolar bud. Enlargement and elevation of the whole breast is stage III (B3). Areolar mounding, which is very transient and may not necessarily appear, is stage IV (B4). The final stage, V (B5), is the attainment of mature breast contour. Presexual pubic hairs (stage II, PH2) are short, light, and straight and may not be obvious on cursory examination. Sexual pubic hairs (stage III, PH3) are long, dark, and curly, appearing on the labia majora before spreading to the pubis. Stage IV (PH4) is progression of pubic hair that does not spread to the medial surface of the thighs. The final stage is progression to the mature female escutcheon (inverted triangle pattern, stage V, PH5). Axillary hair usually appears about a year later than pubic hair and passes through similar stages.

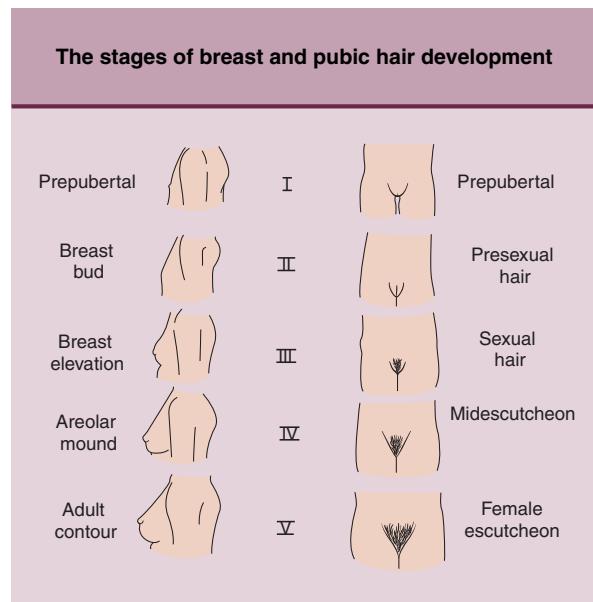

For many years, the estimated onset of pubertal milestones was based on data from standards derived from North American children over 20 years ago.<sup>2,3</sup> Lately there has been considerable debate about whether the age of puberty has become earlier. The Third National Health and Examination Survey (NHANES III) has recently reported data obtained between 1988 and 1994. This study represented the total U.S. population, with intentional oversampling of non-Hispanic blacks (Blacks) and Mexican Americans to increase the reliability of these estimates relative to non-Hispanic whites (Whites). Trained physicians assessed pubic hair and breast stages by inspection in 2145 girls who were 8.0 to 19.0 years of age. Menarche was documented by questionnaire in 2510 girls who were 8.0 to 20.0 years of age. The median age of menarche was 12.43 years for the general population, not significantly different from that in the earlier National Health and Examination Survey (12.8 years). Current estimates are shown in Table 31-1.<sup>4,5</sup> Black girls were significantly earlier than white girls for all pubertal milestones, and Mexican-Americans were intermediate. A separate analysis showed that early sexual maturation was significantly positively associated with overweight and obesity in girls.<sup>6</sup>

## NORMAL PUBERTAL PHYSIOLOGY

The aspects of normal pubertal physiology that are key to understanding disorders of puberty are as follows:<sup>1</sup> (1) Childhood is a state of physiologic gonadotropin-releasing hormone (GnRH) deficiency due to the central nervous system (CNS) restraint that develops during infancy. (2) Pubertal gonadotropin secretion has a diurnal variation, with sleep-associated onset, and is cyclic in girls from the beginning. Luteinizing hormone (LH) levels are more indicative of the degree of pubertal maturation of the neuroendocrine system than are follicle-stimulating hormone (FSH) levels. (3) A certain level of general somatic maturity must normally be reached before the CNS permits pubertal GnRH and gonadotropin production. The bone age (the average age at which a given skeletal maturation begins) correlates with this maturity better than chronologic age, leading to the practical rule of thumb that puberty typically begins at a pubertal bone age (Table 31-2). Bone age is related to pubertal stage with 25% less variance than chronologic age. Height potential can be predicted from the bone age, too. Accurate bone age interpretation requires an experienced reader.

## DEFINITION AND EPIDEMIOLOGY

Puberty is delayed when breast bud development (B2) has not begun by 13.0 years of age.<sup>1</sup> On statistical grounds, this is approximately 2.0 standard deviations (SD) later than average

**Figure 31-1 Stages of breast and pubic hair development.** (From Rosenfield RL: Puberty in the female and its disorders. In Sperling M [ed]: Pediatric Endocrinology, 3rd ed. Philadelphia, W.B. Saunders, 2002, pp 455–518.)

(see Table 31-1).<sup>4,5</sup> Puberty is also considered delayed if it does not progress at a normal tempo, as indicated, for example, by arrested breast development or failure of menses to occur within 4.5 years of the onset of puberty. Typically, the chief complaint is lack of menstruation when girls enter high school at 14 years of age and realize that most of their friends are menstruating. Menarche will be delayed if pubertal onset is delayed; the average time from the onset of breast development to menarche is  $2.3 \pm 1.0$  years, though there is a tendency for the tempo of puberty to be more rapid in those in whom it begins relatively late.<sup>8,9</sup> Primary amenorrhea is defined as the absence of menses by 15 years of age.

## ETIOLOGY

Normal function and interaction of the hypothalamus, pituitary, and ovary, as well as normal development of the genital tract and uterus, are required for appropriate pubertal development and

**Table 31-1**  
Current Estimates for Year of Onset of Pubertal Milestones in Girls in the United States\*

Pubertal Stage	Whites		Blacks	
	Median	(5% to 95%)	Median	(5% to 95%)
Breast buds (B2)	10.4	(8.3–12.5)	9.5	(7.0–12.0)
Pubic hair, presexual (PH2)	10.6	(8.4–12.8)	9.4	(6.8–12.2)
Menarche	12.55	(11.0–14.1)	12.06	(10.1–14.0)

\*Italicized figures are estimated from fitted data.

menses to occur. Delayed puberty results from lack of pubertal maturation of the neuroendocrine-gonadal axis. It may result not only from neuroendocrine or ovarian disorders themselves but from chronic disorders of virtually any organ system because they affect the function of this axis (Table 31-3).<sup>15</sup>

### Constitutional Delay of Pubertal Development

Most commonly, delayed puberty occurs as an extreme variation of normal, which is termed *constitutional delay in growth and pubertal development*. For this discussion, the term constitutional delay of puberty (CDP) is used. CDP occurs in an otherwise healthy child but is eventually normal (Table 31-4).<sup>7</sup> It has familial precedents about half the time.<sup>11-13</sup> Therefore, a family history of delayed puberty is compatible with, but not diagnostic of, constitutional delay. Puberty onset is retarded to about the same extent as bone age and begins at a skeletal age appropriate for puberty, typically approximating 11 years. Although starting late, puberty begins by 16 years of age. When puberty does ensue, it is perfectly normal in tempo, and endocrinologic status is normal for the stage of puberty.

### DIFFERENTIAL DIAGNOSIS

It is important to distinguish CDP from the many disorders that can mimic it. It is most difficult to distinguish it from gonadotropin deficiency. Investigation should be begun for delayed puberty when breast development has not begun by the chronologic age of 13 years or if menses fails to occur within 4.5 years of the onset of puberty.

The evaluation should always begin with a history of current and previous medical problems and their treatment. An algorithmic approach to the differential diagnosis for delayed puberty and primary amenorrhea is dependent on the stage of breast development, as outlined in Figures 31-2 and 31-3, respectively. A girl may present with absent or immature breast development secondary to constitutional delay or primary amenorrhea (see Fig. 31-2), while a girl who has mature breast development may present with absence of menarche secondary to primary amenorrhea (see Fig. 31-3). Once breast development

has matured (B5), the breast contour does not substantially regress even in the absence of ovarian function. Particular focus should be directed at a history of growth retardation (all disorders that retard bone maturation retard the onset and progression of puberty), anosmia (suggestive of congenital gonadotropin deficiency), intracranial or visual symptoms (pituitary mass), radio- or chemotherapy (damage to neuroendocrine-gonadal axis), emotional or eating disorders (anorexia nervosa), and athletic activity (athletic amenorrhea). Use of corticosteroids, opiates, cocaine, or phenothiazine neuroleptics (hyperprolactinemia) can delay puberty.

### CLINICAL FEATURES

Key features of the physical examination are height and weight, with derivation of weight for height age or body mass index (BMI), and growth rate as well as vital signs (hypothermia, bradycardia, hypertension). Short stature is the rule, since the pubertal growth spurt has not occurred, but extreme short stature suggests extraovarian endocrinopathy (such as hypopituitarism, hypothyroidism, and Turner's syndrome).

Weight-for-height is an important clue to eating disorders and chronic disease. In prepubertal girls, undernutrition is defined by weight below the 10th percentile for height age. In pubertal girls, undernutrition should be considered if weight is below the 10th percentile of body fatness for height or BMI less than the 10th percentile. Body fat less than 10% to 15% of body mass is the critical parameter, and this may not be reflected accurately by weight-for-height parameters in athletes who have a disproportionately great muscle mass. Anorexia nervosa is a symptom complex consisting of amenorrhea, voluntary starvation, and a self-delusional disturbance in the perception of body fatness. Body fat determination by dual photon x-ray absorptiometry or bioimpedance monitoring may assist in the documentation of low body fat in girls with eating disorders (anorexia nervosa and bulimia nervosa).

Not only should the physician focus on clues from the history and review of systems, but the examination also should include evaluation of eye movements, visual fields, and optic fundi (for tumor or congenital abnormalities), as well as a search for midline facial defects (for acquired or congenital hypopituitarism). Patients should be evaluated for anosmia, which can be associated with hypogonadism (Kallmann syndrome). Pectoral hypoplasia may be a clue to breast aplasia (Poland's syndrome). Categorization of the stage of sexual development is essential. Careful examination of the introitus, hymen, and clitoris are important to identify the possibility of intersex or pseudointersex disorders.

### Laboratory Evaluation

A chronic disease panel, serum gonadotropins and estradiol, prolactin level, and bone age should be determined initially. It is essential that high-sensitivity ("third generation") assays be used for the FSH, LH, and estradiol determinations, as discussed following, rather than the rapid assays in routine gynecologic use. The latter are often too insensitive and thus too imprecise for this purpose. A chronic disease panel screens for the chronic endocrine, metabolic, and systemic disorders that attenuate or retard growth (Table 31-5).<sup>7</sup>

If the tests for undernutrition and chronic diseases are all negative, then gonadotropins, estradiol, prolactin, and a bone age should be determined. If marked prolactin excess is detected, a brain MRI study for a pituitary adenoma may be consistent with a prolactinoma. Prolactin excess is a potential, but rare, cause of gonadotropin deficiency; hypoestrogenic patients do not manifest galactorrhea. If FSH is not elevated in a prepubertal patient, determination of bone age is important in the interpretation of gonadotropin levels (Table 31-6).<sup>15</sup> If bone age is below 11 years, neuroendocrine puberty may not yet have occurred, in which case premature ovarian failure is not yet hypergonadotropic<sup>15</sup> and the physician must consider both primary and secondary hypogonadism (hypogonadotropic hypogonadism), as well as delayed puberty. Partial ovarian failure is the only other situation in which premature ovarian failure occurs in the presence of normal baseline gonadotropin levels; in these patients, GnRH or GnRH agonist testing will show exaggerated FSH responses.

If FSH is not elevated and the bone age is more than 11 years, proceed to determine the degree of estrogenization. Absence of

breast development ordinarily means lack of estrogen. On the other hand, immature breast development indicates that there has been estrogen exposure, but it does not mean that there is active feminization; estradiol levels are particularly important when there is concern that puberty has begun but has arrested. Diurnal variations must be taken into account in interpreting estradiol and gonadotropin levels in premenarcheal girls. Determination of vaginal hormonal cytology is most indicative of overall estrogen exposure but is not well tolerated by children and adolescents. If a girl with delayed puberty is well estrogenized and has no breast development, she has the rare disorder of breast aplasia; this may be associated with Poland's syndrome (hypoplasia of the pectoral muscles with rib deformities, webbed fingers, and radial nerve aplasia). Otherwise, the breast development is immature.

Daytime estradiol levels below 10 pg/mL, LH levels below 0.15 U/L, and FSH levels below 2.5 U/L are typical of the prepubertal state. However, these values do not rule out the onset of puberty, since they are found in some early pubertal normal children. A plasma estradiol level of 10 pg/mL or greater strongly suggests that puberty has begun, as does an LH level over 0.15 to 0.6 mIU/mL in a "third generation" monoclonal assay.<sup>1</sup> Daytime LH levels between 0.15 and 0.6 mIU/mL are "gray zone" values that suggest the onset of puberty but are not definitive. Estradiol levels of 20 pg/mL and LH levels of 1.0 mIU/mL or greater are clearly indicative of the onset of puberty.

Constitutional delay is the most likely diagnosis until the bone age reaches 13 years (see Table 31-6). If studies to this point show no pathology, the differential diagnosis is between idiopathic gonadotropin deficiency and delayed puberty. This distinction may be difficult. The parameters that help distinguish between gonadotropin deficiency and constitutional delay of puberty are summarized in Table 31-7.<sup>15</sup> Once puberty begins in constitutional delay, it goes to completion.

## Delayed Puberty and Primary Amenorrhea

GnRH testing may permit the differentiation between hypogonadotropic hypogonadism and constitutionally delayed puberty. The GnRH test, measuring the gonadotropin response to a 50- to 100- $\mu$ g bolus, strongly suggests that the delayed puberty is a variation of normal if it elicits a brisk response of LH (7.0 IU/L or more by monoclonal assay). However, the GnRH test has limitations because some normal teenagers have minimal responses and because about one third of hypogonadotropic subjects have clear-cut responses. GnRH agonist testing, using 10  $\mu$ g/kg of leuprolide, may discriminate between these disorders better and adds the dimension of assessing the gonadal secretory response to the secreted gonadotropins.<sup>16</sup> Normal sleep-associated increase of LH secretion into the pubertal range is the most definitive early hormonal evidence of puberty, but has not been proved to necessarily distinguish hypothalamic dysfunction from constitutional delay of puberty.<sup>17</sup> Thus, it may not be possible to definitively establish the diagnosis of gonadotropin deficiency until puberty fails to begin by 16 years of age. MRI of the hypothalamic-pituitary area is an important ancillary measure in the distinction of gonadotropin deficiency from constitutional delay.

Recent evidence suggests that constitutional delay of puberty can be better distinguished biochemically from hypogonadotropic hypogonadism by measuring GnRH-stimulated peak/basal ratio of the free  $\alpha$ -subunit of the glycoprotein hormones.<sup>18</sup> Although this study included only boys and adult men, it is possible that free  $\alpha$ -subunit measurements may improve the distinction between CDP and hypogonadotropic hypogonadism.

Congenital causes of hypogonadotropic hypogonadism are associated with cerebral, hypothalamic, or pituitary dysfunction or as an isolated defect.<sup>1</sup> Gonadotropin deficiency may be congenital or acquired, organic or functional. Congenital defects in hypothalamic-hypophyseal formation may be associated with midline facial defects. Congenital hypothalamic dysfunction may be associated with other neurologic or endocrine dysfunction, such as Prader-Willi syndrome (congenital hypotonia, neonatal failure to thrive followed by hypothalamic obesity, sometimes with hypopituitarism) or Laurence-Moon-Biedl syndrome (short stature, retinitis pigmentosa, obesity, polydactyly, renal anomalies, mental deficiency). Kallmann syndrome is the association of anosmia with gonadotropin deficiency and is less frequent in females than in males (1:5 sex ratio), reflecting the predominance of the X-linked disorder.<sup>19</sup> Mutations in the *KAL1* gene on the pseudoautosomal region of the X chromosome account for half of the X-linked pedigrees, 1% to 5% of sporadic cases.<sup>20,21</sup> The cause in females is unknown. The *KAL1* gene encodes a protein product with cellular adhesion function that is important for normal migration of olfactory nerves and GnRH neurons during development.<sup>22</sup> Eunuchoid body proportions (upper/lower body ratio <0.9 and arm span greater than height by more than 5 cm) is associated with Kallmann syndrome. In addition, there also are associated renal anomalies, cleft palate, dental agenesis, and mirror movements. Special MRI views often demonstrate absence of the olfactory tracts. In 10% of patients with Kallmann syndrome, mutations in the fibroblast growth factor receptor 1 (*FGFR1*, also known as *KAL2*) have been identified.<sup>23</sup> Patients with *FGFR1/KAL2* mutations have typical Kallmann phenotype (hypogonadotropic hypogonadism and anosmia) with or without cleft palate and dental agenesis.<sup>23</sup>

Another genetic cause of gonadotropin deficiency has been associated with autosomal recessive mutations in *PROP1*, a gene important for pituitary development.<sup>24,25</sup> Patients with *PROP1* mutations also have combined pituitary hormone deficiency.

Other causes of gonadotropin deficiency result from defects in the GnRH receptor, LH, FSH, or receptors for LH and FSH. To date, no mutations in the GnRH gene in humans have been identified as a cause for hypogonadotropic hypogonadism. Isolated gonadotropin deficiency arises from GnRH receptor mutations in about half of autosomal recessively inherited cases.<sup>26</sup> The degree of hypogonadism is variable, even within a family, with delayed puberty and delayed menarche as one presentation.<sup>27-29</sup> Isolated hypogonadotropic hypogonadism also has been reported in a woman homozygous for a nonsense mutation of the X-linked *DAX1* gene, which was associated with adrenal insufficiency in her brother.<sup>30</sup> Isolated FSH deficiency caused by mutation in the  $\beta$ -subunit has been reported to cause primary amenorrhea in association with a unique test panel (low FSH, elevated LH, and low testosterone levels by immunoassay.) In contrast, the *LH $\beta$*  gene inactivating point mutation reported in a male was characterized by an elevated serum level of immunoreactive LH but low LH receptor binding activity. To date no mutations in the *LH $\beta$*  gene have been identified in females.

Mutations in a gene encoding a G protein-coupled receptor, GPR54, have been found in patients with idiopathic hypogonadotropic hypogonadism.<sup>31</sup> A GPR54 homozygous mutation was found in six members of a Saudi Arabian family who had hypogonadotropic hypogonadism. A compound heterozygous mutation was identified in a patient with normosomic idiopathic hypogonadotropic hypogonadism. To determine whether these mutations could alter the function of the receptor, wild type and mutant GPR54 constructs were transfected into kidney (COS-7) cells and phosphatidylinositol turnover was measured. Both mutations decreased phosphatidylinositol turnover by 65% to 67% after stimulation with a natural ligand for GPR54. Additional studies showed that the patient with the compound heterozygous mutation had reduced secretion of GnRH as indicated by low-amplitude pulses of LH and a leftward-shifted dose-response curve after intravenous administration of exogenous GnRH. Furthermore, studies in a GPR54-deficient mouse model showed normal responses to exogenous gonadotropins and GnRH, indicating that GPR54 is important for normal secretion of GnRH.<sup>31</sup>

Acquired gonadotropin deficiency may be secondary to a variety of organic CNS disorders, varying from hypothalamic-pituitary tumors (craniopharyngiomas, germinomas, or pituitary adenomas) to irradiation damage to empty sella syndrome. Hyperprolactinemia may be caused by prolactinomas, which secrete excess prolactin, or secondary to interruption of the pituitary stalk by large hypothalamic-pituitary tumors or other types of injury. The latter cause variable pituitary dysfunction, which may include secondary hypothyroidism. Medications, such as neuroleptic agents, can also cause hyperprolactinemia, which can also disrupt secretion of gonadotropins. In addition, infiltrative processes (granulomatous diseases and Langerhans cell histiocytosis) can cause acquired gonadotropin deficiency. Autoimmune hypophysitis is a rare disorder, sometimes accompanying a polyendocrine deficiency syndrome. The

## Pediatric and Adolescent Gynecology

prototypic form of functional gonadotropin deficiency is anorexia nervosa. Idiopathic hypogonadotropic deficiency may sometimes occur in families with anosmia, suggesting a relationship to Kallmann syndrome.

FSH elevation indicates premature ovarian failure (POF). The workup for POF should begin with determination of chromosomes to rule out Turner's syndrome and other forms of gonadal dysgenesis. Patients missing only a small portion of an X chromosome may not have the Turner syndrome phenotype. Indeed, among 45,X patients the classic Turner syndrome phenotype is found in less than one third (with the exception of short stature in 99%).<sup>14</sup> Ovarian function is sufficient for 10% to undergo some spontaneous pubertal development and for 5% to experience menarche.<sup>14</sup> Other chromosomal abnormalities associated with POF include mosaicism (45,X/46,XX) and deletions of the X chromosome.<sup>32,33</sup> Pubertal development and menstruation occur in 12% of 45,X/46,XX individuals. In addition, isolated premature ovarian failure with a genetic basis localized to the X chromosome has been associated with fragile X permutations. Other autosomal genetic disorders causing ovarian failure include trisomy 21, galactosemia, blepharophimosis, and myotonia dystrophica.

If there is no obvious explanation for the hypogonadism, autoimmune oophoritis should be considered. The patient should be assessed for autoimmune endocrinopathy, such as chronic autoimmune thyroiditis, diabetes mellitus, adrenal insufficiency, and hypoparathyroidism. Assays for antiovarian antibodies are not generally available. Rare congenital gene defects should also be considered in such cases. These include 17 $\alpha$ -hydroxylase deficiency, which causes mineralocorticoid excess, classically associated with hypokalemic alkalosis and low renin hypertension, and mutations of the gonadotropins or their receptors. Pelvic ultrasound may demonstrate an absent uterus in intersex but cannot be relied upon to demonstrate hypoplastic ovaries in a girl with delayed puberty. Ovarian biopsy is seldom diagnostically useful, since histology is variable in premature ovarian failure.

Functional ovarian failure can also result from disorders in the ovary. Resistance to gonadotropin action (Savage syndrome) is a rare cause of functional hypogonadism. The ovary is resistant to both endogenous and exogenous gonadotropins. FSH levels are typically elevated and hyperrespond to GnRH testing. Ovarian histology shows a normal number of primordial follicles but a paucity of growing follicles. Certain hereditary defects in the biosynthesis of androgens and estrogens can also cause functional ovarian failure. Enzyme blocks can cause gonadal insufficiency in genetic males who are phenotypic females. This occurs in lipoid congenital adrenal hyperplasia (CAH), 17 $\alpha$ -hydroxylase deficiency, 17,20-lyase deficiency, and 17 $\beta$ -HSD3 deficiency; all but the last two are associated with CAH. Lipoid CAH is unique in that the StAR mutation that underlies most cases has little direct impact on ovarian function, so that genetic females with this disorder can go through puberty, but the enzyme deficiency leads to gradual buildup of intraovarian lipid deposits that cause ovarian damage with late ovarian failure.

### Primary Amenorrhea

As stated earlier, if menarche does not occur by age 15 years or if no menses occur 4 to 5 years after the appearance of breast

development, further workup for causes of primary amenorrhea should be pursued. Girls with extended delay in puberty will have primary amenorrhea. If breast development is immature, the algorithm shown in Figure 31-2 should be used to determine the cause of the delayed puberty.

On the other hand, if breast development is mature the differential diagnosis of primary amenorrhea proceeds according to the algorithm shown in Figure 31-3. As with delayed puberty, patients with primary amenorrhea should also have an initial screening evaluation for undernutrition, chronic diseases, and common endocrinologic disorders that can affect puberty (growth hormone deficiency, thyroid disease, glucocorticoid excess) and for prolactin excess. If initial screening test results are normal, then characterization of the stage of sexual development (pubic hair and external genitalia) is critical for diagnosing some causes of primary amenorrhea (see Fig. 31-3).

If the external genitalia are abnormal, intersex syndromes and structural abnormalities of the reproductive tract should be considered. Patients with intersex syndromes—those whose genitalia are ambiguous or inappropriate for their gonadal sex as a result of endocrinopathy—may come to a physician's attention for the first time at puberty. These syndromes are termed *true hermaphroditism* (if both ovarian and testicular tissue are present), *female pseudohermaphroditism* (if the genotype is female and there are only ovaries), and *male pseudohermaphroditism* (if the genotype is male and there are only testes). Patients with any of these disorders may undergo inappropriate puberty. They may present with clitoromegaly and be found upon examination to have a mild degree of genital ambiguity that was previously overlooked. Virilization beginning at puberty is sometimes the presenting complaint. True hermaphroditism or female pseudohermaphroditism due to CAH is compatible with fertility if treated appropriately. Testicular feminization syndrome may present as primary amenorrhea in an otherwise normal adolescent girl. In about 5% of females operated on for inguinal hernia, a testicular gonad will be found.

If the external genitalia are normal and a screening test for pregnancy is negative, then failure of the onset of menses can result from structural abnormalities of the genital tract that do not have an endocrinologic basis. The vagina may be aplastic or have an imperforate hymen; if the uterus is intact, hydrometrocolpos will occur. This type of structural defect that causes outflow obstruction should be considered if a girl complains of cyclic abdominal pain. The uterus may be congenitally aplastic in the presence of testicular tissue, which secretes antimüllerian hormone as seen in intersex syndromes (congenital deficiency of enzymes necessary for testosterone biosynthesis or metabolism, or androgen-insensitive syndrome/testicular feminization due to a defect in the androgen receptor). Uterine synechiae develop as the consequence of endometritis, which may result from infection or irradiation (Asherman's syndrome). Congenital absence of the vagina may be associated with varying degrees of uterine aplasia; this is the Rokitansky-Küster-Hauser syndrome. This syndrome seems to occur as a single-gene defect or as an acquired teratogenic event involving mesodermal development and the mesonephric kidney, the latter resulting in abnormalities of the genital tract and sometimes the urinary tract. The distal vagina may be normal, with aplasia of the

## Delayed Puberty and Primary Amenorrhea

upper vault, or there may be complete vaginal aplasia. When the vagina is blind and the uterus aplastic, this disorder must be distinguished from androgen resistance and, if the external genitalia are ambiguous, other causes of intersex.

In a girl with normal breast development and normal external genitalia, testosterone levels should be checked to exclude disorders of hyperandrogenism that may cause primary amenorrhea. Plasma total testosterone of a normal sexually mature female is 20 to 70 ng/dL (0.7 to 2.4 nM), and that of a normal adult male is greater than 320 ng/dL ( $>11$  nM). Plasma free testosterone is a more accurate measure of the bioavailable testosterone. If testosterone levels are in the normal female range, then a screening test for pregnancy should be performed. If the patient is not pregnant, then a pelvic ultrasound should be performed to identify structural abnormalities of the genital tract. If testosterone levels are in the male range, androgen resistance should be suspected. Androgen resistance is characterized by a male plasma testosterone level (when sexual maturation has concluded), male karyotype (46,XY), and an absent uterus. External genitalia may be ambiguous (partial form) or normal female phenotype (complete form). If testosterone levels are intermediate or slightly elevated (70 to 320 ng/dL), then causes of hyperandrogenism should be sought, to exclude Cushing's syndrome, nonclassic CAH, virilizing tumors, and polycystic ovary syndrome (PCOS).

### **MANAGEMENT**

Underlying chronic and systemic disorders must be treated appropriately. When pubertal delay or primary amenorrhea is caused by the stress of eating disorders, behavioral modification and psychological counseling are indicated rather than estrogen replacement therapy. Surgical consideration is particularly important in the treatment of genital tract disorders, such as vaginal synechiae that do not lyse spontaneously with estrogenization, vaginal aplasia, or imperforate hymen. Most hypothalamic-pituitary tumors, with the exception of prolactinomas, require surgery with or without radiotherapy.

In the case of managing delayed puberty, two aspects of therapy are uniformly involved: psychological support and hormone administration.<sup>1</sup> Patients with delayed development that is a variation of normal should be reassured that there is nothing wrong, only a delay in timing of the onset of puberty. The wide normal variation in the pattern and time of the pubertal growth spurt should be explained in detail, and the girl should be informed of her predicted eventual height. The majority of children with delayed puberty do not have overt psychological symptoms. Complex compensations and sublimations obviously occur. However, peer group pressures may make adjustment to sexual infantilism especially difficult when the age of 13 is approached, and a poor self-image may lead to social withdrawal and feelings of hopelessness. Physical immaturity may prolong psychological immaturity. The physician should discuss the fact, when the evidence permits, that the odds are overwhelmingly in favor of the "timer in the subconscious area of the brain" eventually turning on. The length of time before this will happen can be approximated from the bone age, since maturation in constitutional delay proceeds at a normal pace. The physician should not hesitate to advise more intensive

psychological counseling if it becomes apparent that the concern about puberty is but one aspect of a more general maladjustment. Ultimately the decision as to whether to undertake treatment for delayed puberty is up to the patient and her family.

It is important to assure the teenager with an organic basis for hypoestrogenism that feminization will occur, although it will require appropriate hormone treatment. There are two caveats. Attainment of normal breast development in the girl with panhypopituitarism requires replacement of growth hormone and cortisol deficits. Also, it is difficult to induce secondary sex characteristics in some patients with systemic chronic inflammatory disease, such as lupus erythematosus.

In patients for whom short stature is a major concern, as in Turner's syndrome, other treatment modalities must be considered before undertaking estrogen replacement. Growth hormone is approved for the treatment of the short stature of Turner's syndrome and improves the adult height potential when started prepubertally.<sup>34</sup> Oxandrolone 0.0625 mg/kg/day does not seem to interfere with the realization of the genetic height potential and is synergistic with growth hormone. It is safest once the bone age reaches approximately 10 years. Clitoromegaly is ordinarily negligible on this dosage.

Some children with delayed puberty benefit from a short (6-month) course of physiologic estrogen treatment to help alleviate their anxieties; however, there are several challenges in using estrogen to induce puberty. First, estrogen should be given to mimic the normal changes in estrogen during puberty, with the intent to allow the patient to experience a normal progression through puberty. Second, since linear growth can be affected by estrogen therapy, careful examination of growth before and during treatment with estrogen is important to achieve the predicted adult height. Third, the bioavailability of oral synthetic estrogens can be variable owing to gastrointestinal absorption and hepatic metabolism. Fourth, delaying estrogen replacement can prevent achievement of normal peak bone mass. Finally, as discussed earlier, estrogen therapy can have a significant impact on socialization, personal development, and other psychological issues in girls with delayed puberty. Overall, estrogen therapy can be beneficial in the treatment of delayed puberty.

To induce puberty, estrogen can be administered orally, intramuscularly, or transdermally. Traditionally, oral synthetic estrogens have been the mainstay of therapy; however, they have potential disadvantages. For example, ethinyl estradiol is an analog of estradiol, the natural estrogen, that is, it has an ethinyl group covalently attached at the 17 $\alpha$  position. This modification prevents metabolism of ethinyl estradiol to estradiol and allows it to bind to the estrogen receptor and be retained in tissues longer. Although oral estrogens are effective at inducing puberty, the commonly used dose of oral estrogens may not be optimal for linear growth. This is because estrogen has been shown to have a biphasic effect on growth, and high doses inhibit growth and the generation of somatomedin C.<sup>35,36</sup>

The authors previously reported the use of intramuscular doses of depot estradiol compared with routine orally administered equine estrogens on linear growth in girls aged 12 to 15 years with Turner's syndrome who had been treated with growth hormone for 6 months or more.<sup>37</sup> After 2 years of

## Pediatric and Adolescent Gynecology

treatment, girls given depot estradiol gained 2.6 cm more in height compared with those treated with routine estrogen. The most effective dose for growth was 0.2 mg to 0.6 mg of depot estradiol given monthly. In a previous study, growth was still achieved with a dose up to 1 mg of depot estradiol given monthly.

Therefore, estrogen replacement therapy can be started at a chronologic age of 12 years with a very low dose of synthetic estradiol to maximize both growth potential and age-appropriate feminization.<sup>37</sup> The authors recommend that a physiologic form of treatment is to begin with intramuscular depot estradiol 0.2 mg/month, which will usually induce breast budding; the dose can safely be increased by 0.2 mg every 6 months. (Midpubertal sex hormone production is approximated by delivering 1.0 to 1.5 mg of estradiol per month, which typically induces menarche within 1 year.<sup>38</sup>) Pubertal development and growth should be monitored every 6 months with bone age determinations at 6-month intervals to determine whether there is appropriate response to therapy.

A reasonable alternative regimen begins with 5 µg ethinyl estradiol (one fourth of the smallest available tablet) by mouth daily for 3 weeks out of 4.<sup>39</sup> Adult replacement doses of estrogen (20 mcg ethinyl estradiol or 0.625 mg conjugated estrogen daily) will stop growth.

One study has shown that estrogen can be administered transdermally to induce puberty. Transdermal estradiol patches have been recently shown to be an effective treatment for delayed puberty in girls aged 12 to 18 years by allowing the achievement of estradiol levels that mimic those seen during the normal onset of puberty.<sup>40</sup> In this study, a matrix patch of 17 $\beta$ -estradiol (25 µg per 24 hours) was cut into quarters (6.2 µg per 24 hours) and attached to the buttock overnight (10 PM to 8 AM). This low dose was used for 4 to 14 months and then increased subsequently to mimic estradiol levels in midpuberty. Breast development was observed 3 to 6 months after starting therapy in the majority of the girls treated. There was good correlation between serum 17 $\beta$ -estradiol levels with the 17 $\beta$ -estradiol patch dose, and the serum levels attained on one eighth (3.1 µg per 24 hours), one sixth (6.2 µg per 24 hours), or one quarter (6.2 µg per 24 hours) of a patch were similar to estradiol concentrations in normal girls undergoing spontaneous early puberty. Approximately 50% of girls on one half of a patch (12.5 µg per 24 hours) to three quarters of a patch (18.8 µg per 24 hours) achieved 17 $\beta$ -estradiol levels within the range for midpuberty. Therefore, low-dose estrogen administered transdermally in fractionated doses by patch seems to be an effective means of inducing puberty in girls with delayed puberty, although linear growth was not examined in this study.

Progestin should be added to estrogenic regimens 1 to 2 years after menarche or when bleeding begins to occur at unpredictable times, indicating endometrial proliferation. A simple regimen is to use 100 mg of natural progesterone (Prometrium) at bedtime for 7 to 14 days during the second to third week of estrogen therapy<sup>1</sup> or equivalent doses of medroxyprogesterone acetate (5 to 10 mg/day) or norethindrone acetate (5 mg/day). This will bring about normal menstruation during the week preceding resumption of estrogen therapy. The addition of progestin will decrease the risk of endometrial hyperplasia and endometrial carcinoma, but increase premenstrual symptoms.

Once optimal height is achieved, most patients can be managed effectively on birth control pills because these doses will halt growth. The pills containing the lowest dose of estrogen that will result in normal menstrual cycles are advisable. The lowest estrogen dosages currently available in the contraceptive pills with third-generation progestins in the United States contain 20 to 30 µg ethinyl estradiol.

After one 6-month course of therapy, it is advisable to wait 6 months for spontaneous puberty to occur if CDP is suspected. In the unlikely event that it does not occur, or if the patient has primary amenorrhea, then treatment depends on the underlying cause of the primary amenorrhea. Patients with gonadotropin deficiency, premature ovarian failure, androgen insensitivity, or XY gonadal dysgenesis will need lifelong estrogen therapy, and progestin should be added as previously discussed. In women with androgen insensitivity, XY gonadal dysgenesis, or uterine aplasia, estrogen replacement is needed but progesterone is not required. Once optimal height is achieved, patients may prefer to take oral contraceptives.

Adolescents with mature breast development and normal external genitalia who have primary amenorrhea first should be given a course of progesterone 100 mg or an equivalent progestin daily for 7 to 10 days. A positive response, withdrawal bleeding beginning a few days after completion of the course of therapy, will occur only if there is adequate estrogenization. This may occur especially if testosterone levels are elevated, as in the case of PCOS. In the perimenarcheal girls who respond well to this, progestin therapy may be repeated in 2- to 3-month cycles in order to detect the emergence of spontaneous menses that signals the resolution of physiologic anovulation of adolescence.

GnRH pulsatile treatment in patients with hypogonadotropic hypogonadism can induce puberty, but this type of therapy is not practical in adolescents and is used more frequently as therapy for infertility in adults.

## SUMMARY

The most common cause of delayed puberty is an extreme variation of normal, termed *constitutional*, delay of pubertal growth and development. Constitutional delay is a benign variation of normal, which is a prolongation of the functional gonadotropin deficiency of childhood. It can be mimicked by chronic disease, however, and can be difficult to distinguish from organic gonadotropin deficiency. In the early teenage years, before the bone age reaches a pubertal level, serum gonadotropin concentrations may not indicate POF. In the later teenage years, MRI imaging of the hypothalamic-pituitary area is a useful ancillary procedure to help distinguish constitutional delay from gonadotropin deficiency. Documentation of sleep augmentation of LH release is the most definitive finding, though imperfect, and gonadotropin responses to GnRH (or GnRH agonist) testing may be useful. Management requires anticipatory guidance and, occasionally, the use of low doses of estrogen that do not interfere with growth.

When there is an extended delay in puberty, or menarche does not occur by age 15, adolescents should be evaluated for causes of primary amenorrhea. Most of these adolescents may have mature breast development, unlike the majority of girls with delayed puberty. The diagnostic workup for CDP and

## Delayed Puberty and Primary Amenorrhea

primary amenorrhea is similar. The treatment options for both CDP and primary amenorrhea are also similar. Overall, exogenous hormone therapy is necessary for normal menstrual cycles, but the impact on future fertility is controversial.

# Chapter 32

# Medical Management of Gynecologic Problems in the Pediatric and Adolescent Patient

Eduardo Lara-Torre, MD, and S. Paige Hertweck, MD

## KEY POINTS

### Gynecologic Examination of the Pediatric and Adolescent Patient

- Perform an overall physical assessment prior to completing a prepubertal genital examination.
- Prepubertal genital anatomy is not estrogenized and therefore is easily traumatized.
- Appropriate examination techniques and positioning assist the examiner in performing a prepubertal genital examination.
- Preventive health care visits for the adolescent should begin between ages 13 and 15.

### Vulvovaginal Dermatologic Conditions in the Pediatric Patient

- Vulvovaginal complaints or concerns are the most common reasons prepubertal girls see the gynecologist.
- The hypoestrogenic state of the prepubertal vulva and vagina predispose young girls to skin conditions of the external genitalia.
- Vulvovaginal conditions range from inflammatory to infectious to manifestations of systemic diseases.
- Many conditions, such as chronic nonspecific vaginitis and labial agglutination, resolve at puberty.

### Hirsutism

- In adolescents, hirsutism may be idiopathic or an early sign of a tumor or a pathologic condition of the ovary or adrenal gland.
- Hirsutism can be the first sign of impending virilization (clitoromegaly, temporal hair recession, deepening of the voice, changes in muscle pattern, breast atrophy).

### Adolescent Contraception

- Refusal to have a pelvic examination at an initial contraceptive visit should not be a barrier to prescribing hormonal contraception to an adolescent.
- An adolescent's selection of birth control should ideally include both a hormonal and a barrier method.
- Use of emergency contraception (EC) decreases risk of pregnancy from 8% to 1–2% after a single episode of unprotected coitus.
- An advance prescription of EC ensures increased use of method over EC counseling alone.

### Dysmenorrhea and Endometriosis

- Adolescents with worsening dysmenorrhea should have a pelvic assessment prior to treatment to rule out an outflow tract obstruction.
- Dysmenorrhea that is unresponsive to use of NSAIDs and OCPs may involve endometriosis.
- Atypical "clear" or "red" endometriotic lesions are common in the adolescent, as opposed to the typical "powderburn" or "chocolate" lesions seen in adults.

## GYNECOLOGIC EXAMINATION OF THE PEDIATRIC AND ADOLESCENT PATIENT

Examination of the external genitalia is a normal part of the routine physical examination. Assessment of the internal genitalia in pediatric patients is indicated in cases of genitourinary complaints or suspected cases of genitourinary pathology (Table 32-1). The proper, nontraumatizing office examination of the child or adolescent provides the gynecologist with the opportunity to establish an adequate relationship with the patient, allowing for the early diagnosis of common conditions found in this age group. Key components of any examination should be covered to the extent allowed by the patient and in no way should be forced

either by the physician or by the parents, since it may prevent successful future gynecologic examinations in these patients.

### Prepubertal Female

The prepubertal examination should focus initially on obtaining the cooperation of the child. Explain what the examination will entail, and allow the child to have a sense of control to enlist their cooperation (e.g., give the child a choice of examination gown to wear). Perform an overall assessment of the child before initiating the genitalia examination.

Inspection of the genital region should follow a focused general examination. Initiating the examination with auscultation of heart and lung sounds will provide an opportunity for

**Table 32-1**  
**Indications for Genital Examination in the Pediatric Patient**

- Vaginal bleeding
- Vaginal discharge
- Vulvar trauma
- Vulvovaginal cystic or solid masses
- Vulvovaginal ulcerative/inflammatory lesions
- Congenital anomalies
- Sexual abuse

the clinician to assess body habitus, hygiene, and presence of skin disorders while allowing the young patient to feel more comfortable in the examination room setting. It is also important to evaluate height and weight percentiles, assess breast development, and perform an abdominal and inguinal examination as part of the comprehensive examination. Once the patient is comfortable with the examiner, the genitalia may be examined.

#### **Positioning the Patient for Examination**

Appropriate positioning is a key component to a successful pediatric gynecologic examination. Multiple positions have been described to allow adequate visualization of the area. In some situations more than one position may be required to adequately visualize the genitalia. The patient's age may determine the best position. The frog leg position is the most commonly used position in the younger patient and allows for the patient to have a direct view of the examiner and herself (Fig. 32-1). As the child grows older, the use of stirrups and the lithotomy position may provide the best visualization of the area. Having the mother hold her daughter on her lap may also be of assistance (Fig. 32-2). The knee-chest position is adjunctively helpful in

some cases in visualizing the lower and upper vagina with the use of an otoscope or other low power magnification.<sup>1</sup> This position may be especially helpful in those patients for whom a vaginal discharge or a foreign body may be a complaint (Figs. 32-3 and 32-4). In certain instances, even the most experienced examiner will be unable to complete the examination or get the patient to comply; in these patients, the emergent nature of the complaint and the clinical consequence of the pathology must be considered. A multivisit examination or an examination under anesthesia may be warranted.

#### **Using Appropriate Examination Techniques**

The examiner must be careful not to cause any trauma or pain in the area, as it will promptly make the patient uncomfortable and possibly end the examination. In the prepubertal female, the unestrogenized nature of the hymeneal tissue makes it sensitive to touch and easily torn. The use of gentle traction with lateral and downward pulling may improve visualization while maintaining the integrity of the normal prepubertal genitalia (Figs. 32-5 through 32-7).

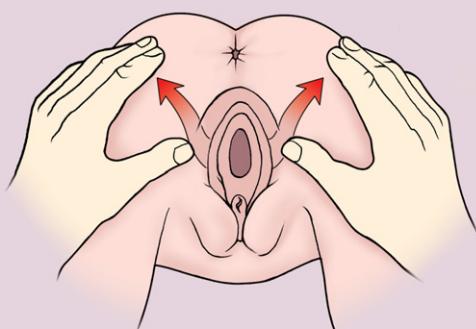

Although the evaluation of the internal pelvic organs may not be easy, the use of a recto-abdominal examination may assist in the palpation of the internal organs as well as possible pelvic

**Child in knee-chest position for genital examination****Labial separation technique for examination of female genitalia**

masses. This part of the examination is particularly important in cases of suspected vaginal foreign body, pubertal aberrancy, or pelvic pain for which the differential diagnosis includes a pelvic mass.

Proper nomenclature of the female genitalia should be used when reporting a pediatric examination to prevent confusion between examiners (Fig. 32-8). Components of such an examination include assessment of pubertal development (Tanner stage), visualization and measurement of the clitoris, and description of the labia majora and minora including any discoloration, pigmentation, or lesion. The urethra and the urethral

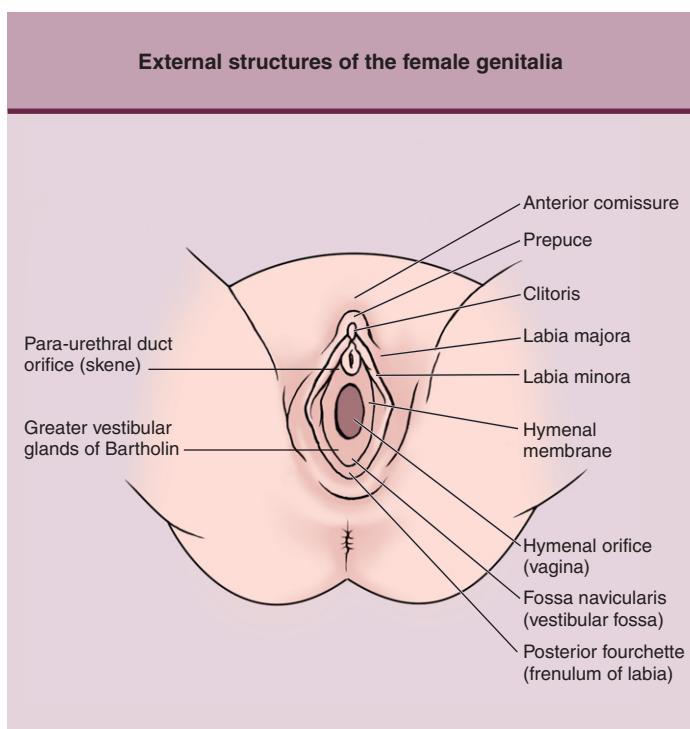

**Figure 32-7 Examples of the techniques of labial separation and lateral traction for viewing the hymen of a prepubertal girl.** (Used with permission from Yordan EE [ed]: The PediGYN Teaching Slide Set. Farmington, Conn, North American Society for Pediatric and Adolescent Gynecology, 1996.)

meatus should also be described. A proper description of the hymen, including type or shape, estrogen status, and abnormalities should be detailed. The prepubertal hymen is thin, red, and unestrogenized. Estrogenization at puberty thickens the hymen and it becomes pale pink and is often more redundant in its configuration. Normal and abnormal variants as well as common hymenal anomalies are shown in Figures 32-9 through 32-16. Other findings including presence of hemangiomas or

**Figure 32-9 Crescentic hymen.** (Used with permission from Perlman SE, Nakajima ST, Hertweck SP: Clinical Protocols in Pediatric and Adolescent Gynecology. London, Parthenon Publishing Group, 2004, p 132.)

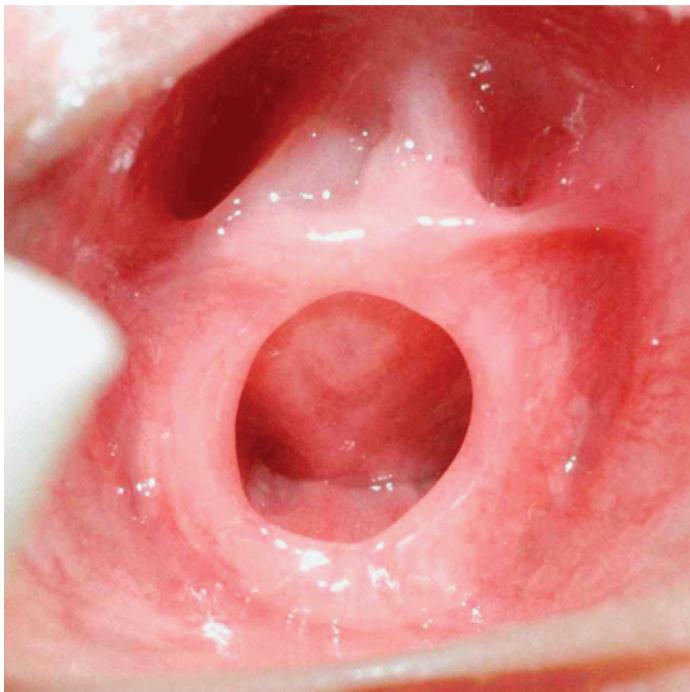

**Figure 32-8 Proper nomenclature of the prepubertal external genitalia.** (Used with permission from Finkel MA, Giardino AP [eds]: Medical Examination of Child Sexual Abuse: A Practical Guide, 2nd ed. Thousand Oaks, Calif, Sage Publications, 2002, pp 46–64.)

other vulvar-vaginal lesions should also be described. If the cervix is visualized in the knee-chest position, it is important to document its appearance.

#### Using Special Techniques to Obtain Specimens

When vaginal specimens for culture must be collected, moistened small Dacron swabs (male urethral size) may be used (Fig. 32-17). The hymenal aperture is small in this age group, and traditional large-sized cotton swabs create discomfort. Another helpful method is a catheter-within-a-catheter technique in which a four-inch intravenous catheter is inserted into the proximal end of a No. 12 red rubber bladder catheter. This is then connected to a fluid-filled syringe passed carefully into the vagina. The fluid is then injected and aspirated multiple times to allow a good mixture of secretions. These specimens may be sent for culture as needed (Fig 32-18).<sup>2</sup>

When suspected foreign bodies need to be flushed from the prepubertal vagina, a pediatric feeding tube connected to a 20-mL syringe may be used to irrigate the contents of the vagina and determine the nature of the foreign object. This can make the need for specula unnecessary in these prepubertal patients who have a small hymenal aperture that would be injured with insertion of a speculum.

**Figure 32-10 Annular hymen.** (Used with permission from Perlman SE, Nakajima ST, Hertweck SP: Clinical Protocols in Pediatric and Adolescent Gynecology. London, Parthenon Publishing Group, 2004, p 132.)

**Figure 32-11 Redundant hymen.** (Used with permission from Perlman SE, Nakajima ST, Hertweck SP: Clinical Protocols in Pediatric and Adolescent Gynecology. London, Parthenon Publishing Group, 2004, p 133.)

#### Documenting the Examination

Genital examinations in prepubertal girls should be documented and each genital structure that was examined listed to aid future examiners who may need previous examination results for the basis of their findings. This is particularly helpful in suspected cases of abuse in which a structure (e.g., the hymen) may have been altered by trauma. Therefore, the physician should document visualization of labia majora, labia minora, hymenal shape or variations (e.g., bumps, clefts) as well as urethral, vaginal, and rectal findings, even if normal. A clock face is helpful in delineating the location of any abnormal findings (Fig. 32-19). Findings and variations should be merely described and, importantly, no diagnostic descriptions should be made in the documentation of the examination. Conclusions (e.g., “an interrupted hymen suggestive of sexual abuse is seen”) should be placed in the impression and plan portion of the documentation.

#### Adolescent Gynecologic Examination

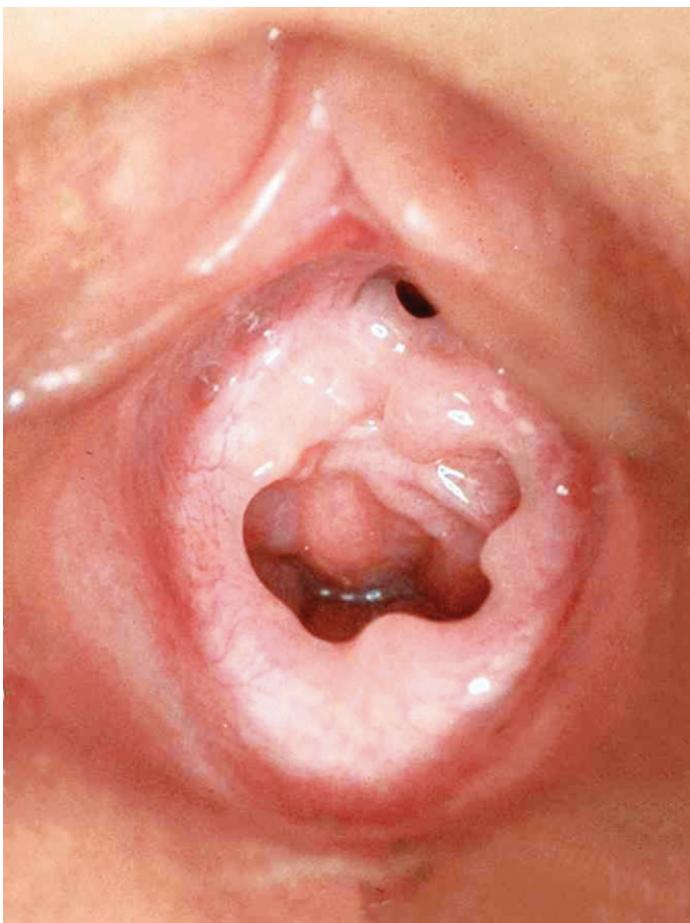

The peripubertal and adolescent patient may present a challenge for the examining practitioner. Although estrogenization may already have occurred, the patient’s self-consciousness about her own body may make the examination even more difficult to perform. Extreme variation in psychosocial and sexual development at this age also contributes to the challenge of an examination. Teens develop at varying rates, for example, some are menarcheal at 10 while others may just be starting their pubertal development at 13; therefore, careful interviewing and counseling should precede an examination. The use of educational videos that explain the examination process and the common reasons why they are done may benefit your interaction with the patient. Delay of the genital examination, even if the patient is sexually active,

may prevent her from having reservations about her examiner. While some teens may like to know and see everything that will happen, some prefer not to look. These preferences should be taken into account to make the experience as nontraumatic as possible.

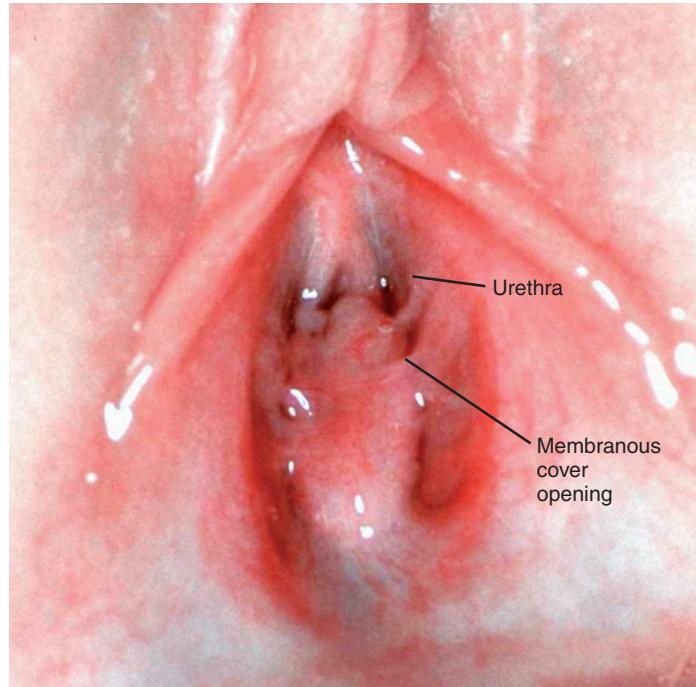

As for other patients, preventive health care should be part of the medical management in this age group. The initial visit to the obstetrician gynecologist should occur between 13 and 15 years of age.<sup>3</sup> During this visit, important components of general health such as immunizations, risk prevention, screening for tobacco and substance abuse, as well as depression and eating disorders should be completed. This visit does not necessarily include a pelvic examination. Table 32-2 lists indications

**Table 32-2**  
**Indications for Pelvic Examination in the Adolescent**

Pubertal aberrancy
Abnormal bleeding
Abdominal/pelvic pain
History of vaginal coitus

## Pediatric and Adolescent Gynecology

for a pelvic examination in the adolescent. After the initial gynecologic evaluation, annual/semiannual visits should be scheduled thereafter. Sexually active teens should be screened for sexually transmitted diseases (STDs) with each new sexual partner.

Adolescents are primarily interested in confidentiality from a consistent provider who will ask the questions that they won't (e.g., about STDs, contraception, acne, weight, menses, how their bodies work, and sexual behaviors such as kissing, petting, intercourse). To facilitate obtaining adequate screening for such issues as well as other risk-taking behaviors, the American College of Obstetricians and Gynecologists (ACOG) Tool Kit for Teen Care has a confidential screening questionnaire to be used at each visit and an adolescent-specific history and physical examination record (Fig 32-20).

With adolescents, if possible, it is important to meet initially with the adolescent/teen and her parents/guardian together to explain the concept of confidentiality and privacy. After both parent and teen have completed an initial history form together, the sensitive/confidential part of the history may be taken alone with the teen (e.g., alcohol, drug, and substance use; dating and sexual history). With sensitive questions, it may be helpful to give a wide range of acceptable answers. For example, "Some teens can talk about sex with their parents; others can't. How do you feel?" Creating a context for questions may be helpful, as in, "A lot of girls your age . . . how do you feel about that?" When screening, begin with less sensitive issues such as safety (e.g., seat belt use) prior to exploring more sensitive ones (e.g., sexuality).

Before completing the initial gynecologic examination, take time to explain the process. In all patients, assess height, weight, blood pressure, and body mass index (BMI). Examination of the neck including a thyroid and lymph node assessment followed by evaluation of skin and breast development should precede the pelvic examination. The external genitalia should be examined, if allowed, in all patients who come in for preventive care, as this will determine the presence of any genital anomalies as well as be the first step toward a pelvic examination. The initial pelvic examination may be delayed, although care should be taken to counsel the sexually active patient about the consequences of nondetection of sexually transmitted infections (STIs) such as asymptomatic chlamydia. Urine screening for STIs should be completed in sexually active teens who choose not to undergo a pelvic examination. Asymptomatic patients who are not sexually active may delay their initial pelvic examination up to the age of 21.<sup>3</sup> Papanicolaou (Pap) testing is required within 3 years of the onset of sexual activity. Annual Pap testing should be considered beginning with the initial visit in patients with multiple partners, who are immunocompromised, and for whom follow-up is unlikely.

The external genitalia should be thoroughly described as for the pediatric patient. Those who require a pelvic examination because of suspected pathology or for annual screening should be properly instructed in the methods used. Proper equipment for this age group should be available. The use of a speculum may be more acceptable in tampon-using adolescents. The use of a pediatric or a Huffman speculum ( $\frac{1}{2}$  in. wide  $\times$  4 in. long) may be of help in those patients not sexually active. A Huffman

or Pederson speculum ( $\frac{7}{8}$  in. wide  $\times$  4 in. long) may be used in patients who are sexually active or use tampons (Fig. 32-21).

Use of the "extinction of stimuli" may be of benefit in those undergoing their first pelvic examination. Using a finger to apply pressure to the perineal area, away from the introitus or thigh, will lessen or diffuse the sensation from the examiner's finger at the introitus. Once a finger has been placed in this area, the insertion of a speculum may be easier and the cervix and vagina can be visualized adequately. Once access to the cervix is gained, screening cervical cytology and cultures may be collected if indicated. A rectovaginal or single-digit bimanual examination should be used to palpate the internal organs. The approach will depend on the patient's preference, tolerance, and sexual history as well as the pathology suspected. All adolescents should be reassured that the examination, while uncomfortable, is not usually painful and will not alter their anatomy. This may reassure those who may believe that the examination will alter their "virginity."

After the examination, it is helpful to meet again with the family and the patient together to explain the examination findings and to plan further management. If confidentiality is a concern in the sexually active teen, first discuss findings with the patient alone while in the examination room. Make a plan together about how to discuss with the parent/guardian before meeting with the family together. Encourage the patient to allow the clinician to be the liaison between her and the family, stressing the benefits of informing everyone of her use of contraception and her situation. Ensure that the adolescent assumes the role of decision maker and help empower her to take charge of her own health care with the guidance and assistance of her parents and health care providers.

## VULVOVAGINAL DERMATOLOGIC CONDITIONS IN THE PEDIATRIC PATIENT

### Vulvovaginitis

#### **Presentation, Etiology, and Risk Factors**

Nonspecific vulvovaginitis accounts for 25% to 75% of the vaginitis seen in this age group.<sup>4</sup> Patients generally complain of vaginal discharge with or without a color or odor, vulvar pain, redness, itching, bleeding, or dysuria. Signs of irritation such as erythema and labial adhesions are seen commonly and may be the sole cause for the consultation. The etiology is unknown, but multiple contributing factors play a role in pathogenesis of the condition (Table 32-3). The use of tight nylon underpants and clothing, close fitting jeans, and leotards may contribute to the irritation and subsequent colonization of the unestrogenized skin. Although some bacteria such as *Bacteroides* and *Peptostreptococcus* have been seen more commonly in these patients, a true relationship has not been proved.<sup>5</sup>

As in adults, vulvitis in children may be caused by the presence of certain bacteria. Respiratory flora (group A *Streptococcus* [Fig. 32-22A and B], *Haemophilus influenzae*), enteric bacteria (*Escherichia coli*, *Shigella*, *Yersinia*), *Candida* (Fig 32-23), STDs, pinworms, and foreign bodies may also present with similar symptoms.<sup>6</sup> In many instances, the appearance of the vulva and the result of the diagnostic workup may be the only source of confirmation.

<b>Relationships</b>		<b>For doctor/nurse use</b>
Are you going out with anyone?	<input type="checkbox"/> Yes <input type="checkbox"/> No	
Who do you find yourself attracted to sexually?	<input type="checkbox"/> Guys <input type="checkbox"/> Girls <input type="checkbox"/> Both	
Have you ever had sex with anyone? If yes, answer the questions in this section below. If no, do you plan to in the next year? When done answering this question, go to the section on tobacco, alcohol, and drugs below.	<input type="checkbox"/> Yes <input type="checkbox"/> No <input type="checkbox"/> Yes <input type="checkbox"/> No <input type="checkbox"/> Not sure	
How many sexual partners do you have now? How many in the past?	Now: _____ Past: _____	
How old were you the first time you had sex (intercourse)?	Age: _____	
Have you ever had sex with a person of your same sex?	<input type="checkbox"/> Yes <input type="checkbox"/> No	
Do you use anything to prevent pregnancy?	<input type="checkbox"/> Yes <input type="checkbox"/> No If yes, what do you use?	
Do you and your partner(s) always use a condom when you have sex?	<input type="checkbox"/> Yes <input type="checkbox"/> No	
Do you ever have sex for money or drugs?	<input type="checkbox"/> Yes <input type="checkbox"/> No	
Are you worried about your parents knowing that you are having sex?	<input type="checkbox"/> Yes <input type="checkbox"/> No	
Do you ever participate in other sexual activities, such as touching or oral or anal sex? If yes, do you use anything to prevent disease?	<input type="checkbox"/> Yes <input type="checkbox"/> No <input type="checkbox"/> Yes <input type="checkbox"/> No If yes, what do you use?	
<b>Tobacco, Alcohol, and Drugs</b>		
Have you or your close friends ever smoked cigarettes or cigars, used snuff, or chewed tobacco?	<input type="checkbox"/> Yes, I have <input type="checkbox"/> No, I haven't <input type="checkbox"/> Yes, friends have <input type="checkbox"/> No, friends haven't	
Have you or your close friends ever gotten drunk on wine, beer, or alcohol?	<input type="checkbox"/> Yes, I have <input type="checkbox"/> No, I haven't <input type="checkbox"/> Yes, friends have <input type="checkbox"/> No, friends haven't	
How much alcohol do you drink at one time?	<input type="checkbox"/> Don't drink <input type="checkbox"/> 1-2 glasses <input type="checkbox"/> 3 or more	
Do you ever drink more than 5 drinks in a row?	<input type="checkbox"/> Don't drink <input type="checkbox"/> Yes <input type="checkbox"/> No	
In the last year, have you been in a car or other motor vehicle when the driver is drunk or has been drinking alcohol or using drugs? (This includes when you were the driver as well as other people.)	<input type="checkbox"/> Yes <input type="checkbox"/> No	
Would you call your parent(s) or guardian(s) for a ride if you were stranded because the person who was supposed to drive you home had been drinking? (This includes when you were the driver as well as other people.)	<input type="checkbox"/> Yes <input type="checkbox"/> No <input type="checkbox"/> Not sure	
Have you or your close friends ever used marijuana or other drugs (like cocaine, heroin, or ecstasy) or sniffed inhalants?	<input type="checkbox"/> Yes, I have <input type="checkbox"/> No, I haven't <input type="checkbox"/> Yes, friends have <input type="checkbox"/> No, friends haven't <input type="checkbox"/> Not sure	
Have you ever used alcohol or drugs so much that you could not remember what happened?	<input type="checkbox"/> Don't use drugs or alcohol <input type="checkbox"/> Yes <input type="checkbox"/> No	
Have you ever missed work or school because of use of alcohol or drugs?	<input type="checkbox"/> Don't use drugs or alcohol <input type="checkbox"/> Yes <input type="checkbox"/> No	
<b>Emotions</b>		
In the past few weeks, have you often felt sad and down or as though you have nothing to look forward to?	<input type="checkbox"/> Yes <input type="checkbox"/> No	
Have you ever seriously thought about killing yourself, made a plan or actually tried to kill yourself?	<input type="checkbox"/> Yes <input type="checkbox"/> No	
During the past year, have you had any major good or bad changes in your life (death of someone close, birth, graduation, significant change in close relationship)?	<input type="checkbox"/> Good <input type="checkbox"/> Bad <input type="checkbox"/> No changes

Problem focused	Limited examination of affected body area or organ system
Expanded problem focused	Limited examination of affected body area or organ system AND other symptomatic or related organ systems
Detailed	Extended examination of affected body area(s) AND other symptomatic or related organ systems
Comprehensive	General multi-system examination OR complete examination of single organ system

A nurse or nursing assistant, depending on staff capabilities and facilities, can complete all shaded areas of the record.

## Pediatric and Adolescent Gynecology

**VIII. Testing Ordered/Performed**

	Tests	Date	Results
General	Cholesterol <sup>1</sup> Lipoprotein profile <sup>2</sup> Tuberculin <sup>3</sup>		
Gynecologic	Cervical cytology <sup>4</sup> Gonorrhea <sup>5</sup> Chlamydia <sup>5</sup> Syphilis <sup>6</sup> HIV <sup>7</sup>		
Other			

<sup>1</sup>Adolescents with parental cholesterol >240 mg/dL should be screened for total blood cholesterol (nonfasting) at least once. Adolescents with either unknown family history, or multiple risk factors may be screened for total serum cholesterol level (nonfasting) at least once.

<sup>2</sup>Adolescents with parent/grandparent with coronary artery disease, peripheral vascular disease, cerebrovascular disease, or sudden cardiac death age <55 should be screened with a fasting lipoprotein profile.

<sup>3</sup>If have been exposed to active tuberculosis; have lived in a homeless shelter, been incarcerated, or lived in another long-term care facility; have lived in endemic area; currently working in health care setting; HIV positive; medically underserved or low-income; have history of alcoholism; have medical risk factors known to increase risk of disease if infected.

<sup>4</sup>Cervical cytology should be obtained no later than 3 years after first intercourse.

<sup>5</sup>Routine screening for chlamydial and gonorrhreal infection should be performed for all sexually active adolescents.

<sup>6</sup>Serologic testing for syphilis should be conducted on sexually active adolescents who have a history of prior STDs, multiple sexual partners, exchanged sex for drugs or money, used illicit drugs, been admitted to jail or other detention facility, lived in an endemic area.

<sup>7</sup>Adolescents with the following risk factors should be offered HIV testing: multiple sexual partners, high-risk partner, prior STDs, exchanges sex for drugs or money, long-term residence or birth in an area with high prevalence of HIV infection, history of blood transfusion prior to 1985, use of intravenous drugs.

**IX. Assessment/Plan**

**Figure 32-20, cont'd ACOG Adolescent Visit Questionnaire and ACOG Adolescent Visit Record.** (Used with permission from American College of Obstetricians and Gynecologists [ACOG]: Tool Kit for Teen Care. Washington, DC, 2003, ©ACOG.)

**Table 32-3**  
**Prepubertal Predisposing Risk Factors for Vaginitis**

**Anatomic**

Lack of labial fat pads and pubic hair  
Thin, sensitive vulvar skin  
Thin, atrophic vaginal epithelium  
Prepubertal hypoestrogenic state of vagina  
Neutral pH of vagina  
Closed proximity of vagina to anus

**Hygienic**

Poor hand washing  
Inadequate cleansing of vulva after voiding or bowel movements  
Exposure to vulvar irritants (e.g., dirt, sand, soaps)

**Infectious**

Upper respiratory infection in past month  
Vulvovaginitis in past year

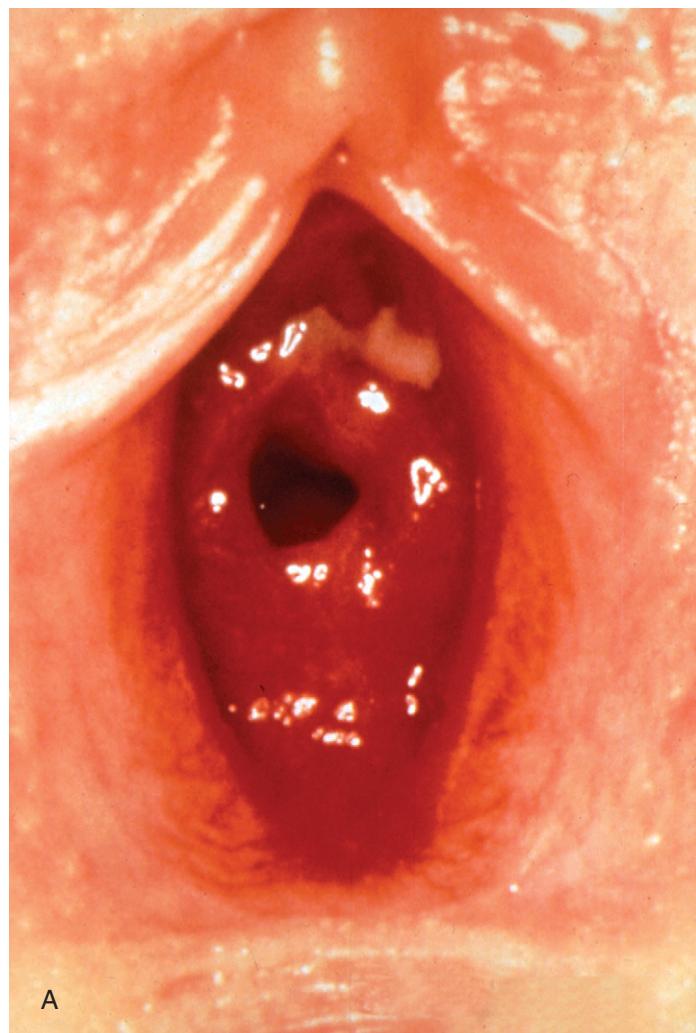

**Diagnosis and Treatment**

The diagnostic approach in these patients should include a complete skin examination to look for other systemic manifestations of disease (e.g., varicella), a complete vulvar examination, and the appropriate use of culture media for the determination of the most common causes. The general treatment of these patients should include hygiene and local measures that prevent the continuing irritation of the area such as sitz baths, discontinuation of the use of chemicals and soaps in the area, cotton underpants, a protective barrier cream (e.g., zinc-oxide-containing diaper-rash creams), and use of laundry detergent free of deodorants or allergenic substances. If a particular infectious agent is identified, the proper antibiotic treatment should be instituted along with the measures listed in Table 32-4.

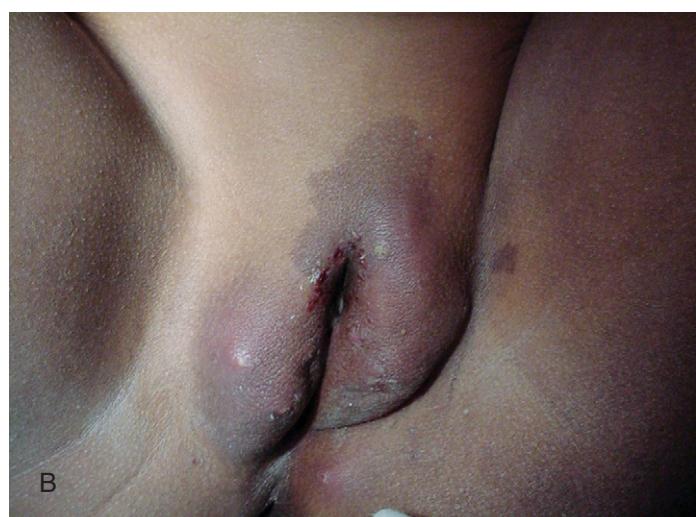

Further investigation may be necessary in patients when conservative management or the appropriate antibiotic does not resolve the symptoms, especially in the presence of purulent discharge or bleeding. Vaginal irrigation or vaginoscopy may be used in determining whether a foreign body or an anatomic lesion is causing the problem (Fig. 32-24). A treatment trial with mebendazole for pinworms or a bedtime dose of antibiotics may be of help if no other causes have been found, although no proof of efficacy is shown in the literature.

**Figure 32-25 Lichen sclerosus in a 5-year-old girl.** (Used with permission from Yordan EE [ed]: The PediGYN Teaching Slide Set. Farmington, Conn, North American Society for Pediatric and Adolescent Gynecology, 1996.)

### Lichen Sclerosus

Other common disorders of the vulva and vagina in this age group are related to primary disorders of the skin. One common condition, lichen sclerosus, may present in this age group with vaginal discharge, itching, and rarely bleeding. The characteristic appearance of the skin disorder (figure-of-eight distribution of parchment-like epithelium often with subepithelial hemorrhages) provides a clue about the etiology, and therefore in most cases a biopsy is not necessary (Fig. 32-25). The etiology of this condition is unknown. The use of hygiene measures is important to prevent scarring and continuing irritation of the area. Prevention of itching with systemic antihistamines may be a choice to decrease the patient's urge to scratch and further decrease scarring. The use of ultrapotent topical steroids (e.g., betamethasone dipropionate 0.05% or clobetasol 0.025% to 0.05% for up to 12 weeks) is the most efficacious treatment. It has even been shown to halt the progression of the disease in children and adolescents.<sup>7</sup> Close surveillance of these children is important to prevent long-term effects of local steroids including epithelial atrophy and telangiectasia. In mild cases, less potent steroids or tapered doses of high-dose topical steroids may also affect the disease positively. Long-term complications of this disease are those associated with scarring prior to treatment and multiple recurrences. In as many as 50% of patients the problem resolves after puberty.<sup>8</sup>

### Vulvar Ulcers

Ulcerative diseases (such as herpes), mononucleosis, and other viral diseases like Coxsackie A16 (hand-foot-and-mouth disease) or varicella may have vulvar presentations in this age group as well. *Behcet's syndrome*, an autoimmune disorder characterized by recurrent genital ulcers, eye lesions, and orocutaneous lesions, may be diagnosed in this age group (Fig. 32-26A and B). Although a viral etiology is suspected, the true origin of the disease is unknown. Therapeutic interventions such as corticosteroids, topical antibiotics, and anesthetics are the mainstay of treatment.

## Medical Management of Gynecologic Problems in the Pediatric and Adolescent Patient

**Labial Adhesions**

Labial adhesions also present commonly in the prepubertal age group, primarily between the ages of 2 months and 6 years of age. These patients are generally seen because their parents have observed the “closed vagina” or they have been referred by their pediatricians because of frequent urinary infections or obstruction of urinary egress. The etiology of this condition is unknown, but chronic irritation along with the hypoestrogenic state of the vulva may predispose to the condition (Fig. 32-27). Most patients do not require treatment given the spontaneous resolution. Also, treatment may not be warranted given the high recurrence rate.<sup>9</sup> On the other hand, those patients with frequent urinary tract infections or urinary obstruction may require intervention. The use of estrogen cream may be efficacious and manual separation under local or general anesthesia may be necessary in the symptomatic patient refractory to medical or conservative management.<sup>10</sup> Recurrences are common, occurring in 25% of cases that have had manual separation.<sup>11</sup>

**Figure 32-27** Labial/vulvar agglutination in a 3-year-old girl. (Used with permission from Yordan EE [ed]: The PediGYN Teaching Slide Set. Farmington, Conn, North American Society for Pediatric and Adolescent Gynecology, 1996.)

**Figure 32-28** Urethral prolapse in a prepubertal girl. (Used with permission from Yordan EE [ed]: The PediGYN Teaching Slide Set. Farmington, Conn, North American Society for Pediatric and Adolescent Gynecology, 1996.)

**Urethral Prolapse**

Urethral prolapse is a common cause of vaginal bleeding in this age group. The classic friable, doughnut-shaped introital mass seen in these children confirms the diagnosis (Fig. 32-28). Pediatric and adolescent gynecologists advocate initial treatment with topical application of estrogen cream, reserving surgical removal for those cases that remain symptomatic and are associated with necrotic tissue.<sup>12,13</sup>

**Genital Neoplasms**

Genital neoplasms may present in this age group and should be able to be recognized by the gynecologist. Hemangiomas of the vulva in general are of no clinical significance and typically resolve spontaneously between 2 and 5 years of age, requiring no further intervention. Large hemangiomas or trauma resulting in active bleeding may warrant careful removal or occlusion of the vessels of these lesions.<sup>14</sup> Sarcoma botryoides, although rare, is a classic pediatric diagnosis in prepubertal patients having a protruding vaginal mass and vaginal bleeding (Fig. 32-29). Primary chemotherapy after initial biopsy allows for excellent tumor control and limits the need for extensive extrirpative surgical procedures while providing 5-year survival rates approaching 85%.<sup>15</sup>

**Inflammatory Vulvar Conditions**

Other less common inflammatory processes of the vulva are also present in this age group such as eczema, seborrheic dermatitis, psoriasis, pemphigus, Stevens-Johnson syndrome, and Crohn’s disease. Pigmentation defects such as vitiligo, acanthosis nigricans, and hyperpigmentation are vulvar manifestations of systemic diseases; the management of these conditions is outside the scope of this chapter.

**HIRSUTISM**

Adolescents with complaints of androgen excess commonly come in with acne and occasionally excessive facial hair growth. Usually what concerns the adolescent the most is the distorted

**Figure 32-29 Sarcoma botryoides (vulvovaginal rhabdomyosarcoma) protruding from the vagina of a 3-year-old girl.** (Used with permission from Yordan EE [ed]: The PediGYN Teaching Slide Set. Farmington, Conn, North American Society for Pediatric and Adolescent Gynecology, 1996.)

self-image associated with these conditions, which necessitates attention, evaluation, and possible treatment.

### Definition

Hirsutism is difficult to define given the interaction of the patient's interpretation of "normal." Hirsutism can be defined as the abnormal excess of terminal hair growth. Multiple causes are associated with this presenting symptom (Table 32-5). To determine the cause of hirsutism, a thorough history should be taken that identifies the speed and timing of hair growth (sudden vs.

long term), as well as the location and other associated androgenic symptoms including clitoromegaly, acne, and male baldness or voice deepening. The characteristics of menses as well as the use of medications (phenytoin) should be investigated to determine other conditions likely to cause hair growth and androgenization. Girls with low birth weight and a history of precocious pubarche in childhood are at high risk of polycystic ovary syndrome (PCOS) in adolescence.<sup>16</sup>

### Diagnosis

The physical examination should focus on anatomic as well as hormonal causes for androgen excess. Assessment of the thyroid, abdomen, and pelvis should be a part of the examination. Stigmata of Cushing's or hyperinsulinemia (e.g., acanthosis nigricans—darkly pigmented, velvety skin at the nape of the neck, axilla, waist) can sometimes be helpful in determining the source of the androgenic state, and the presence of a pelvic-abdominal mass could point toward an androgen-secreting tumor. Adequately documenting the amount and distribution of the hair can be used to standardize the classification of these patients and aids in determining progress after treatment initiation (Fig. 32-30A and B). The presence of clitoromegaly (clitoral glans >5 mm in diameter) should be documented.

The laboratory examination will assist in determining the cause of the hirsutism. While the presence of oligomenorrhea and long-standing hirsutism (>1 year) suggests PCOS, the menstrual history in the adolescent is limited to only a few years. The presentation of virilization or rapid-onset or exacerbation hirsutism may be a sign of significant pathology and requires initial laboratory evaluation.

Assessment of serum levels of testosterone, free testosterone and dehydroepiandrosterone sulfate (DHEAS) is the best initial approach. Some patients may have an increased sensitivity to free testosterone, and even though the total amount is normal, the free component is elevated and is the cause of the hirsutism.<sup>17</sup> The presence of oligomenorrhea or amenorrhea may warrant evaluation of other conditions, and thyroid-stimulating hormone (TSH), follicle-stimulating hormone (FSH), human chorionic gonadotropin (hCG), and prolactin levels should be assessed. Levels of total testosterone higher than 200 ng/dL and of DHEAS above 700 µg/dL suggest the presence of an ovarian or adrenal tumor, respectively. Screen for late-onset congenital adrenal hyperplasia (CAH) with a 7 to 8 AM 17-hydroxyprogesterone (17-OHP) level. 17-OHP levels above 200 ng/dL have an 80% positive predictive value and 100% negative predictive value for 21-hydroxylase deficiency. If the level is greater than 1000 ng/dL, the diagnosis of late-onset CAH can be made without further testing.<sup>18</sup> In those patients with a mild elevation of 17-OHP, a modified ACTH stimulation test, using 0.25 mg of ACTH and measuring base-line and 60-minute levels of 17-OHP, is indicated to make the diagnosis. Levels higher than 1000 ng/dL and usually above 1500 ng/dL are seen.<sup>19</sup>

Some patients with PCOS may have a metabolic syndrome of hyperinsulinemia, abnormal glucose utilization, and abnormal lipid profiles. Consider screening these patients with a fasting lipid profile and glucose tolerance testing.

In the hirsute patient, the presence of a pelvic mass must be considered. In cases where an abdominopelvic examination is not definitive or laboratory tests indicate androgen-secreting

**Table 32-5  
Causes of Hirsutism in Adolescents**

Ovarian disorders
Polycystic ovary syndrome (PCOS)
Hyperthecosis
Tumors
Enzyme deficiency (e.g., 17-ketosteroid reductase deficiency)
Adrenal disorders
Congenital adrenal hyperplasia (21-hydroxylase, 11 $\beta$ -hydroxylase, 3 $\beta$ -hydroxysteroid dehydrogenase deficiencies)
Cushing's disease

## Medical Management of Gynecologic Problems in the Pediatric and Adolescent Patient

Site*	Grade	Definition
1. Upper Lip	1	A few hairs at outer margin
	2	A small moustache at outer margin
	3	A moustache extending halfway from outer margin
2. Chin	4	A moustache extending to midline
	1	A few scattered hairs
	2	Scattered hairs with small concentrations
3. Chest	3 & 4	Complete cover, light and heavy
	1	Circumareolar hairs
	2	With midline hair in addition
4. Upper back	3	Fusion of these areas, with three-quarters covered
	4	Complete cover
	1	A few scattered hairs
5. Lower back	2	Rather more hair, still scattered
	3	Complete cover, light and heavy
	4	A sacral tuft of hair
6. Upper abdomen	1	With some lateral extension
	2	Three-quarters covered
	3	Complete cover
7. Lower abdomen	1	A few midline hairs
	2	Rather more, still midline
	3	Half and full cover
8. Arm	4	A midline streak of hair
	1	A midline band of hair
	2	An inverted V-shaped growth
9. Forearm	3 & 4	Sparse growth affecting not more than a quarter of the limb surface
	1, 2, 3, 4	More than a quarter of the limb surface affected
	3 & 4	Complete cover, light and heavy
10. Thigh	1, 2, 3, 4	Complete cover of dorsal surface; 2 grades of light and 2 of heavy growth
	1, 2, 3, 4	As for arm
11. Leg	1, 2, 3, 4	As for arm

**A**

\*Grade 0 at all sites indicates absence of terminal hair.

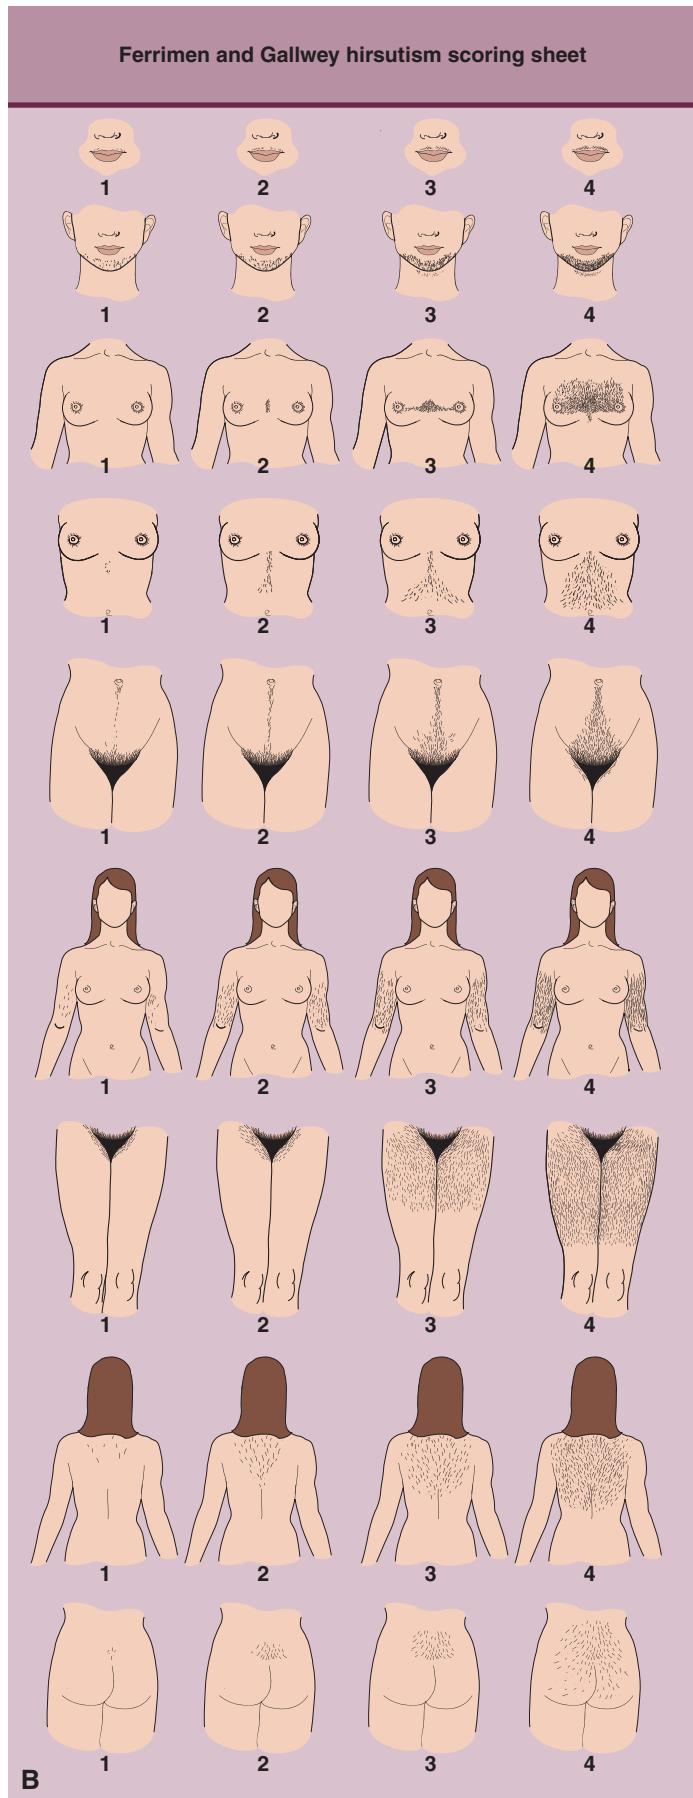

**Figure 32-30 Hirsutism scoring sheet.** A and B, The Ferriman and Gallwey system for scoring hirsutism. A score of 8 or more indicates hirsutism. (Used with permission from Hatch R, Rosenfield RL, Kim MH, et al: Hirsutism: implications, etiology and management. Am J Obstet Gynecol 1981;149:815. Adapted from Ferriman D, Gallwey JD: Clinical assessment of body hair growth in women. J Clin Endocrinol Metab 1961;21:1440. B, Copyright 1961, The Endocrine Society.)

tumors, ultrasound imaging can detect ovarian masses and magnetic resonance imaging (MRI) can identify an adrenal tumor. Patients may also have idiopathic hirsutism (15%) characterized by regular ovulatory cycles and excess hair growth. This is a common diagnosis but one of exclusion.

### Treatment

The treatment of hirsutism is approached on two fronts. One is suppression of the androgen-producing entity and aims to decrease the amount of circulating androgens (surgery, medication). The other looks at the cosmetic component of the treatment, aiming to improve the appearance and confidence of the patient.

The surgical removal of androgen-producing tumors will diminish the amount of circulating androgens, but cosmetic help may still be needed. Medical management of hirsutism is more commonly used for non-neoplastic conditions and includes androgen suppression agents and peripherally acting agents.

### **Management of Excess Ovarian Androgen Production**

Combination estrogen/progestin oral contraceptive pills (OCPs) are commonly used to treat hirsutism. Their mechanism of action is the associated increased levels of circulating sex hormone-binding globulin (SHBG) and suppressed ovarian androgen production that effectively decreases circulating unbound androgens. Generally 50% to 70% of patients improve with this treatment alone. Patients should be aware that this treatment primarily prevents future hair development and the existing hair may need to be cosmetically treated or removed. Gonadotropin-releasing hormone (GnRH) agonists may be used in cases of severe hirsutism refractory to conventional treatment. They function by suppressing luteinizing hormone (LH) levels and thereby ovarian androgen production.<sup>20</sup> Hormonal replacement in the form of norethindrone acetate is helpful in diminishing unwanted side effects such as hot flashes and decreased bone mineral density associated with GnRH agonist use.

Insulin-sensitizing agents, such as metformin, have been shown in adult women to decrease the amount of circulating androgens while improving other metabolic aspects of PCOS.<sup>21</sup>

Initial studies suggest that metformin may be useful in treating PCOS in the obese adolescent with insulin resistance; however, additional studies are needed to determine efficacy and long-term outcome.<sup>22</sup>

Recently, the use of metformin soon after menarche in a group of girls at high risk for PCOS (e.g., history of low birth weight and precocious pubarche) was shown to prevent progression to PCOS.<sup>23</sup> Although metformin monotherapy failed to fully normalize central fat masses, serum androgens, and SHBG, these might be further normalized by addition of an androgen-receptor blocker. Another pilot study has reported that low-dose flutamide (125 mg/day) with metformin improved body shape and body composition by decreasing central fat deposition without implementing any changes in diet, exercise, or lifestyle and without changing total body weight in nonobese adolescents with ovarian hyperandrogenism.<sup>24</sup>

These results indicate that the excess central fat in women with hyperinsulinemic hyperandrogenism is a consequence, rather than a cause, of their endocrine-metabolic state.

### **Management of Excess Adrenal Androgen Production**

The use of dexamethasone, although reported in the literature, has not been consistently shown to improve hirsutism. While steroids may be used in cases associated with CAH<sup>25</sup> its use is associated with osteoporosis. Since adolescents are accruing their peak bone mass in the teen years, more conservative methods of treatment (i.e., OCP use) are more commonly utilized.

### **Management Directed at Hair Follicle**

Peripheral suppression agents are commonly used to manage unwanted hair growth. Spironolactone, an aldosterone antagonist, is widely used in adults and adolescents and reported to be efficacious by binding to and blocking the androgen receptor in target tissues and by reducing androgen biosynthesis. Common dosage for this purpose is between 100 and 200 mg per day divided into two doses, and it generally can be added to the OCP regimen to improve the efficacy of both.<sup>26</sup> Cyproterone acetate, another antiandrogen similar in function to spironolactone but not available in the United States, has proved as efficacious as

the combination of OCP and spironolactone.<sup>27</sup> The use of less commonly prescribed agents like finasteride, flutamide, and ketoconazole is limited by their side effects. A recent prospective randomized trial of the use of spironolactone, finasteride, and cyproterone acetate along with a combination OCP to treat idiopathic hirsutism in adults showed improvement rates to be similar at 12 months. At 1-year follow-up, the spironolactone group showed the most improvement.<sup>28</sup>

The cosmetic aspects of these patients may also be addressed in the form of laser therapy, electrolysis, bleaching, shaving, plucking, waxing, and depilatories for temporary hair removal. Topical treatment with eflornithine cream may also diminish unwanted hair.<sup>29</sup> Weight reduction to decrease the peripheral conversion of androstenedione and to increase the effective amount of SHBG may improve the hirsutism as would smoking cessation.<sup>30</sup>

## **ADOLESCENT CONTRACEPTION**

Teen pregnancy remains a major problem in the United States. Despite the fact that the rate of sexual activity among American teens is not different from that of other industrialized nations, the United States has the highest rate of teen pregnancy of any developed nation, a rate that is 50% higher than pregnancy rates in Europe and Canada.<sup>31</sup> For this reason, the use of appropriate contraception is especially important in this age group. As adolescents mature and become capable of reproduction, visits to their practitioner should include counseling on adequate methods of birth control targeting their needs and abilities to improve their compliance. Providing this information does not result in increased rates of sexual activity, earlier age of first intercourse, or greater number of sexual partners. On the contrary, when adolescents perceive that there is an obstacle to obtaining contraception, they are more likely to experience negative outcomes related to sexual activity.<sup>32</sup> Many factors play a role in adolescent contraception either motivating or inhibiting the teen from contraception (Table 32-6). One significant reason that adolescents hesitate or delay in obtaining family planning services or contraception is concern about confidentiality. While many states allow teens to consent to contraception without parental consent, health care providers need to be familiar with current state and local statutes on the rights of minors to

**Table 32-6**  
**Motivating and Nonmotivating Factors for Adolescent Contraception**

#### **Motivating factors**

- Perceiving pregnancy as a negative outcome
- Having long-term educational goals
- Being of older age
- Experiencing a pregnancy scare or actual pregnancy
- Having family, friends, or a clinician who approves of the use of contraception

#### **Nonmotivating factors**

- Lack of parental monitoring
- Fear that parents will find out
- Ambivalence
- Perception that birth control is dangerous

## Medical Management of Gynecologic Problems in the Pediatric and Adolescent Patient

consent to health care services, as well as the federal and state laws that affect confidentiality. This information must also be discussed with both the adolescent and, where appropriate, her parent or guardian. Likewise, it is important to inform office staff about policies and procedures to assist and ensure adolescent confidentiality.<sup>33</sup> Many teens also perceive the pelvic examination to be a barrier to accessing contraceptive services; therefore, the physical examination may be deferred until after initiation of contraceptives if requested by the patient and judged appropriate by the clinician. Postponement, not waiver, of a pelvic examination may be considered for an adolescent seeking contraception when she does not have genital complaints such as an abnormal vaginal discharge, pruritus, or odor. An explanation of the need for STD testing should be completed and the offer of urinary testing extended to those coitally active patients whose examination is not completed at the time of contraceptive initiation. The need for prevention of STDs as well as available contraceptive choices should be addressed. This section focuses on the appropriateness of various contraceptive methods available for adolescents as well as new approaches to contraception prescription.

### **Abstinence**

Abstinence is the most effective means of birth control. While many teenagers who request contraception are already sexually active, a review of abstinence as a choice should be part of any discussion of options available to the adolescent. The choice to remain or return to abstinence may be difficult for some adolescents. Those who choose abstinence should be encouraged and reminded of the advantages of decreased pregnancy and STD rates.

### **Hormonal Contraceptive Methods**

Hormonal methods of contraception primarily function via inhibition of ovulation through medication taken remote from the act of intercourse. As adolescent sexual activity tends to be sporadic, this contraceptive method provides a distinct and desired advantage. Of all other contraceptive methods, it is the hormonal methods that have undergone the most advance in the last few years. From pills to patches and injections, the variety available fits the profiles of most adolescents. These methods may be classified as combined methods with estrogen and progestin (i.e., OCP, patch, ring, injection) and progestin only (i.e., pill, injection, insert).

#### **Combined Oral Contraceptive Pills**

The combined OCP is the most commonly used method of contraception in the adolescent group, with rates of use approaching 50%.<sup>34</sup> The many available dosages ranging from 20 µg to 50 µg of estrogen (ethynodiol diacetate), and multiple progestin components, make the choice of the best pill difficult. Despite the combination used, the contraceptive and noncontraceptive benefits of the pill are about the same, and the brand should be chosen based on side effect profile as well as practitioner's preference (Table 32-7). Other indications of use such as acne may also modify the choice. Combinations that contain norgestimate and levonorgestrel have been found to be efficacious for this indication.<sup>35,36</sup> Patient preference may also play a role in the selection of the OCP. The newly available

**Table 32-7**  
**Noncontraceptive Health Benefits of Oral Contraceptives**

Increased menstrual cycle regularity
Decreased incidence of dysmenorrhea, menorrhagia, iron-deficiency anemia, dysfunctional uterine bleeding, premenstrual syndrome
Decreased risk of benign breast disease
Decreased risk of pelvic inflammatory disease (and sequelae, including ectopic pregnancy)
Decreased risk of functional ovarian cysts
Decreased risk of acne and hirsutism
Decreased risk of ovarian cancer
Decreased risk of endometrial cancer
Decreased risk of colon cancer
Improved bone density
Decreased risk of rheumatoid arthritis

84/7 day package (30 µg ethynodiol diacetate and 150 µg levonorgestrel) has shown similar efficacy and compliance with only mild increase in the incidence of breakthrough bleeding in the adult population and may be a new option for patients who desire less frequent menses such as athletes and military personal, although studies in adolescents are lacking.<sup>37</sup>

The initiation day of the pill has been controversial. Utilizing a "quick start" (same day as the visit) method versus the traditional Sunday start initiation seems to improve compliance and still maintain an acceptable side effect profile. This innovative method may be yet another way to encourage adolescent patients to take their method of birth control even before they leave the office with the hope of improving their compliance.<sup>38</sup>

#### **New Hormonal Methods**

The contraceptive transdermal patch uses the technology of a medicated adhesive that allows the skin to absorb and maintain a constant hormonal level, without the fluctuations seen with orally absorbed forms. In the adult population, failure rates and side effect profile are similar to those of combination OCPs. While studies are lacking in adolescents, this form may improve compliance by decreasing the dosing needed to once a week.<sup>39</sup>

The vaginal contraceptive ring (15 µg ethynodiol/120 µg etonorgestrel) is another recently approved method of birth control. This method requires motivation from the patient to insert and remove the contraceptive device from the vagina once a month, and it has not been well studied in adolescents. The adult population studies have been reassuring, confirming the reliability of the method, low side effect profile, and acceptability by users.<sup>40</sup>

The monthly injectable combination contraceptive that combines 25 mg of medroxyprogesterone acetate and 5 mg of estradiol cypionate was recalled by the manufacturer and is not available for use in the United States. Previous studies of this product showed good efficacy, and the future release of a revised version of this method is anticipated.

#### **Progestin-Only Methods**

Progestin-only OCPs are available in the form of norgestrel or norethindrone. They are a choice for adolescents who are

breastfeeding and for those with contraindications to the use of estrogen such as thrombophilias and certain other medical conditions. The efficacy of this product is similar to that of the combination OCP, and the failure rate may be due to patient noncompliance and short half-life, which requires taking the pill around the same time of the day (within 3 hours).<sup>41</sup> To enhance adolescent compliance, extensive education should be provided regarding irregular bleeding that may occur in the first 3 months and the need to take the pill at a similar time each day.

Depot medroxyprogesterone acetate (DMPA) is used by the adolescent population because of the minimal intervention on their part required to achieve compliance. The application of one intramuscular dose of 150 mg every 3 months increases convenience but still requires compliance to continue the method. Although its efficacy has been shown to be better than that of the OCP, most of its effect is probably related to compliance and ease of use. Weight gain and irregular bleeding are common and unpleasant side effects for adolescents. One concern has been the effect of the hypoestrogenic state on bone density in adolescents created by long-term use of DMPA. The use of DMPA has been shown to decrease bone mineral density in adolescent users when compared with normal menstrual controls and OCP users; however, the potential effect on future bone health is unknown.<sup>42</sup> The lack of long-term prospective trials, as well as the potential bone loss associated with pregnancy in the absence of contraception, make DMPA a valid and reliable method to prevent adolescent pregnancy until further data is obtained. Appropriate calcium intake (1200 to 1500 mg/day) and monitoring of bone density should be encouraged in adolescent long-term users, especially those who become and continue to be amenorrheic with use.

Progestin subdermal implants in the form of levonorgestrel were previously commonly used in the adolescent population because of the long-term contraception provided (5 years). The difficulty in removing the six rods as well as the voluntary recall of certain lots by the manufacturer during 1999 limited the use of this method. The introduction of a single etonogestrel implant with a 3-year contraceptive duration plus easy insertion and removal will make this an alternative for adolescents looking for long-term contraception. This product is completing its phase III trials in the United States and is awaiting Food and Drug Administration (FDA) approval.<sup>43</sup>

### **Emergency Contraception**

Emergency contraception (EC), the use of nonabortifacient, hormonal medications within 72 to 120 hours after unprotected/underprotected coitus for the prevention of unintended pregnancy, is an important part of the contraception counseling in adolescents. Use of EC decreases the risk of pregnancy from 8% to 1–2% after a single episode of unprotected coitus.<sup>44,45</sup> Two common regimens have been described. The Yuzpe regimen originally described in 1977 includes the use of 200 µg of ethinyl estradiol and 2 mg of dl-norgestrel taken within 72 hours after the episode of intercourse. This regimen is divided in two doses taken 12 hours apart.<sup>44</sup> The second method consists of levonorgestrel 1.5 mg divided into two doses taken 12 hours apart, and recent studies show that this regimen may be more effective in preventing pregnancy than the Yuzpe regimen.<sup>45</sup> Another

distinct advantage of this progestin-only regimen is the decrease in associated nausea and emesis as compared with the combination regimen. Timing is of importance, but recent studies have shown that even if more than 72 hours have passed, either regimen is efficacious and should be offered with the understanding that there may be an increase in the pregnancy rate the more remote from the unprotected coitus it is taken.<sup>46</sup> Dedicated products for emergency contraception may not be available in some pharmacies; therefore, commonly available combination oral contraceptives may be used to achieve the needed amount of hormone for efficacy. Each two doses must contain a minimum of 100 µg ethinyl estradiol and the equivalent of 0.50 mg levonorgestrel per dose (Table 32-8). Advance prescription of EC has been shown to increase the likelihood of use in young women and teens when needed and yet not increase sexual or contraceptive risk-taking behavior when compared with those receiving education only about EC.<sup>47–52</sup>

### **Barrier Contraceptive Methods**

Barrier methods include devices such as male condoms, female condoms, cervical caps, diaphragms, spermicidal and contraceptive foam, and ovules. Although effective, the use of these devices by adolescents is not consistent, even when chosen by them as their method to protect against STDs.<sup>53</sup> The need for application prior to each sexual encounter decreases the use of the method by “decreasing the spontaneity” of the act, as some teens explain. Latex condoms significantly reduce the transmission of STDs and should be used by all sexually active adolescents regardless of whether an additional method of contraception is used. Therefore, practitioners should encourage the use of barrier methods, such as the male and female condom. In addition to providing condom samples, education should be provided regarding the efficacy of barrier methods in decreasing the transmission of human immunodeficiency virus (HIV). Those adolescents who are most likely to use condoms understand that they can prevent HIV/acquired immunodeficiency syndrome (AIDS), carry them, are not embarrassed to use them, and are concerned about getting AIDS<sup>54</sup> (Table 32-9).

### **Intrauterine Devices**

The experience with intrauterine devices (IUDs) in adolescents is limited. Traditionally, use of IUDs has been avoided in adolescents as this population has the highest rates for STDs. Most practitioners feel that these patients may not be the best suited for this kind of contraception because of their risk of STDs and the possibility of ascending infection when the IUD is in place. However, no increase in infertility or STD incidence is seen with the use of these devices.<sup>55</sup> Most of the ascending infections are probably related to lack of condom use rather than the presence of the IUD facilitating it.<sup>56</sup> While not typically the first choice for adolescent contraception, with proper counseling and condom use, an IUD may be a viable option for some teens, regardless of their gravidity and parity status, and should be considered one of the available tools for contraception. STD prophylaxis at the time of insertion, if cultures are not available, may be of value for those patients in whom the STD incidence is higher than 5%.<sup>57</sup> Scheduling the first follow-up visit about 7 days later may allow detection of early infection.<sup>58</sup>

## Medical Management of Gynecologic Problems in the Pediatric and Adolescent Patient

**Table 32-8**  
**Pharmacologic Methods of Emergency Contraception**

Brand Name	Generic Name and Dose	No. and Color of Tablets to Take Within 120 Hours after Unprotected Coitus	No. and Color of Tablets to Take 12 Hours after the First Dose
<b>Plan B</b>	Levonorgestrel 0.75 mg	1 white	1 white
<b>Yuzpe regimens</b>			
Preven	Levonorgestrel 0.25 mg/ethinyl estradiol 50 µg	2 blue	2 blue
Ovral	Norgestrel 0.5 mg/ethinyl estradiol 50 µg	2 white	2 white
Lo-Ovral	Norgestrel 0.3 mg/ethinyl estradiol 30 µg	4 white	4 white
Nordette or Levlen	Levonorgestrel 0.15 mg/ethinyl estradiol 30 µg	4 light orange	4 light orange
Levora	Levonorgestrel 0.15 mg/ethinyl estradiol 30 µg	4 white	4 white
Triphasil or Tri-Levlen	Levonorgestrel 0.125 mg/ethinyl estradiol 30 µg	4 yellow	4 yellow
Trivora	Levonorgestrel 0.125 mg/ethinyl estradiol 30 µg	4 pink	4 pink
Alesse or Levlite	Levonorgestrel 0.1 mg/ethinyl estradiol 20 µg	5 pink	5 pink
Ovrette	Norgestrel 0.075 mg	20 yellow	20 yellow

The earlier, the more effective.

**Table 32-9**  
**Characteristics of Adolescents Likely to Use Condoms**

- Understand that condoms can prevent HIV/AIDS
- Carry condoms with them
- Not embarrassed to use condoms
- Worried about getting AIDS

### Assisting Adolescents in Choosing a Contraceptive

Health care practitioners should counsel and offer all these methods of contraception to their patients as part of their sexual counseling. From a developmental standpoint, younger adolescents tend to live for the moment, and methods of contraception that require planning and daily compliance may not be the first choice. Older adolescents have more decision-making skills and are more capable of higher level planning; therefore, daily contraception may be more appropriate. Certain medical conditions require specific types of contraceptives (Table 32-10). Despite high motivation and confidence in their ability to comply with medications, some patients, particularly postpartum adolescents, may not fully understand or possess the knowledge required for OCP use and may be better suited to longer acting contraceptives such as DMPA.<sup>58,59</sup>

### Enhancing Compliance and Continuation Rates in Adolescents

Adolescents may have difficulty in complying with contraception. Adolescent continuation rates for OCPs vary based on the population served. In free urban community and hospital-

based clinics, rates of OCP use after 1 year range from 9% to 40%,<sup>60-62</sup> whereas in a suburban practice, OCP use after 1 year was 75%.<sup>63</sup> In addition to varying rates of continuation, various patterns of use that have also been described among adolescents include intermittent use of contraception, method switching, and periodic abstinence.<sup>64</sup>

To improve compliance and continuation rates, practitioners need to be aware of factors that are associated with incorrect or inconsistent use of contraception as well as factors that may inhibit or delay use of needed contraception (Table 32-11). It is equally important to remember that level of knowledge about how to use contraception effectively does not always correlate with consistent use.<sup>58,65-70</sup>

Adolescents have common difficulties in adhering with oral contraceptive compliance including not refilling OCP prescriptions, starting the next pill pack late, not using a back-up method when needed, and using pills sporadically. One study noted that up to one third of teens missed a pill in the previous 3 months of use.<sup>71</sup> All of this reinforces the need for simplified OCP instructions on when to start the pill, to take the pill at the same time every day, and to call with any questions. Contraceptive instruction and information should be reiterated and reinforced at frequent follow-up visits during the first year of contraceptive use until the patient matures enough to be compliant.

### DYSMENORRHEA AND ENDOMETRIOSIS

Pelvic pain and dysmenorrhea are common complaints in adolescents. The differential diagnosis can be quite challenging because of the multiple causes of acute and chronic pelvic pain in this age group (Tables 32-12 and 32-13). This section provides a

**Table 32-10**  
**Contraceptive Options for Adolescent Women with Medical Conditions\***

Patient Disability	Contraceptive Options	Comment
Physical disability	Combination OC, progestin-only OC, DMPA, progestin implant, IUD	Small pill packages require dexterity Partner or caregiver can assist Combination OC is contraindicated in patients with immobility or impaired circulation
Mental disabilities and psychiatric illness	Combination OC, progestin-only OC, DMPA, implant, IUD	Long-acting progestins may be recommended to improve successful use May be at increased risk for STDs
Epilepsy/seizure disorders	Combination OC, DMPA, IUD	Anticonvulsant therapy may increase catabolism in liver, prompting use of a higher dose combination OC
Systemic lupus erythematosus (SLE)	Progestin-only OC, DMPA, implant, IUD	Progestin-only OCs are not associated with increase in SLE flares
Chronic anticoagulation	Combination OC, progestin-only OC, DMPA, progestin implant, IUD	Use combination OCs only if underlying condition is not an absolute contraindication for estrogen use Use caution with DMPA, progestin implant, and IUD owing to risk of bleeding
Hypercoagulable states associated with: Cardiovascular disease: history of venous or arterial thrombus; coagulopathies (activated protein C resistance, antithrombin III deficiency)		
Anticoagulation	Combination OC, progestin-only OC, DMPA, implant, IUD	Use estrogen-containing OCs only if therapeutically anticoagulated Give iron supplementation with IUD
Not anticoagulated	Progestin-only OC, DMPA, implant, IUD	Use of estrogen-containing method is contraindicated
Cardiovascular disorders: thrombophlebitis, thromboembolic disorders, coronary artery disease, myocardial infarction	Progestin-only OC, DMPA, implant, IUD	Estrogen promotes clotting and should not be used when patient is at increased risk for a thrombotic event
Dyslipidemia	Combination OC, progestin-only OC, DMPA, implant, IUD	In women with hypertriglyceridemia ( $TG \leq 250$ mg/dL), use less estrogen-dominant (lower estrogen dose or more androgenic progestin) combination OCs or other methods
Diabetes	Combination OC, progestin-only OC, DMPA, implant, IUD	Use low-dose combination OCs in normotensive, well-controlled diabetic women Diabetic women using hormonal contraception should have periodic $HbA_1c$ glucose levels, annual fasting lipid profile
History of gestational diabetes	Combination OC, IUD Progestin-only OC if not breastfeeding	Select low-estrogen dose OC with low dose of progestin In breastfeeding women, do not use progestin-only OCs (associated with 3-fold increased risks of diabetes mellitus) DMPA and implants are second-choice methods; if combination OCs are contraindicated and long-acting progestin is required for compliance, implant preferred over DMPA (owing to lack of carbohydrate metabolic effect) Postpartum and annual diabetes testing Achieve ideal body weight; encourage daily exercise
Human immunodeficiency virus (HIV)	Combination OC, progestin-only OC, DMPA, implant	Consistent and correct male condom use needed to prevent transmission of HIV Combination OCs should not be used if migraine is with focal neurologic symptoms and there are other risk factors for stroke

DMPA, depot medroxyprogesterone acetate; IUD, intrauterine device; OC, oral contraceptive.

\* Barrier methods can be used by all women, but due to high failure rates, barrier methods are often not optimal for women with medical conditions. IUD use should only be by monogamous women with no risk of pelvic inflammatory disease.

brief overview of the diagnosis and treatment of dysmenorrhea and endometriosis in adolescents; other causes of pain are covered in other chapters.

Dysmenorrhea is defined as painful menstruation. Primary dysmenorrhea is diagnosed in the absence of gross disease in the pelvic organs, while secondary dysmenorrhea is associated with a particular cause (e.g., endometriosis). An adolescent with dysmenorrhea, particularly lower abdominal pain that predates or begins at menarche, must be evaluated to rule out an outflow tract obstruction. In patients in whom a pelvic examination is not possible, a pelvic ultrasound is strongly advised. Although a

diagnosis of exclusion, primary dysmenorrhea is a treatable entity, with the treatment focus on preventing the release of prostaglandins prior to and during menses.

Nonsteroidal anti-inflammatory drugs (NSAIDs) and OCPs are the mainstay of treatment. NSAIDs such as ibuprofen, diclofenac, naproxen, mefenamic acid, and others have been well studied in the literature and provide adequate relief.<sup>72</sup> Cyclooxygenase (COX II) inhibitors such as rofecoxib, valdecoxib, and celecoxib have been shown to work as well as first-generation NSAIDs, but have not shown superiority; thus, they may be used as alternatives when first-generation

## Medical Management of Gynecologic Problems in the Pediatric and Adolescent Patient

**Table 32-11**

**Adolescent Factors Associated with Incorrect or Inconsistent, or Nonuse or Delay in Use of Contraception**

**Incorrect or inconsistent**

Younger adolescents not involved in stable, long-term relationships  
Youth involved in casual relationships  
Adolescent subjected to involuntary sexual intercourse  
Developmental factors  
    Reluctance to acknowledge one's sexual activity  
    Sense of invincibility  
    Denial of possibility of pregnancy  
Lack of education or misconception about appropriate contraceptive use  
Those taking a virginity pledge  
Those with older partners  
Those who had a greater number of friends, who knew their first partner  
Kissing and telling their partners they liked or loved them

**Nonuse or delay in use**

Lack of parental monitoring  
Fear that parents will find out  
Ambivalence  
Perception that birth control is dangerous

**Table 32-12**

**Causes of Acute Pelvic Pain in Adolescent Females**

**Gynecologic causes**

Pregnancy complications (e.g., incomplete or threatened abortion, tubal pregnancy)  
Infections (e.g., postabortal endometritis or acute pelvic inflammatory disease)  
Ovarian cyst—rupture, torsion, or hemorrhage  
Obstructive anomalies of the müllerian duct system (e.g., hematocolpos, complete transverse vaginal septum)

**Nongynecologic causes****Gastrointestinal causes**

Acute appendicitis  
Volvulus  
Meckel's diverticulitis  
Intestinal obstruction  
Mesenteric adenitis  
Regional enteritis  
Ulcerative colitis  
Pancreatitis

**Urinary tract causes**

Acute cystitis  
Acute pyelonephritis  
Ureteral calculus

**Other causes**

Bone and joint infections of the sacrum, ileum, or hip  
Slipped femoral epiphysis  
Intra-abdominal abscess

NSAIDs fail.<sup>73,74</sup> The choice of formulation depends on the patient's characteristics as well as the side effect profile of each preparation. Once-a-day dosing with a COX II inhibitor may be preferable in certain patients not compliant with multiple dosing. The use of a scheduled dose prior to the initiation of menses (24 to 48 hours) may provide better relief by blocking prostaglandin substances already produced before the menstrual flow starts. Other options for treatment in patients who require contraception or for whom three cycles of NSAIDs have not provided relief may be the use of OCPs. The efficacy of this medication has been well documented and is an excellent choice for the sexually active adolescent.<sup>75</sup>

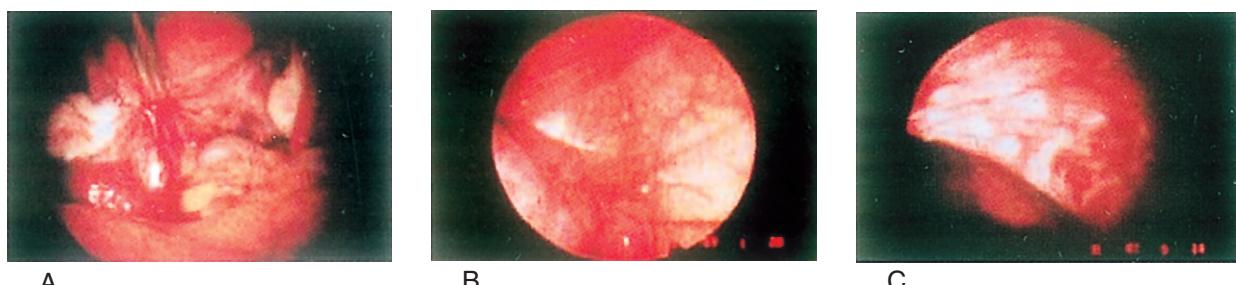

In cases where the combination of NSAIDs and OCPs for dysmenorrhea fails to relieve the pain, organic causes such as endometriosis should be strongly considered, and other diagnostic (i.e., laparoscopy) or therapeutic options (GnRH agonists) may be needed. Endometriosis is defined as the presence of endometrial glands and stroma outside the uterus. The prevalence in the adolescent population whom treatment with NSAIDs and OCPs fail has been reported as high as 70%.<sup>76</sup> Endometriosis was previously believed to affect only adult women but is increasingly being recognized in the adolescent population. In recent years, the increase in the use of laparoscopy as a diagnostic tool in adolescents has increased the awareness of this condition, and practitioners are more likely to include it in the differential diagnosis of pelvic pain.

Endometriosis in the adolescent differs from that of the adult in two ways: presentation and gross appearance. Whereas adults are diagnosed with endometriosis during a diagnostic evaluation for infertility, adolescents primarily present with pelvic pain in the form of acquired or progressive dysmenorrhea, acyclic pain, or dyspareunia. Interestingly, adolescents with endometriosis unresponsive to NSAIDs and OCPs most commonly have cyclic and acyclic pain (62.5%) as opposed to acyclic pain alone (28.1%) or cyclic pain alone (9.4%).<sup>76</sup> The gross appearance of adolescent endometriosis is more commonly clear or vesicular lesions (Fig. 32-31), sometimes referred to as "atypical" as opposed to the "classic" powderburn lesions seen in the adult.<sup>77</sup> Redwine has demonstrated that these atypical lesions occur at a mean age of 10 years earlier than the "black" lesions seen more commonly in adults.<sup>78</sup>

The treatment of endometriosis has always been controversial (Fig. 32-32). The use of laparoscopy for diagnosis and

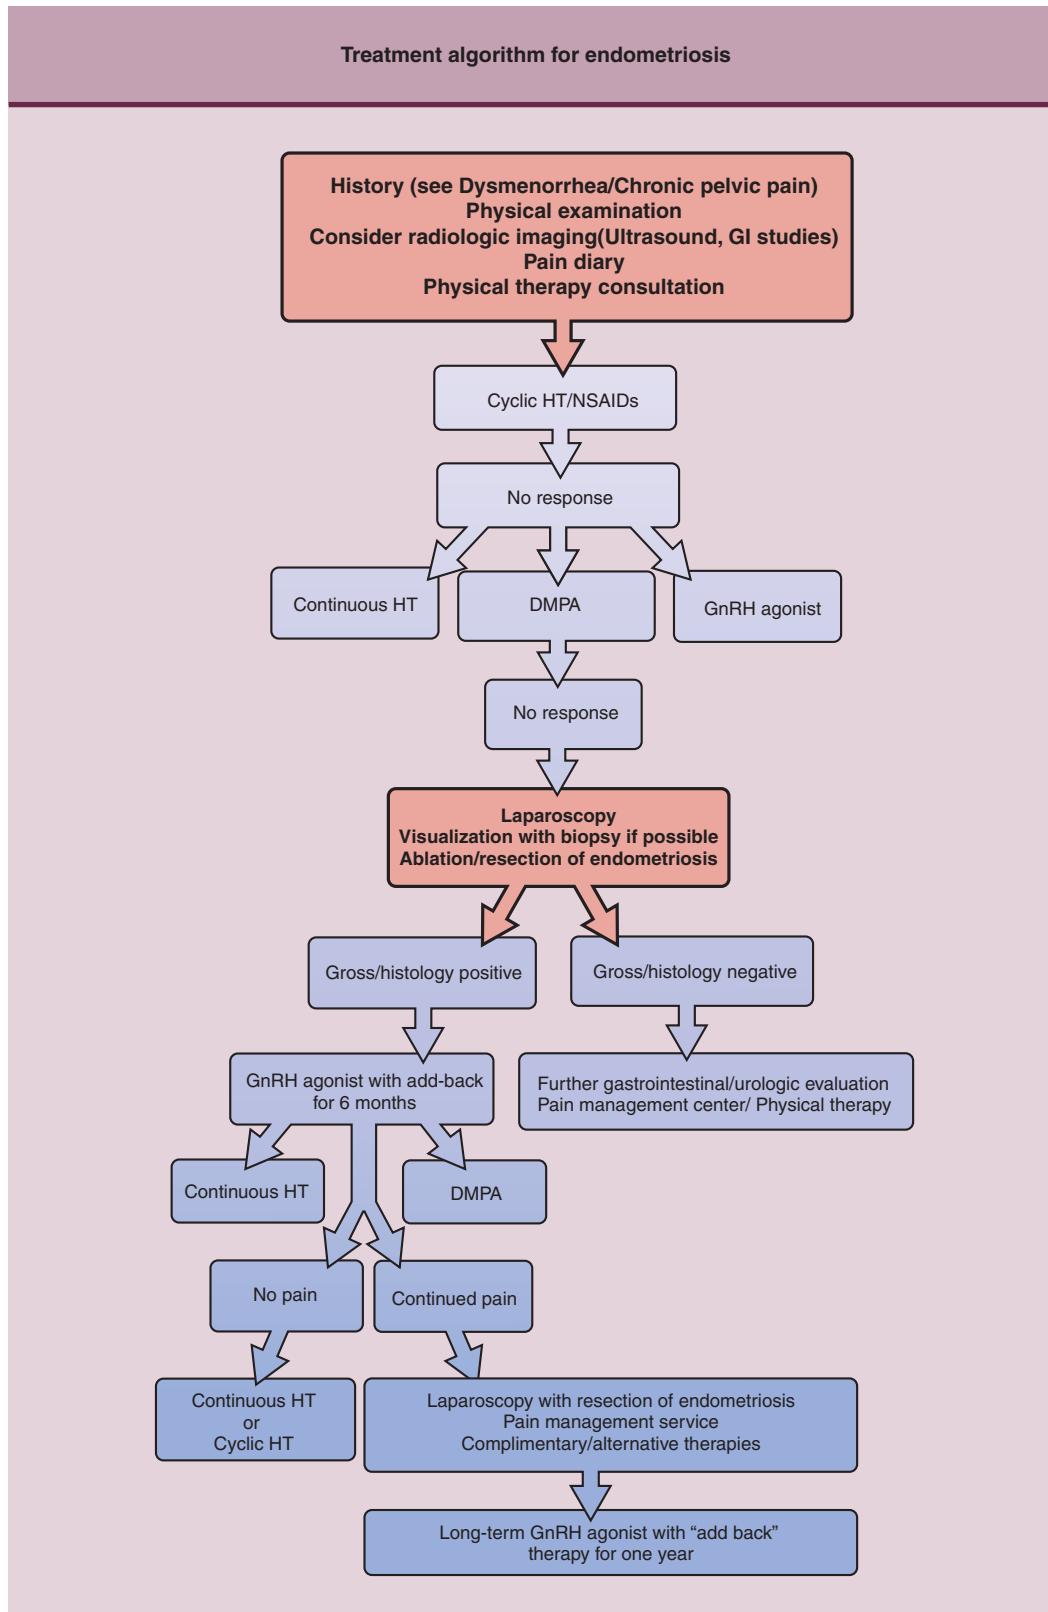

concomitant treatment by ablation or resection of implants if present has been suggested by many as the treatment of choice, followed by the use of continuous OCPs, progestins, NSAIDs, and/or GnRH agonists. Alternatively, the empiric use of a 3-month GnRH agonist as a diagnostic and therapeutic option in patients suspected of having endometriosis has proved beneficial in the adult population. In those patients who respond to the trial, endometriosis is present in up to 78%.<sup>79</sup> When these patients respond to this treatment, the long-term care is still difficult and not fully studied. The use of GnRH agonists for up to 1 year in the adult population, using "add-back" therapy with progestins, has been described without significantly affecting bone health.<sup>80</sup> Data regarding use of GnRH agonists in adolescents are not available. Owing to the lack of information and possible negative impact on bone mineral density in the adolescent, many reserve this option only for empiric use after age 18 and for cases of biopsy-proved endometriosis after age 16.<sup>81</sup> Other less adverse treatments may need to be considered for maintenance. Continuous OCPs combined with NSAIDs after treatment with GnRH agonists may be the treatment of choice, but in those patients with recurrence of pain despite these measures, laparoscopy may still be indicated. Other medications such as progestin-only pills and DMPA are alternatives when combination OCPs are contraindicated or unsuccessful in abating symptoms. Progestational agents commonly used include norethindrone acetate (15 µg daily by mouth), medroxyprogesterone acetate (30 to 50 mg daily by mouth), and DMPA (150 mg intramuscularly every 1 to 3 months). The use of progestins improves symptoms in 80% to 100% of patients with endometriosis.<sup>81-83</sup> Androgenic medications such as danazol, a 17 $\alpha$ -ethynodiol derivative, also have proven efficacy comparable to that of a variety of GnRH agonists, but dose-related side effects may limit their use in the adolescent patient population.<sup>83</sup>

Regardless of treatment used, supportive care is of the essence. Risk factors associated with worsening pelvic pain during their menses such as obesity, smoking, and alcohol consumption should be addressed and proper counseling given.<sup>84</sup> Behavioral therapy and support groups, transcutaneous electric nerve stimulation (TENS), and alternative medicine treatments, in the form of fish oils, may also be of benefit and may be offered to patients as supplements.<sup>84,85</sup>

## KEY POINTS

- Proper evaluation and treatment of genital injuries is paramount to avoid significant long-term morbidity.
- Sexual assault should be considered in virtually all cases of genital injuries.
- Patients with severe genital injuries should be treated like trauma patients.
- A thorough evaluation must be performed to determine the extent of injury (i.e., involvement of bladder, bowel, abdominal cavity) in all patients.
- Surgical treatment should aim to restore both anatomy and function.
- Chronic pelvic pain should be evaluated via a multisystem approach, that is, gastrointestinal, genitourinary, gynecologic, musculoskeletal, and psychological/psychiatric.

## GENITAL INJURIES

Managing genital injuries in young girls can be a trying experience and one that causes much anxiety, but gynecologists should have the ability to evaluate and treat such injuries. These injuries induce so much anxiety for all involved because they present so many questions: "How will this impact her future fertility or her psychosexual development?" "How can we evaluate the injury without causing more trauma to the patient?" "Is this injury the result of an accident or sexual abuse?" Though most genital injuries do not result in an immediate threat to life, proper evaluation and treatment of genital injuries is paramount to avoid significant long-term morbidity.

It is difficult to assess the true incidence of genital injuries in the pediatric and adolescent population. This is secondary to a relative lack of data concerning the subject. The majority of publications written on the topic are anecdotal case reports or series drawn from skewed populations (e.g., suspected child abuse cases). Genital injuries in this population can be secondary to falls, straddle injuries, chemical or thermal burns, pelvic fractures, high-pressure liquid injection (e.g., ski douche injury), or penetration (sexual and nonsexual).<sup>1</sup> Though a significant portion of these injuries is secondary to sexual abuse, a more thorough discussion of this issue is beyond the scope of this chapter.

### Clinical Features

The clinical features associated with genital injuries are varied and depend on their cause and severity. Furthermore, the patient's age plays a role in the clinical presentation. Neonates

and young toddlers have relatively high estrogen levels secondary to transplacental passage. The estrogen stimulates the vaginal and vulvar mucosa to thicken and become more elastic. This thickened, elastic mucosa is more resistant to bleeding when traumatized. As the child gets older, the estrogen level drops and the mucosa becomes more atrophic.<sup>2</sup> Owing to the rich blood supply of the external genitalia and the increased exposure of the underlying capillary beds, relatively minor injuries in this age group can lead to profuse bleeding.

The site of the injury can help classify genital injuries. A common type of genital injury is vulvar hematoma. Vulvar hematomas are usually the result of straddle injuries or blows to the area, such as falling on the crossbar of a bike or being kicked in the groin (Fig. 33-1). The force of the impact ruptures or tears blood vessels beneath the mucosa or skin, and the blood then dissects into the loose areolar tissue along the vaginal wall and along the fascial planes overlying the symphysis pubis and lower abdominal wall. In such accidents, the urethra, hymen, and inner vagina are usually spared injury because they are protected by the labia<sup>1</sup> (Fig. 33-2).

Vulvar hematomas can be of any size, with larger ones being greater than 15 cm in diameter and extending from the clitoris to the perineum. The size of the hematoma depends on the amount of subcutaneous bleeding. Patients usually come in with a round, tense, purple-red swelling in the vulvar region. These masses are quite painful, since they separate tissue planes as they expand. Very large hematomas exert pressure on the overlying skin and, if not treated promptly, can cause necrosis in this area leading to severe infections.<sup>3</sup>

Hematomas are usually the result of blunt trauma, whereas perineal and vulvar lacerations are secondary to sharp trauma or a penetrating injury. Most of these injuries involve only a limited portion of the perineum and vulva, but a thorough examination must be done to rule out injury to the bladder, urethra, upper vagina, or rectum. The location of simple lacerations is dependent on the child's position at the time of injury, the injuring object, and the force of the injury. The outer aspect of the labium majus is most often involved, and these injuries do not usually cause excessive blood loss.<sup>3</sup>

Vaginal injuries are usually due to penetrating trauma, and most are associated with some degree of vulvar injury. They often are the result of a fall onto sharp or pointed objects (Fig. 33-3). The penetration usually causes some degree of hymeneal tearing. The injury to the hymen, in general, does not cause much bleeding and does not require much treatment. The injury inside the vagina may be quite extensive owing to its thin, inelastic nature. An examination, usually under anesthesia, must be performed to rule out injury to other intrapelvic viscera. Many vaginal lacerations are superficial and involve only the mucosa

**Figure 33-1 Vulvar ecchymosis after a fall onto a bicycle crossbar.**

(From Merritt DF, Rimza ME, Muram D: Genital injuries in the pediatric and adolescent female. In Sanfilippo JS, Muram D, Lee P, et al (eds): Adolescent Gynecology, 2nd ed. Philadelphia, WB Saunders, 2001. Used with permission from Diane F. Merritt, MD.)

and submucosa. These patients usually complain of very little pain, and bleeding may be minimal unless a major vessel was injured.<sup>3,4</sup>

When evaluating penetrating vaginal injuries, the physician must include sexual assault in the differential diagnosis. Injuries due to insertion of the penis often cause hymenal tears between the 4 and 8 o'clock position and can also involve the posterior vaginal wall and perineum (Fig. 33-4). This is due to the posterior pressure exerted by the penis during penetration. If excessive, deep force is used, the tear can extend past the rectovaginal septum and into the rectum. Predisposing factors for vaginal injury during intercourse include first occurrence of penetration, congenital anomalies of the vagina, inebriation of either party, violence, and insertion of foreign objects.

Another type of vaginal injury is called a high-pressure insufflation injury. It is seen when the vagina is rapidly expanded, usually with water, and the distention results in tears to the vagina. These types of injuries are associated with falls from water skis or jet skis, sliding down water slides, and direct contact with spa jets.<sup>1</sup>

The most severe types of genital injury are those that involve other intrapelvic viscera (rectum or bladder) or entry into the

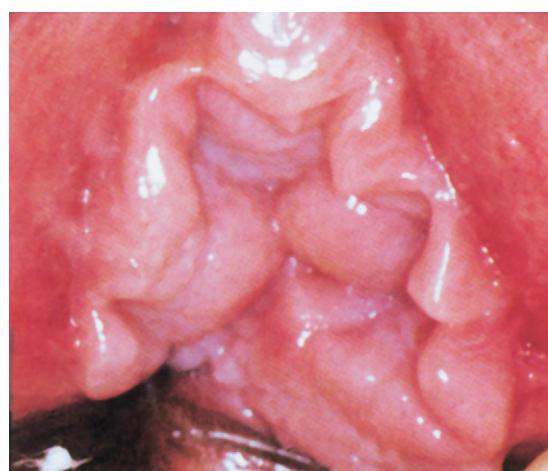

**Figure 33-3 This perineal laceration extended from the vagina into the rectum. It occurred when an 8-year-old girl slid down an incline onto a protruding nail.** (From Huffman JW, Dewhurst CJ, Capraro VJ: The Gynecology of Childhood and Adolescence. Philadelphia, WB Saunders, 1981.)

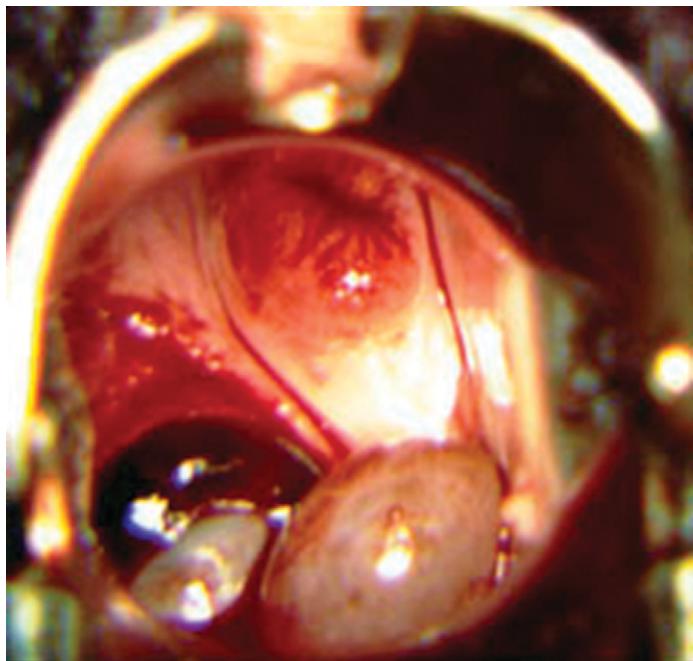

peritoneal cavity. This is often seen if the traumatizing force is excessive or if the penetrating object is longer than the length of the vagina. Once the peritoneal cavity is entered, there is the risk of evisceration through the site of trauma (Fig. 33-5). These patients are at high risk for peritonitis and hemorrhage. Depending on the amount of bleeding, these patients can quickly go into shock. This is usually seen when the injury extends above the pelvic floor and major blood vessels (i.e., the ovarian, uterine, iliacs) are lacerated. Once lacerated, these vessels retract into the abdominal cavity and cause massive hemorrhage into the retroperitoneal space.<sup>5</sup>

**Figure 33-2 Stable vulvar hematoma.** Hematomas of this size can be managed expectantly. (From Merritt DF, Rimza ME, Muram D: Genital injuries in the pediatric and adolescent female. In Sanfilippo JS, Muram D, Lee P, et al (eds): Adolescent Gynecology, 2nd ed. Philadelphia, WB Saunders, 2001. Used with permission from Diane F. Merritt, MD.)

**Figure 33-4 Vaginal-hymenal tear at 8-o'clock secondary to sexual abuse.**

**Figure 33-5 Evisceration of small bowel into the vagina after a penetrating injury of the posterior fornix.** (From Merritt DF, Rimza ME, Muram D: Genital injuries in the pediatric and adolescent female. In Sanfilippo JS, Muram D, Lee P, et al (eds): Adolescent Gynecology, 2nd ed. Philadelphia, WB Saunders, 2001. Used with permission from Diane F. Merritt, MD.)

Bowel injuries are usually of two types. The first is similar to fourth-degree obstetric tears. They extend from the vagina, through the rectal sphincter and rectovaginal septum, and into the rectum. These injuries can not only result from sharp trauma (e.g., falling onto an object), but also from blunt trauma. Blunt trauma, if forceful enough and directed posteriorly, can penetrate the relatively thin, weak rectovaginal septum into the rectum. The second type of bowel injury involves penetration of the abdominal cavity. After entering the abdomen, the penetrating object secondarily injures the bowel. In these types of injuries, the bowel can be directly injured or its mesentery injured. Direct injury to the bowel can result in spillage of contents into the abdominal cavity. This is a surgical emergency, and patients can present with peritoneal signs (rebound and guarding). If the mesentery is injured, clinical signs and symptoms can be delayed until the bowel becomes devitalized.

Urethral injuries are rarer in females than in males. This is secondary to the shorter length of the female urethra in comparison to the male urethra and its anatomic position. The female urethra is hidden behind the osseous pubic arch, and it is more mobile without significant attachment to the pubic bone. Injuries can occur as a result of pelvic fractures, with bone fragments from the ruptured pelvis causing urethral lacerations. They can also occur from blunt trauma or straddle injuries. With urethral stretching and bladder displacement, complete avulsion can occur. In the setting of a pelvic fracture, the clinician should have a high index of suspicion for a urethral injury. Clinical signs include blood at the introitus or meatus, hematuria, urethrorrhagia, inability to void in a conscious patient, or urine leakage through the vagina.<sup>1,6</sup>

Bladder injuries are relatively rare because of the position in the pelvis. The bladder is afforded protection by the bony pelvis. When the bladder is full though, it is more susceptible to injury because it now extends into the abdominal cavity. Bladder injuries can be classified as intra- and extraperitoneal injuries.

Intraperitoneal injuries involve rupture of the bladder into the abdominal cavity, with extravasation of urine into this space. This type of injury is seen most often with high-velocity trauma (e.g., motor vehicle accidents) with a full bladder, which results in rupture of the dome at its weakest point. Extraperitoneal injuries result in urine leakage limited to the perivesical and retroperitoneal space. This is almost always associated with pelvic fractures causing shearing forces or bony spicules to injure the bladder. Patients with these types of injuries complain of suprapubic or pelvic pain, dysuria, inability to void, or hematuria. On physical examination, blood can be seen at the urethral meatus, and patients may have a high, palpable intra-abdominal bladder.<sup>1,5</sup>

### Evaluation

When evaluating a child with genital injuries, the physician must take the clinical context into account. In a well-appearing child who just suffered a straddle injury on her bike, it is appropriate to obtain a history and build rapport with the patient prior to proceeding with the physical examination. On the other hand, a child who was involved in a motor vehicle accident and suffered a pelvic fracture requires prompt evaluation and/or intervention. Of paramount importance in all situations is ensuring the medical stability of the child.

Children with severe genital injuries are treated as trauma victims and are assessed as such. Their airway (A), breathing (B), and circulation (C) are assessed and addressed. Any child with bleeding must be evaluated immediately for hemodynamic stability. Once the patient has been deemed stable, a complete physical examination should be performed to ascertain the extent of injuries. The physician should be on the lookout for other, nongenital, injuries that may require attention.

In nonacute cases, the physician has a bit more time to evaluate the patient. As stated before, genital injuries are anxiety provoking for both the patient and her family. The physician should try to establish rapport with both prior to proceeding with the examination. The role of the history is to determine the cause of the injury and associated symptoms. These clues can often be used by the physician to guide the examination. The physician should be suspicious when the history and physical condition do not match, since this may be a sign of sexual abuse or assault.

Prior to the genital examination, the parents and patient should be informed of the nature and purpose of the examination. A decision then needs to be made as to the need for intravenous sedation or general anesthesia. Generally agreed upon indications for general anesthesia include extension of the injury through or above the hymen in a prepubertal child, vaginal lacerations that extend into the rectum or peritoneal cavity, unexplained vaginal bleeding, other injuries that require surgical management, and any obstacle to determining the full extent of the injury.<sup>7</sup> Physicians should have a low threshold of suspicion for examination under anesthesia because the morbidity associated with missed injuries is quite high, and serious injuries can often present without significant external findings.

When examining the pediatric patient with a genital injury, the physician must be aware of anatomic differences between children and adult patients. In the newborn, the labia minora, labia majora, and clitoris are all relatively large and prominent. As the child develops, their relative size decreases. Until puberty is reached, the vaginal wall is quite thin. At puberty, under the influence of estrogen and acid-forming bacteria (*Lactobacillus acidophilus*), the microenvironment of the vagina changes and the epithelium thickens. The internal reproductive organs also change as the patient develops. The uterus weighs only 14 to 17 g at puberty and grows to a final weight of 30 to 40 g in adulthood. The ovaries increase from 0.6 g (combined) in the infant to 5.0 g in the adult. The length of the vagina increases from 3 cm to over 8 cm. The central orifice of the hymen is about 0.4 cm in diameter at birth and enlarges to only about 0.5 cm in diameter at 5 years of age. The physician must keep these anatomic differences in mind and tailor the examination appropriately (e.g., using a nasal speculum to evaluate the vagina in a child with an intact hymen).<sup>8</sup>

Once the child has been made comfortable so that she may tolerate the examination, the physician should approach the examination in a systematic fashion. First, the physician should evaluate the external genitalia and vulva. All injured external structures should be thoroughly assessed and their extent determined. The physician should always have a high suspicion for involvement of other structures (bladder, rectum, etc.), and this possibility should always be investigated. Palpation can be used to determine the extent of hematomas, and an internal examination can help determine extension into spaces within the pelvis. If the physician cannot determine the extent of spread, imaging studies may be helpful. If the injury was caused by a penetrating object, the physician should request that the object be brought to the hospital. This allows the physician to determine if the traumatizing object has the potential length to penetrate above the pelvic floor. If the object has the potential to penetrate above the pelvic floor, a complete examination under anesthesia is likely warranted. If the object does not have projections, an external assessment is likely adequate.

Once the external genitalia have been investigated, the physician should evaluate the urinary and gastrointestinal (GI) systems before proceeding with the internal examination. Injuries to the external anal sphincter are rare without coincident injuries to the vulva and vagina. Tears of the sphincter usually are extensions from the vagina unless they are posterior in location. Digital palpation of the sphincter throughout its circumference and visual inspection of the capsule give a good assessment of the sphincter's integrity. Injuries that penetrate the rectovaginal septum can damage the rectum without violating the sphincter. These injuries can often be felt digitally, but in instances where the injury is more distal, proctoscopy may be necessary (Fig. 33-6).

An evaluation of the urethra and bladder is considered next if an injury to one of these organs is suspected. A urinalysis will often show hematuria with these injuries, but the sensitivity and specificity of hematuria for these injuries are poor. Therefore, if an injury is suspected, more accurate diagnostic tests are warranted. If an injury to the urethra is suspected, placement of a catheter prior to evaluation is inadvisable. This is because if a partial transection is present, traumatic catheterization may lead

**Figure 33-6** This young girl impaled herself on a broom handle.

The point of entry was the perineum, with the exit wound being in the rectum. (From Merritt DF, Rimza ME, Muram D: Genital injuries in the pediatric and adolescent female. In Sanfilippo JS, Muram D, Lee P, et al (eds): Adolescent Gynecology, 2nd ed. Philadelphia, WB Saunders, 2001. Used with permission from Diane F. Merritt, MD.)

to a complete transection.<sup>2</sup> The evaluation for a urethral injury in female patients is more difficult than in male patients owing to the inability to perform accurate urethrography. A vaginal examination or vaginoscopy may be helpful in diagnosing a urethral injury if there is extension into the vagina or if there is a palpable hematoma, but urethroscopy remains the gold standard for the diagnosis of urethral injuries. After urethroscopy confirms an intact urethra, then a catheter can be placed.

Bladder injuries can be diagnosed with either computed tomography (CT) or conventional cystography, depending on the availability of the imaging modalities. With both, intraperitoneal bladder injuries show extravasation of contrast into the abdominal cavity with pooling of material around loops of bowel. Extraperitoneal bladder injuries, on the other hand, are associated with material contained within the pelvis, and the material can be best appreciated on postdrainage radiographs<sup>5</sup> (Fig. 33-7). If bladder and urethral injuries have been ruled out, the physician must assess whether the patient can void spontaneously prior to moving on to other parts of the examination. Often injuries to the vulva can cause spasms of the urethra or lead to obstructive swelling that can cause urinary retention. If this is the case, a Foley catheter should be placed until the condition resolves.

Examining the vagina is the next step in the evaluation and often the most difficult. Even with a patient under general anesthesia, the physician is often limited by the size of the introitus. In adolescents whose hymens are no longer intact, a speculum examination can be performed unhindered. It is in the pediatric population and in those whose hymen is intact that examination can be difficult. Nasal speculums are useful tools in younger girls but may not be long enough to expose the cervix and fornices in older girls. In these patients, special pediatric vaginal speculums can be used, or vaginoscopy may be required (Fig. 33-8). Whichever instrument is used, the physician must be sure that the entire vagina is inspected, especially the fornices. Often injuries to the vagina occur in the fornices and are hidden by redundant mucosa. A digital vaginal examination is performed only in those patients whose introitus allows such an examination. In some situations, a rectoabdominal examination may be substituted for a digital vaginal examination.

**Figure 33-7 CT scan showing significant extraperitoneal bladder rupture after trauma.** The dye is no longer contained by the bladder. (Brohi K: Classic cases: Lateral compression pelvic injury and extraperitoneal rupture of the bladder. Trauma.org, 2002(7:1). Available at <http://www.trauma.org/cases/classic001.html>. Accessed 5/19/05.)

Other portions of the evaluation must be tailored to the particular situation. Imaging modalities, such as ultrasonography or CT, may be utilized if the clinical picture dictates. An example would be the use of CT scanning to diagnose a retroperitoneal hematoma. If the peritoneal cavity is entered, laparotomy is indicated as part of the evaluation for intra-abdominal injuries. Some physicians have used laparoscopy instead of laparotomy in a limited number of cases. Though they have been successful, the procedure has not been evaluated thoroughly enough to be the standard of care.

**Figure 33-8 Vaginoscope used to evaluate a pediatric patient.**

### Treatment

Many vulvar hematomas can be treated with expectant management, but some do require surgical intervention. Treatment is often determined by the size of the hematoma. Small hematomas (i.e., smaller than the size of an egg) can often be initially treated with pressure and an ice pack. The injured area should be observed in order to assess whether the hematoma is stable or expanding. In most small hematomas, the pressure created by the stretched vaginal mucosa will compress the bleeding vessel and limit its expansion.<sup>4</sup> Large or expanding hematomas must be opened to limit their expansion and prevent necrosis of the overlying skin (Fig. 33-9). An incision is made lateral to the vaginal orifice in the mucosa. Clot and devitalized tissue are removed, and an attempt to identify the bleeder is made. Absorbable mattress sutures can be placed to help control bleeding. If a specific bleeder is not identified, the hematoma cavity is packed with gauze and pressure is applied. The gauze is removed after 24 hours, at which point most bleeding has ceased. To close the defect created by the hematoma, placement of a suction drain may facilitate evacuation of transudates, exudates, and blood. While the drain is in place and the tissue healing, prophylactic antibiotics are given to prevent infection at the injury site. In all patients with hematomas, their ability to void should be assessed. Large hematomas may physically obstruct the urethra, and smaller hematomas may induce swelling in the region of the urethra leading to retention. If a patient experiences urinary retention, a Foley or suprapubic catheter should be placed until she is able to void spontaneously<sup>1,3,7</sup> (Fig. 33-10).

Treatment of vulvar and perineal lacerations begins with a thorough physical examination to rule out injury to adjacent

**Figure 33-9 This large hematoma was not surgically drained, which led to necrosis of the overlying skin.** (From Merritt DF, Rimza ME, Muram D: Genital injuries in the pediatric and adolescent female. In Sanfilippo JS, Muram D, Lee P, et al (eds): Adolescent Gynecology, 2nd ed. Philadelphia, WB Saunders, 2001. Used with permission from Diane F. Merritt, MD.)

**Figure 33-10 Vulvar hematoma that has been incised and drained.**

Note incision, which has been closed with absorbable sutures, on medial aspect of left labium. A urethral catheter is in place for bladder decompression and closed suction drain exits the most dependent aspect of the vulva. (From Merritt DF, Rimza ME, Muram D: Genital injuries in the pediatric and adolescent female. In Sanfilippo JS, Muram D, Lee P, et al (eds): Adolescent Gynecology, 2nd ed. Philadelphia, WB Saunders, 2001. Used with permission from Diane F. Merritt, MD.)

structures. If there is no evidence of any other injuries, the wound site can be cleansed thoroughly and bleeding vessels controlled. Deep injuries may require surgical repair, but the surgeon should try to avoid sutures in the skin, especially those not in the midline. Lateral sutures have a tendency to pull out when placed under tension, which occurs when a young girl sits and applies pressure to her perineum. Injuries to the lateral walls of the vestibule heal quite well by secondary intention and usually do not require surgical repair.<sup>8</sup>

As with other types of genital injuries, treatment of vaginal injuries begins with evaluation of the patient for involvement of the bladder, bowel, or other abdominopelvic viscera. Injuries confined to the mucosa and submucosa can be treated with absorbable sutures. The tissue is reapproximated and hemostasis is obtained in a similar fashion to an obstetric repair. Care must be taken to ensure that all bleeding points are controlled because hematomas of the vaginal wall can occur if bleeding vessels are not ligated prior to closing the mucosa.<sup>4</sup> Small fluid collections can sometimes form in dead space within a repair. These collections can usually be drained in the office by releasing one or two stitches. Once drained, the space should be left open to prevent fluid reaccumulation. Prophylactic antibiotics are recommended in repaired vaginal injuries.

Vaginal injuries that are superficial or inaccessible to surgical repair can be treated with packing. The packing will apply pressure to the site and stop bleeding. It is best if the gauze is lubricated, especially with estrogen cream. Lubrication of the gauze will make removal of the packing easier and inhibit adherence of the gauze to the wound. Estrogen cream facilitates healing of the mucosa and prevents the formation of granulation tissue, which develops quite commonly on unestrogenized, traumatized tissue. Estrogen cream can also be applied topically to the vulva to aid in the healing of vaginal injuries.<sup>2</sup>

Treatment of injuries that involve abdominopelvic organs usually requires surgical intervention. A vaginal or abdominal approach is used depending on the severity and extent of the injuries. After a thorough evaluation rules out extension of an

injury into the peritoneal cavity, a vaginal approach can be attempted. This would include rectal injuries similar to fourth-degree obstetric tears and bladder injuries extending into the vagina. The repair should reapproximate tissue in layers and have as its objective the restoration of normal anatomy. A urologist or colorectal surgeon should be consulted if necessary. Since strictures and scar tissue can have devastating long-term morbidity, the physician should be vigilant for their formation. Vaginal strictures can be released with the use of successively larger dilators over a period of time. Severe cases may require surgical intervention. If an injury results in a tear through the rectal sphincter, stool softeners may be prescribed during the healing period to reduce the effort required for bowel movements and to decrease strain on the newly repaired tissue.

If there is any question about whether abdominal viscera are involved from the injury, an abdominal approach is warranted. A thorough assessment of the abdominal cavity should be performed in order to detect any concealed injuries. The bowel should be run along its entire length to rule out any enterotomies, and the mesentery of the small and large bowel should be evaluated for any injury that may lead to devitalized tissue. Injured loops of bowel can either be primarily repaired or resected, depending on the extent of injury. The retroperitoneum should also be explored, as an injury in this area can easily be hidden. An injury to the vasculature can lead to a large hematoma, and the retroperitoneum is able to conceal a large quantity of blood. Common vessels that are injured include the uterines, ovarians, and iliacs (Figs. 33-11 and 33-12). If a hematoma is expanding or the patient is becoming hemodynamically unstable, the retroperitoneum should be entered and the bleeding vessel identified. Depending on the vessel that is bleeding, it either can be ligated or require repair by a vascular surgeon. Stable hematomas can be managed expectantly, as the pressure from the hematoma will compress and occlude the offending vessel.

Partial lacerations and contusions of the female urethra can be effectively treated with prolonged catheterization. Larger lacerations can be repaired by a layered closure over an indwelling catheter. Because of the low incidence of complete urethral avulsion or laceration, there has not been standardization of treatment for these types of injury. Some surgeons favor a staged approach, with initial urinary diversion through a suprapubic tube and subsequent reconstruction. Others favor immediate repair at the time of the injury. Ideally, to prevent the long-term complications of strictures, incontinence, or fistulas, these repairs should be undertaken with the help of a urologist.<sup>5,6</sup>

Treatment of bladder injuries depends on the location (intra- or extraperitoneal) and type of injury. All intraperitoneal bladder ruptures require surgical exploration and direct repair through a layered closure. Some surgeons recommend opening the bladder in the midline to determine the size and location of all injuries. Stent placement may be warranted to assess the position of the ureteric orifices and the trigone prior to commencing with the repair. Injuries are repaired in two layers and the bladder decompressed for 2 weeks with either a Foley catheter or a suprapubic tube. Drains (i.e., Jackson-Pratt) should also be left in place near the area of repair. Prophylactic antibiotics are recommended. Most extraperitoneal bladder ruptures can be treated with Foley catheter drainage alone. Drainage should be

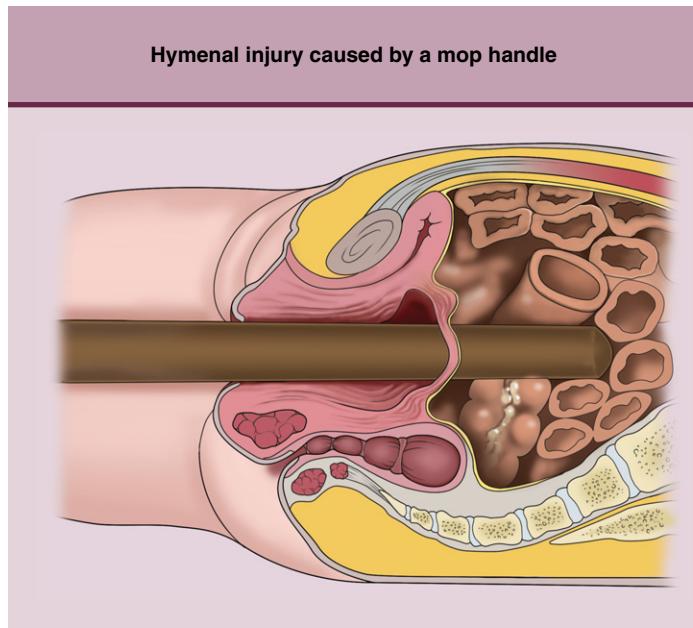

**Figure 33-11 A small tear in the hymen and vagina of a young girl.**

This is the vulva of the patient depicted in Figure 33-12. This case illustrates the need for a high index of suspicion for intra-abdominal injuries in all patients with genital trauma, no matter how minor the trauma appears. (From Huffman JW, Dewhurst CJ, Capraro VJ: *The Gynecology of Childhood and Adolescence*. Philadelphia, WB Saunders, 1981.)

for approximately 2 weeks, and the physician should be vigilant for blood clots that may obstruct the tube and worsen the rupture. If the patient's other wounds warrant laparotomy, then these injuries can be repaired at that time. Bladder injuries that are limited to the posterior wall and extend into the vagina can be closed transvaginally in two layers.

An important issue in the treatment of genital injuries is the prevention of such injuries. There is little literature concerning this topic, and prevention strategies are difficult to enforce as they may limit the normal active lifestyle of a child. Parents should be vigilant when buying toys with sharp points and avoid toys that may present a fall risk, such as sprinklers that encourage children to jump over them. Safety equipment should also be stressed. This includes wearing durable pants during jumping or climbing activities. Wet suits are recommended during water skiing to prevent the high-pressure insufflation injuries. Unfortunately, no matter what precautions are taken, genital injuries will occur; thus, it is important that clinicians be educated in the proper evaluation and treatment to reduce long-term morbidity.

**Figure 33-12 Depiction of the injury sustained by the same patient as in Figure 33-11.** The mop handle impaled the girl through the pouch of Douglas and then ripped the peritoneum off the left common iliac vessels and tore 8 cm of mesentery away from a portion of the ileum.

## CHRONIC PELVIC PAIN IN ADOLESCENTS

The problem of chronic pelvic pain (CPP) often remains an enigma for clinicians dealing with this patient population. Defined as cyclic lower abdominal pain of at least 6 months' duration or noncyclic pain of 3 months' duration, either of which affects normal activities.<sup>9</sup> The International Association for the Study of Pain defines CPP as a "chronic or recurrent pelvic pain that has a gynecologic origin but for which no definitive lesion or etiology is identified." Four criteria are established that focus on the behavioral components related to CPP<sup>10</sup>:

1. Pain that is refractory to medical management
2. Significant impairment of physical function, including sexual function
3. Vegetative signs of depression
4. Patient's role within the family has changed secondary to the pain, or the family perceives the pain to be the "highest priority" problem

CPP is a common and serious problem with a prevalence of 14% to 16% of all women. In the adult it is a major indication for the hysterectomies performed annually in the United States. In the adolescent, the problem often proves to be burdensome to both patient and parent. It may be used as a way to gain attention.

The initial evaluation requires a detailed history and physical examination. At that time a multisystem approach encompassing evidence for a urinary tract, GI, musculoskeletal, gynecologic, or psychological etiology must be determined.

A general physical examination that includes a pelvic examination is recommended. Tenderness may be elicited in the cul-

## Pediatric and Adolescent Gynecology

de sac, although this finding is far less common in the adolescent than in the adult. Determination of trigger points, straight-leg raising, and evaluation of gait are integral segments of the physical examination.

### **Pathophysiology**

#### **Cartesian and Gate Control Theories**

One early theory of pain perception is that of the Cartesian model. In this model, stimulation of peripheral nerve pain fibers activates the pathway directly to the cerebral cortex with the end product being the perception of pain. Gate theory complements the Cartesian model and identifies transmission of nociceptive or discomfort signals reflecting innervation of several types of peripheral fibers, including C fibers, which are sensitive to heat, mechanical pressure, and chemical mediators of inflammation (Table 33-1). This association is predicated on bidirectional transmission of information from the periphery to the brain and from the brain to the spinal cord. Both motivational and affective states modulate the peripheral nociceptive signals. The modulation occurs via descending impulses, which release neuromodulators at the control transmission cells of the spinal cord.<sup>11</sup> The spinal cord acts as a “gate,” regulating transmission of peripheral nociceptive signals to the brain by way of the spinothalamic pathways. According to the Gate theory, the longer the pain remains present, the less pertinent is the tissue damage that initially caused the release of neuromodulators.

#### **Operant Conditioning Model**

Proposed by Fordyce, the operant conditioning model focuses on pain being based on communication between the patient and other individuals, either verbal or nonverbal. The communications are subject to reinforcement; that is, pain behaviors may be maintained by the responses elicited from others, such as attention, avoidance of undesirable activities, or financial compensation.<sup>12</sup>

#### **Cognitive Theories**

Conscious thought processes or cognitions appear to be significant in influencing behavior and relationships as well as in modulating levels of pain. This theory expands the Gate theory. It provides a basis to understand the patient’s thoughts as she experiences pain. Attributions regarding pain etiology as she perceives it, the meaning of it to her, all can heighten her perception of pain. Therapeutic interventions, from the psychological treatment perspective, may then be applied.

### **Psychological Perspectives**

There are “pain-prone personality” characteristics of individuals. Sexual abuse, including in one’s childhood, may be one such factor. This as well as domestic violence must always be inquired about. Family or personal history of depression is important to determine. The latter may be the prime source, a predisposing factor, or a result of CPP. Alteration of endogenous opioid and serotonergic pathways is associated with the perception of pain. The pathways facilitate transmission of pain signals to the sensorium. Use of the Minnesota Multiphasic Personality Inventory (MMPI) allows determination of depression scales and personality assessment. Psychomimetic changes in these studies correlate with the severity and duration of the pain rather than severity per se.<sup>13</sup> Other problems include hypochondriasis, somatization, and somatic delusion.

### **Urologic**

Urethral syndrome, recurrent bacterial cystitis, and interstitial cystitis should be considered. See Table 33-2.

### **Gastrointestinal**

Constipation is a frequent problem in the adolescent with CPP. In part this may reflect dietary habits in this age group. In addition, the patient with changes in bowel habits, including constipation alternating with diarrhea, should be considered for irritable bowel disease. Clinical conditions such as Crohn’s disease present in this age group. If there is a predominance of GI-related signs and symptoms the patient is best served by a GI consultation (Table 33-3). Extensive discussion of these entities is beyond the scope of this textbook.

### **Musculoskeletal**

Table 33-4 lists the musculoskeletal causes of pubic pain. The most common muscular problem responsible for pelvic pain is “pelvic floor tension myalgia.”<sup>14</sup> It is associated with intermittent or constant contractions of the levator plate that are associated with intense pain.

Levator spasms are a “falling out” pressure sensation over the involved musculature. It is associated with dyspareunia and is primarily focused in the mid-vaginal area. The pain frequently radiates to the low back. Lying supine often relieves the pain and discomfort. On physical examination, tenderness to palpation and reoccurrence of the pain is associated with trigger point assessment.

Piriformis spasms are characterized by pain in the morning on arising. In addition, there is exacerbation when climbing stairs or driving a car. The physical findings include pain elicited with external rotation of the thigh. On palpation, tenderness is often noted over the involved musculature. This may manifest on pelvic examination.

Myofascial pain is focally located in the lower quadrants of the abdominal wall and reflects entrapment of the genito-femoral or ilioinguinal nerves. This problem is more commonly noted following a Pfannenstiel incision. Myofascial trigger points are elicited on abdominal palpation.<sup>15</sup> Fibromyalgia is associated with chronic fatigue, depression, and sleep disturbances.

#### **Gynecologic**

Table 33-5 summarizes the gynecologic causes of pelvic pain.

#### **Endometriosis**

While theories of retrograde menstruation, totipotential müllerian rest cells, and hematogenous and lymphatic spread abound, the exact cause remains unknown. In the adolescent as well as in the adult, the exact incidence also remains unknown. Diagnosis is surgical and histopathologic. In adolescents with a history of CPP, studies have noted an incidence of 25% to 38% of endometriosis.<sup>16-18</sup>

In adolescents with persistent pelvic pain or dysmenorrhea despite medical therapy with oral contraceptives and nonsteroidal anti-inflammatory drugs (NSAIDs), the prevalence of endometriosis may be as high as 70% to 73%.<sup>19,20</sup> The adolescent who is refractory to medical therapy, persists with CPP, and has had other possible etiologies ruled out is a candidate for operative laparoscopy. In one study evaluating adolescents with CPP, endometriosis was diagnosed in 25% of the 180 patients evaluated. Furthermore, ovarian cysts were noted in 7%, paraovarian cysts in 3%, pelvic inflammatory disease (PID) in 3%, and pelvic adhesions in 25%; notably, chronic PID-related findings were noted in 6%.<sup>21</sup> Of the adult patients presenting

## Pediatric and Adolescent Gynecology

with pelvic pain in one other study, 70% were found to have endometriosis.<sup>22</sup> A study by Balasch and colleagues noted that 45% of patients with laparoscopy-proven endometriosis are asymptomatic.<sup>23</sup> Most clinicians agree that in the adolescent population biopsy of lesions believed to be endometriosis is recommended.

### Pelvic Adhesions

Pelvic adhesions can occur postoperatively or as a result of acute inflammatory processes, for example, acute PID or as a sequela to endometriosis. There is conflicting evidence about the relationship between pelvic adhesions and CPP as well as the benefits of adhesiolysis for symptom relief. A study of postappendectomy patients did not find a correlation between CPP and the presence of adhesions, whereas another study noted a higher rate of colon-to-colon as well as to side-wall adhesions in women with CPP compared with controls.<sup>24,25</sup> Of note, adhesions may be found in totally asymptomatic patients.<sup>26</sup> It is possible that a prerequisite for pelvic pain is that the adhesions restrict movement or distensibility of a pelvic or gastrointestinal organ. Little correlation exists between severity of pain and extent of adhesions.

The risks and benefits of adhesiolysis remain a point of discussion. A randomized clinical trial of adhesiolysis by laparotomy revealed no benefit in adhesiolysis when "light or moderate" pelvic adhesions were noted but benefit when there was lysis of severe adhesions.<sup>27</sup> Goldstein et al reported that 89% of adolescents with pelvic pain and documented adhesions had improvement in their symptoms following adhesiolysis.<sup>28</sup> One potential problem is that of re-formation of adhesions following lysis. Current surgical therapy continues to explore adhesion prevention agents for surgical intervention.

### Differential Diagnosis

The differential diagnosis is provided in Tables 33-1 to 33-5.

### History and Physical Examination

A pelvic pain assessment form (Fig. 33-13) is useful in evaluating patients with CPP.

### Treatment

Multidisciplinary pain centers are most helpful in management. These centers as a general rule do not set "cure" as a goal but

rather establishment of a level of tolerance, at least at the beginning of therapy.

Management in large part is dependent on the underlying etiology. In the patient who is refractory to NSAIDs and suppressive therapy with oral contraceptives, operative laparoscopy is in order. At the time the diagnosis is established, ideally biopsy-proved, and appropriate ablative and/or excisional therapy applied. Controversy continues regarding the role of presacral neurectomy, which for the most part is reserved for patients with midline pelvic pain.

Other medical suppressive therapy may include use of gonadotropin-releasing hormone agonists. In essence a medical menopause is created with resultant ovarian suppression.

Adhesiolysis as treatment for established adhesions continues to be an area of controversy. The primary problem is recurrence of adhesions. One randomized study noted failure of significant improvement in pain symptoms following lysis of adhesions in comparison with a control group that did not undergo adhesiolysis. Only a subgroup of 15 patients with stage IV adhesions (criteria of Kapur) had symptomatic improvement.<sup>29,30</sup>

Irritable bowel syndrome (IBS) is best treated by elimination of dietary lactose, sorbitol, and fructose. Lactose intolerance can mimic IBS. On the other hand, 40% of patients with IBS also have lactose intolerance. Sorbitol is a common sweetener in "sugar-free" foods. Fructose is present in many processed foods. Caffeinated products and carbonated drinks also contribute to IBS-related discomfort.

Interstitial cystitis is a chronic inflammatory condition of the bladder and responsible for a segment of patients with CPP. It is best diagnosed with cystoscopy. The altered bladder permeability secondary to defective glycosaminoglycan mucous layer deficiency is responsible for the discomfort. The presence of Hunner's ulcers on cystoscopy and increased sensitivity on potassium intravesical instillation provide the basis for the diagnosis. Treatment remains controversial and includes bladder instillation of dimethylsulfoxide (DMSO), intravesical capsaicin, and placement of Calmette-Guérin bacillus into the bladder. Other treatment includes use of sodium pentosan polysulfate as well as cyclosporine and antihistamines such as hydroxyzine. Treatment focuses on the primary underlying etiology of CPP; for example, progestins including depot preparations can be administered when the cause is believed to be gynecologic.

## Section 6 Minimally Invasive Surgery

# Chapter 34

## Laparoscopic Instrumentation

Raedah Al-Fadhli, MD, Togas Tulandi, MD, MHCM, and Eric J. Bieber, MD, MHCM

### KEY POINTS

- The laparoscopic surgeon should be familiar with a number of instruments for performing laparoscopic surgery.
- High-flow insufflators facilitate operative laparoscopy.
- The laparoscopic surgeon should be comfortable placing several different types of trocars.
- Multiple surgical devices are available for tissue incision and dissection, including unipolar, bipolar, ultrasonic, and laser. Device choice largely depends on surgeon preference.
- Electric tissue morcellators facilitate removal of large masses.
- Robotic surgery is presently being investigated for use in gynecology.
- Virtual reality trainers allow improvement in hand-eye coordination that may enhance performance of surgery.

Proper instrumentation is required for the ease and safe conduct of any procedure. This is especially essential for advanced laparoscopic surgery. Equally important is the surgeon's familiarity with the equipment and instruments. There are a plethora of laparoscopic instruments, but basic principles apply to the use of all of them. Depending on the volume of patients, a minimum of two complete sets of laparoscopic instruments per operating room is needed. Basic instruments for a single laparoscopic set are depicted in Table 34-1 and Figure 34-1. This chapter focuses on basic instruments required for operative laparoscopy.

### INSTRUMENTS REQUIRED FOR OPERATIVE LAPAROSCOPY

#### Camera and Monitor

High-quality visualization of the operating field is crucial during laparoscopic surgery. Image quality may be enhanced with the use of a three-chip endovision video camera, high-intensity light, and a high-resolution video monitor. A three-dimensional camera is also available, but it remains unclear if this facilitates surgery.

The modern camera should be lightweight; have a zoom lens, automatic color setting, and high-speed shutter to decrease or eliminate overexposure; and should be easily sterilized. The number of pixels on a chip determines the resolution capacity of the camera. A single-chip camera with 450 lines per inch provides fair quality resolution; a three-chip camera with 700 lines per inch provides better resolution and color accuracy.

Although laparoscopic surgery can be performed with a single monitor between the patient's legs, having at least two monitors in the operating room may decrease surgeon fatigue. This allows viewing of each monitor by both the surgeon and the assistant in a comfortable position (Fig. 34-2). A properly designed imaging trolley should accommodate the monitor at a convenient height (Fig. 34-3). It should have space for the camera control unit, light source, video recorder, printer, and the insufflators. The use of antifogging solution or laparoscopic warming devices helps prevent condensation of fog that might obscure the field.

Some surgeons use three or more flat-screen monitors attached to the ceiling with an adjusting unit for better placement. A video recorder to record the conduct of the procedure can be utilized for documentation and for teaching purposes. More recently it has become possible to digitally record surgeries on hard drives. Printers should be available in the operating room (Fig. 34-4) and may be most helpful in later discussing the surgical findings with the patient and in maintaining the patient's chart. Alternatively, the image could be recorded on a floppy disk in digital mode, which can be then enhanced with the computer for printing. This may ultimately be stored in a digital format in an electronic medical record.

#### Light Source

The best illumination for laparoscopic surgery is by xenon light (Fig. 34-5). It is associated with minimal heat conduction via a light cable to the laparoscope. However, direct contact of the cable with a patient's skin or operating drapes can result in a thermal burn. The light should only be turned on after the light cable is attached to the laparoscope. Most of the light sources available are capable of manual and automatic adjustment for optimal illumination. The light cables may be fiberoptic or liquid gel with a diameter between 3.5 mm and 6 mm, with the length ranging from 180 to 350 cm. These cables have a limited life span and should be treated carefully because the individual fibers may break, ultimately diminishing the amount of transferred light to the endoscope.

#### High-flow Insufflators

The availability of a high-flow electronic insufflator that can administer several liters of CO<sub>2</sub> gas per minute is mandatory for advanced laparoscopic surgery (Fig. 34-6). Frequent instrument changes, as well as irrigation and aspiration during a procedure, lead to a rapid loss of pneumoperitoneum. Gas will only flow into the peritoneal cavity under pressure. The higher the pressure, the greater the risk of gas being forced into the circulation, with

## Minimally Invasive Surgery

Table 34-1 Basic Laparoscopic Instruments for a Single Laparoscopic Set	
Instrument	Number
Laparoscopes	
10-mm straight forward 0-degree laparoscope	2
5-mm 0- or 30-degree laparoscope	1
Trocars	
10-mm primary trocar	1
10-mm secondary trocar	1
5-mm secondary trocars	2
20-mm trocar for the morcellator	1
10 to 5 mm, 20 to 10 mm, and 20 to 5 mm reduction sleeves	3
Suction irrigation system	1
Bipolar forceps with cable	
Bipolar grasping forceps	2
Bipolar microforceps for tubal surgery	1
Unipolar instrument with cable	
1-mm needle electrode for ectopic pregnancy	1
Unipolar scissors for myomectomy	1
Forceps	
Atraumatic grasping forceps	1
5-mm grasping forceps with 2 × 2 teeth	2
10-mm claw forceps	1
Scissors	
Metzenbaum scissors	1
Hook scissors	1
Microdissecting scissors	1
Suture and ligature	
Needle holder	1
Assistant needle holder	1
Suture manipulator (knot pusher)	1
5-mm laparoscopic aspiration needle	1
Optional	
Morcellator, possibly in a separate set for myomectomy or hysterectomy	1
Disposable scissors, laparoscopic pouch, pretied ligature, lens defogger	Separate

**Figure 34-5** Xenon light source. (Courtesy of Stryker Corporation, San Jose, CA)

a possible risk of gas embolism. A pressure of 10 to 15 mm Hg is usually adequate.

During initial insufflation a small amount of gas should be instilled to ascertain appropriate placement. Once this has occurred and trocars are in place, insufflation may be set to as much as 40 L/min.

More recently, insufflators that allow heating of gas before entry into the peritoneal cavity have been developed. These bring the gas to core temperature, which may decrease hypothermia and improve patient recovery.<sup>1</sup>

### Laparoscope

Different diameter laparoscopes are available, ranging from 1.8 to 12 mm. The straight forward telescopes with 0-degree angle are generally preferred by gynecologists as they look into the pelvic cavity because there is a large viewing angle.

However, the choice of telescope depends on the surgical procedure. For laparoscopy under conscious sedation a small laparoscope is preferable, whereas a larger one is usually used for procedures under general anesthesia or where tissue removal will be required.

Laparoscopes do not magnify the image as does a microscope, but the closer the scope is to the tissue the greater the magnification. Depending on the camera, zoom capability, and the

**Figure 34-6** High-flow insufflator. (Courtesy of Stryker Corporation, San Jose, CA)

distance between the lens and the tissue, magnification of up to 40x can be achieved. This is especially important for procedures such as tubal reanastomosis.

Having both a 5- and 10-mm laparoscope available on the tray may be beneficial to the surgeon, because many surgeons use a larger 10-mm or greater port infraumbilically and 5-mm ancillary ports. This allows the surgeon the ability to readily move from one port to another with either size laparoscope.

Foreoblique laparoscopes may also be of value in performing advanced laparoscopy. For example, a 30-degree laparoscope may be helpful in performing work deep in the pelvis or in patients with substantial adhesive disease.

Another option is an operative laparoscope, which contains an operating channel through which various grasping and other laparoscopic instruments may be placed. Some surgeons prefer this type of instrument because it may decrease the need for an additional ancillary trocar. Other surgeons feel that the necessary diminution in the size of the endoscope to allow the operating channel, as well as the inability to move the operating instrument used through this channel outside of the axis of the instrument, limit its usefulness.

### Veress Needle

Although some surgeons choose to use either direct or open trocar insertion, many gynecologists prefer using a Veress needle for insufflation prior to trocar insertion. There are disposable and nondisposable types of Veress needle. The Veress is a long needle with a blunt hollow spring-loaded trocar in its center. The blunt trocar springs back at and through the resistance of the abdominal wall, and springs out again to protect the viscera from the needle once the resistance disappears within the abdominal cavity. Gas flows through the hollow to create the initial pneumoperitoneum. The bore of the needle limits the initial flow during insufflation. The surgeon will have tactile sensation to feel the entrance of the needle through the abdominal wall, especially the fascia and the peritoneum. This may be limited if the patient has had prior surgery and significant scarring exists.

More recently, radially dilating devices have been developed that allow dilation to be performed outward after placement of the device (Fig. 34-7). In essence these are a hybrid of a Veress needle and a trocar.

### Trocars, Reducers, and Access Devices

A variety of disposable and reusable trocars are available. The cannula or port is a tubular device through which operative access is obtained. Many cannulae have a sharp trocar to facilitate passage through the abdominal wall and a valve or membrane to prevent the leakage of gas when no instrument is in place.

Most of the cannulae have a rubber seal at the top through which telescope and instruments may be passed without the loss of pneumoperitoneum. There are three general types of trocars: a conical trocar, which is less traumatic to the tissue but requires greater force for entry; a pyramidal trocar that makes it easier to enter the abdominal wall with less force; and a Hasson cannula, a blunt trocar that is used for the open laparoscopy technique.<sup>2</sup>

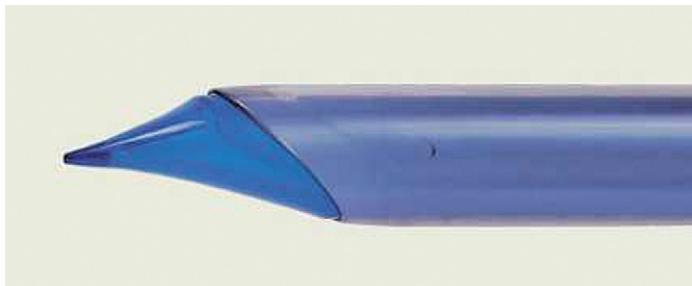

Many surgeons use three or more trocars when performing advanced laparoscopy, a 10-mm primary trocar at the infraumbilical area for the laparoscope and two secondary 5-mm

**Figure 34-7** Radially dilating trocar with needle. (Courtesy of U.S. Surgical, Norwalk, CT.)

trocars. One of the two secondary trocars may be 10 mm or larger if removal of a specimen is anticipated. For removal of a large or solid mass such as a uterus or myoma, a 15- or 20-mm trocar is used to accommodate a morcellator.

More recently, blunt-tip nonbladed trocars have been developed that are able to penetrate through the various layers of the abdominal wall (Fig. 34-8). In some cases this penetration may be performed with a laparoscope in place to observe the trocar moving through the tissues. Unfortunately, no large com-

**Figure 34-8** Blunt-tip trocar. (Courtesy of Taut, Inc., Geneva, IL)

parative trials exist to better define if a specific trocar type is inherently safer than another.

### Suction-Irrigation

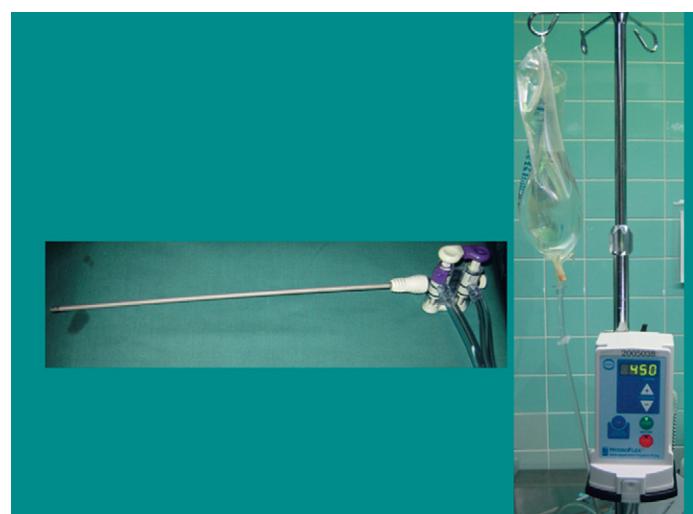

The addition of simple suction and irrigation devices was important historically for the evolution to advanced endoscopic techniques. With modern irrigators we are able to quickly evacuate blood, fluid, and ovarian cysts, markedly facilitating surgery. A powerful suction-irrigator that can deliver pressure of up to 800 mm Hg is thus invaluable for operative laparoscopy. The suction-irrigation probe should have a single channel for both functions, with the flow controlled by a hand-valve system (Fig. 34-9).

### Laparoscopic Aspiration Needle

A 5-mm aspiration needle is used to aspirate peritoneal fluid for cytology (alternatively the suction-irrigator may be used). It can also be used to inject vasopressin into the uterus or myoma, or saline solution for hydrodissection.

### Bipolar and Unipolar Instruments

The main principles of a good electrosurgical system are to cut, coagulate, and vaporize tissue (Fig. 34-10). The electrosurgical tool uses electrons in a closed electrical circuit. In the bipolar system, the active electrode and the neutral electrode (grounding pad) are built into the tip of the instrument. Thus interaction is limited to a small area of tissue, which may result in a safer and lower energy input. A bipolar grasping forceps should always be available for hemostasis at any laparoscopic surgery. These cannot be substituted by unipolar forceps or laser. Most bipolar forceps are available in a 5-mm diameter. A microbipolar forceps allows precise and limited coagulation during delicate surgery such as laparoscopic tubal anastomosis. One such device, the Ligasure, has been developed. It uses the principles of the bipolar system and can be used as a grasping or clamping instrument (Fig. 34-11). Another variation is the “tripolar device,” in which a sharp blade is passed through bipolar forceps once tissue has been coagulated (Fig. 34-12).

**Figure 34-9** Disposable unit of suction-irrigation system.

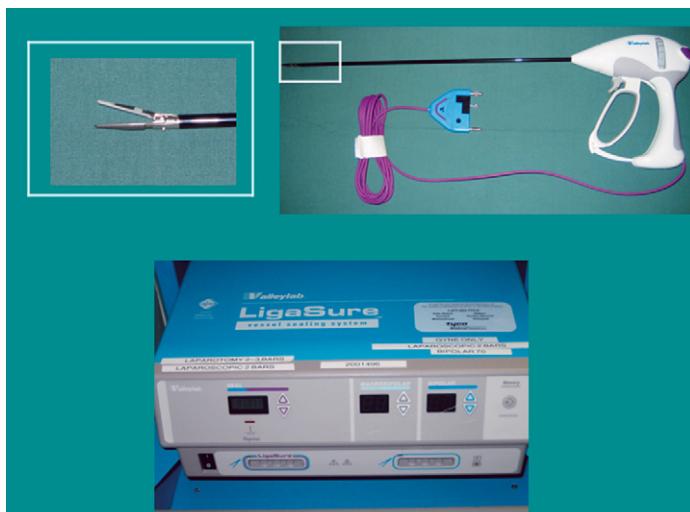

**Figure 34-10** Bipolar/unipolar generator. (Courtesy of ConMed Corporation, Utica, NY.)

Unipolar forceps are rarely used today. However, many other types of unipolar instruments may be safely and effectively used during laparoscopic surgery. In this system, electrons flow from the electrosurgical unit to the active electrode. From the tip of the electrode, the current will flow through the air to the tissue. The current then will be conducted through the body to the ground plate attached to the patient and returns to the electrosurgical unit. Some examples of unipolar instruments include unipolar needle electrodes to perform salpingostomy for ectopic pregnancy and occasionally for laparoscopic ovarian drilling and unipolar scissors to make a uterine incision during myomectomy or lysis of adhesions.

### Laser

There are several types of surgical lasers, including CO<sub>2</sub>, argon, potassium titanium phosphate (KTP), and neodymium:yttrium aluminium garnet (Nd:YAG). Their properties depend on the characteristics of the laser beam, the nature and the color of the

**Figure 34-11** Ligasure device. (Courtesy of Valleylab, Boulder, CO.)

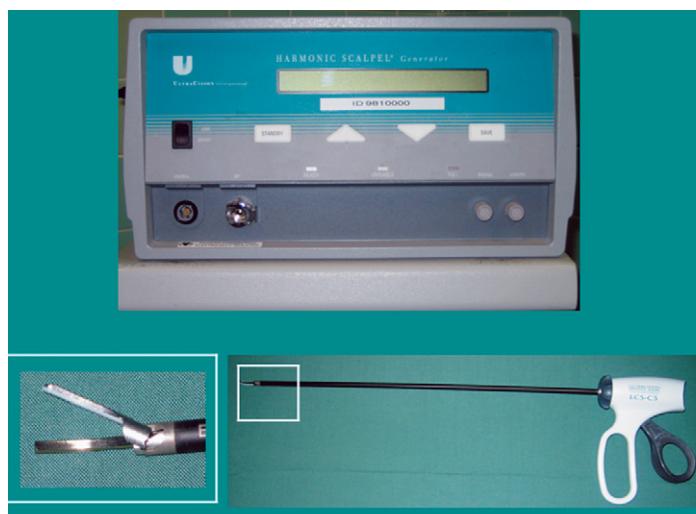

**Figure 34-12** “Tripolar” device. (Courtesy of Circon-ACMI, Stamford, CT.)

structure in its path, the irradiation spot size, and the exposure time. Lasers with long wavelength are more effective for tissue vaporization but poor for coagulation. Lasers with short wavelength, on the other hand, have good coagulation but poor vaporization properties.

Studies have shown that the results of laser surgery are similar to those with conventional laparoscopic instruments. Therefore, use will depend on surgeon preference and experience.

### Ultrasonic Vibrating Scalpel (Harmonic Scalpel)

The ultrasonic scalpel consists of a generator and a handpiece that houses the ultrasonic transducer (Fig. 34-13). When activated, the scalpel blade moves longitudinally at 55,000 vibrations per

**Figure 34-13** Harmonic scalpel. (Courtesy of Gynecare, a division of Ethicon, Inc., a Johnson & Johnson company, Somerville, NJ.)

**Figure 34-14** Different types of laparoscopic forceps.

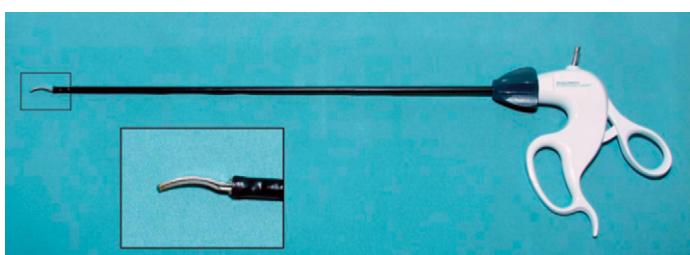

second. This allows several different tissue effects, including the ability to cut through tissue as well as seal vessels. Because little heat is produced (usually under 80°C), necrosis and charring are minimal. Initially the ultrasonic scalpel was available only in larger handpieces, but newer technology has allowed development of 5-mm handpieces, which no longer require control with a footswitch.

#### Dissecting and Grasping Forceps

Grasping instruments are available in different sizes, shapes, and forms (Fig. 34-14). There are two types of grasping forceps: traumatic or atraumatic. Traumatic forceps, such as the 5-mm grasping forceps with 2 × 2 teeth, allows secure grasping of tissue. Babcock atraumatic forceps are invaluable for gentle handling of fallopian tubes. A 10-mm claw forceps used with a morcellator permits efficient removal of a solid specimen. There are also many different types of handles: scissors type, angled, or non-angled. Their use depends on surgeon preference.

#### Scissors

It is important to have scissors that cut and do not tear the tissue. A wide variety of scissors is available (Figs. 34-15 and 34-16). The curved-jaw scissors are multipurpose but are usually used for dissection. Fine-pointed curved or straight microscissors are used for microdissection. Hooked scissors are used for cutting ligated vessels. In practice, all these instruments are used interchangeably.

**Figure 34-15** Disposable scissors.

**Figure 34-16** Reusable scissors.

A combination of cutting and coagulating can be obtained by incorporating unipolar current to the scissors. Nondisposable scissors used many times tend to become dull; therefore, many surgeons prefer to use disposable scissors.

#### Instruments for Laparoscopic Suturing

Laparoscopic suturing is needed in several procedures, including myomectomy, tubal anastomosis, or closure of the vaginal cuff during laparoscopic total hysterectomy (Fig. 34-17). Suturing might also be needed to repair intestinal laceration and ureteral or bladder injury.

#### Needle Holder

Besides a longer shaft, the design for the needle holder used in laparoscopic suturing is similar to that used for conventional surgery. The handles could be offset aligned or aligned in the axis as the shaft. The offset alignment is beneficial if the surgeon's arm is extended, whereas the in-line variety is useful for suturing near the anterior abdominal wall.

The jaw could be aligned with the shaft or curved. Side-loading needle holders are available for curved needles; however,

**Figure 34-17** Basic instruments for a single laparoscopic set.

Instruments for suturing are not shown.

the handle is often very stiff. Most needle holders are 3 to 5 mm in diameter.

#### **Needles and Sutures**

The type and size of needles and sutures depend on the procedure. For example, a curved needle with 1-0 suture is used to repair a uterine defect after a myomectomy, and 6-0 to 8-0 sutures are needed for laparoscopic tubal anastomosis. Conventional laparoscopic suturing can be done using ski or straight needles with 3-0 or 4-0 sutures.

#### **Knot Pusher**

Sutures can be tied intracorporeally or extracorporeally. The use of a knot pusher or suture/knot manipulator allows extra-corporeal knot tying. Compared to an open-end knot pusher, the closed end ensures that the suture stays connected to the end of the device. After suturing, the needle is extracted from the abdominal cavity and inserted into the fenestration of a closed-end knot pusher. The surgeon makes a knot and the knot is pushed into the abdominal cavity.

#### **Ligature**

Endoloop (Ethicon, Somerville, NJ) is a loop with a preformed slipknot that can be positioned around the tissue to be removed. These are best used when a tissue pedicle exists. In the absence of this commercial product, a piece of suture material with or without the needle attached may be used to ligate. Alternatively, the surgeon can ligate a structure using a self-made slipknot prepared extracorporeally and inserted into the abdominal cavity using a knot pusher.

#### **Clips and Staples**

A single- or multiple-clip applier should be available for emergency situations, such as rapid occlusion of an isolated bleeding vessel. They are made of metal or absorbable plastic. In addition, endoscopic GIA staplers have now been readily available for well over a decade. These come in multiple different forms with several sizes of staples.

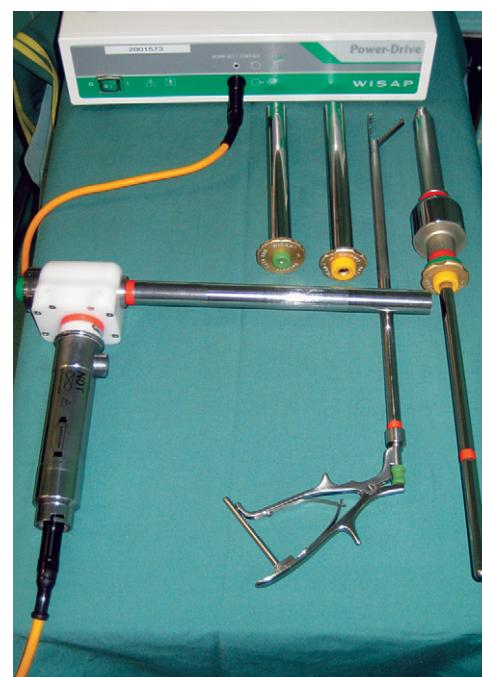

#### **Morcellator**

Use of electronic morcellators has supplanted handheld morcellation devices. Electronic morcellators are able to quickly and efficiently remove large amounts of solid tissue from the abdominal cavity. This is especially helpful during laparoscopic myomectomy or supracervical hysterectomy. In a time and cost analysis, Carter and McCarus found power morcellators to be cost effective.<sup>3</sup>

Tissues are held by the grasping forceps, morcellated in pieces, and subsequently removed. Morcellators are available in multiple different versions and a range of sizes (Fig. 34-18). Generally the morcellator is placed at the site of one of the secondary trocars. It is important when using these devices that tissue is brought toward the morcellator and that the morcellator is not moved toward the tissue where vascular or other injury may occur.<sup>4</sup>

#### **Laparoscopic Pouch**

Removal of an intact cyst using a disposable extraction pouch prevents spillage of the contents of the cyst into the abdominal

**Figure 34-18** Instruments for morcellation. (Courtesy of WISAP, Munich, Germany)

cavity and contamination of the abdominal wall during extraction of the specimen (Fig. 34-19). They are also useful in removing ovaries, adnexa, or other larger pieces of tissue from the abdomen. Multiple different pouches are available in a range of sizes and materials from a number of manufacturers. Care should be used when extracting these bags through small-diameter incisions to avoid rupture of the bag and loss of the contents back into the abdominal cavity.

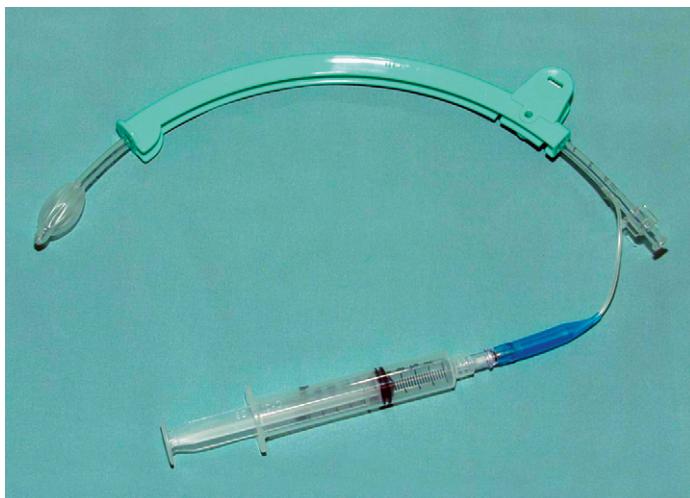

#### **Standard Dilation and Curettage Set**

This set should contain a weighted speculum, tenaculum, uterine sound, dilators, and a uterine manipulator. Disposable and non-disposable uterine manipulators (Fig. 34-20) allow chromoperturbation, anteversion, retroversion, and rotation to maximize surgical access. Another manipulator, the Rumi manipulator (Fig. 34-21), articulates around the cervix and is equipped with two balloons. The intrauterine balloon anchors the instrument within the uterus and seals the cervix, and an intravaginal balloon prevents escape of CO<sub>2</sub> gas at the completion of total laparoscopic hysterectomy.

**Figure 34-19** Endoscopic pouch.

## Minimally Invasive Surgery

**Figure 34-20** A disposable uterine manipulator. (Courtesy of Cooper Surgical Inc., Trumbull, CT)

### Hand Assistance

A novel variation on standard laparoscopy has been the development of devices to allow the endoscopic surgeon the advantage of placing a hand intra-abdominally without the loss of the pneumoperitoneum (Fig. 34-22). This offers the advantage of performing procedures where actually touching tissue with the surgeon's fingers aids the surgery while still keeping the incisions very small. A further modification has been the development of specialized retractors that allow mini-laparotomy to be used either instead of, or sometimes after a portion of the procedure is performed laparoscopically (Fig. 34-23). These devices may also be combined to give further surgical options (Fig. 34-24).

### Other Disposable Instruments

Today, many laparoscopic instruments are available in both reusable and disposable forms. Disposables tend to be lighter than reusable instruments, but questions remain regarding cost efficacy. Compared to reusable scissors and trocars, which could become dull with frequent usage, disposable trocars and scissors are always sharp.

**Figure 34-21** Rumi uterine manipulator. (Courtesy of Superior Medical, Toronto, Canada)

**Figure 34-22** Novel access device to allow intra-abdominal hand placement. (Courtesy of Applied Medical, Rancho Santa Margarita, CA.)

Due to the high expense of disposable instruments, some hospitals use reusable instruments. In any event, disposable instruments should be available in the operating theatre as a backup. The final position of the patient and the surgeons is seen in Figure 34-25 and is discussed further in Chapter 36.

### Robotics

The most recent enhancement of laparoscopic surgery is the introduction of robotics into the operating room.<sup>5</sup> Many surgeons today use voice recognition technology to raise and lower light levels, increase insufflation, and capture digital images. An addition has been the use of systems such as the daVinci Robotic Surgical System (Fig. 34-26). These systems allow the operator to work at a distance from the patient (generally within the same operating room but not necessarily; transcontinental surgeries have now been performed). The robotic instruments have multiple articulating points, which allow approximation of normal surgical movements.

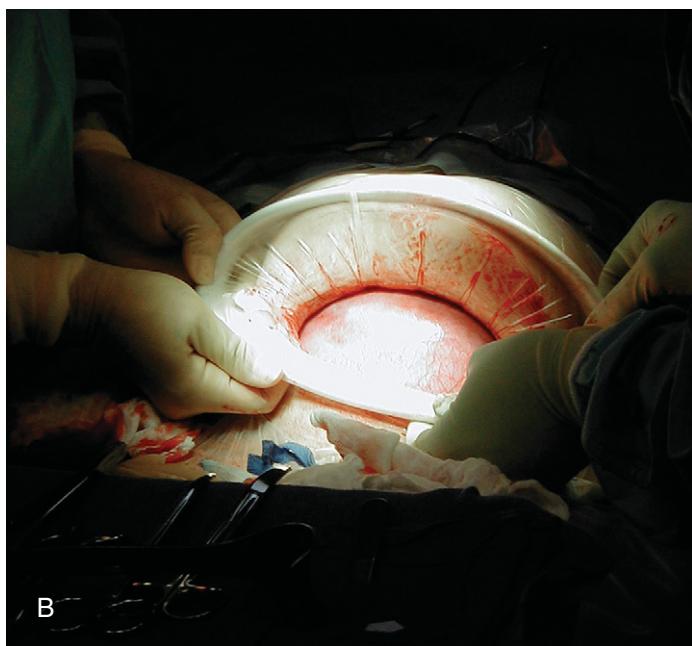

It has been suggested that robotics may allow a surgeon to perform more difficult surgery such as fine suturing (Fig. 34-27). The true cost efficacy, as well as clinical enhancements transferring to improved patient outcomes, are still being evaluated in gynecologic surgery.<sup>6,7</sup> It may be that only some surgeries are enhanced whereas others may be slowed or otherwise encumbered by this technology. A different issue is how to train and credential surgeons in the postgraduate environment on this instrumentation. One group evaluated performance of a standard tubal ligation (once laboratory and didactic training had been given) as a means to train surgeons in a graded manner.

### Simulation and Virtual Reality

Efforts have been directed to enhancing surgeon experience either before or in addition to hands-on training. With the

A

B

**Figure 34-23 A and B, Retractors for mini-laparotomy.** (Courtesy of Applied Medical, Rancho Santa Margarita, CA.)

advent of superfast microprocessors, the technology now exists to attempt to recapitulate the actual surgical experience outside of the operating room (Fig. 34-28). Early trials suggest devices that allow surgeons to improve hand-eye coordination in simulators might improve surgical function in the operating room.<sup>8</sup> In a randomized trial that used blinded and independent reviewers, surgical trainees were scored during a laparoscopic cholecystectomy. Trainees then underwent virtual reality training versus a control group, which received no additional training. Following this, the participants were again scored on an additional case. The experimental group was noted to be significantly faster, with greater improvement in error and economy of movement.<sup>9</sup>

An additional consideration is that often animals have been used to train surgeons. Use of virtual reality trainers may limit the use of animals while also decreasing the substantial costs

**Figure 34-24 Device for hand placement and mini-laparotomy combined.** (Courtesy of Applied Medical, Rancho Santa Margarita, CA.)

associated with training in an animal laboratory. At present, several manufacturers are developing specific programs to model laparoscopic, hysteroscopic, and other procedures. Although development is still in its infancy, programs have become increasingly lifelike. There may come a day when residents will

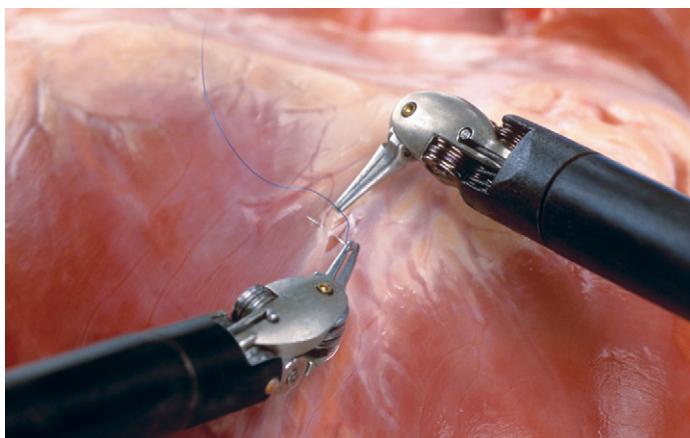

**Figure 34-25 The position of the patient, the surgeon, and the scrub technician during the preparation for surgery.** (Courtesy of Applied Medical, Rancho Santa Margarita, CA.)

## Minimally Invasive Surgery

**Figure 34-26** DaVinci surgical robot. (Courtesy of Intuitive Surgical, Sunnyvale, CA.)

**Figure 34-27** Robotic suturing instruments. (Courtesy of Intuitive Surgical, Sunnyvale, CA.)

**Figure 34-28** Laparoscopic simulation station. (Courtesy of Immersion Medical, Gaithersburg, MD.)

begin their surgical training using only simulators until specific thresholds are met. This may also offer an opportunity for post-graduate training when new procedures are developed and aid in establishing credentialing guidelines in the future.

## KEY POINTS

- Hysteroscopy is a diagnostic or operative procedure in which the distended uterine cavity is examined with an endoscope passed through the cervix.
- A wide selection of equipment and distention media are commercially available.
- Use of hysteroscopes with separate inflow and outflow channels allows improved visualization.
- Systems to monitor inflow and outflow volumes should be in place prior to operative hysteroscopic procedures.
- A common source of inadequate visualization during hysteroscopic surgery is inadequate fluid distention and inadequate outflow.

The invention of endoscopes dates back some 200 years to 1807 when Bozzini used a mechanical light conductor for inspection of body cavities.<sup>1</sup> Pantaleoni, however, performed the first hysteroscopic procedure in 1850. The early endoscopes were rigid and used oil lamps as the light source. Later, small electric filament bulbs produced light. Unfortunately, neither light source was satisfactory because of dim images and significant heat generation. For this reason, hysteroscopy fell into disfavor, and dilation and curettage became the standard of care for evaluation of the uterine cavity up until recent times. Modern hysteroscopic equipment has benefited by advances in high-intensity light sources, fiber optic cables, camera and video equipment, and distention media. No longer should a surgeon look into a “sea of red”; images should be clear with excellent diagnostic and operative capabilities.

## FLEXIBLE HYSTEROSCOPES

Flexible endoscopes have been used extensively in gastrointestinal medicine to view the stomach and colon. The flexible tip can bend 120 to 160 degrees and allow visualization around irregularly shaped structures.

A deflection control is found on the body of the hysteroscope (Fig. 35-1). Light and image bundles inside the scope carry light into the uterus and back to the eyepiece or video chip (Fig. 35-2). Diagnostic flexible hysteroscopes have one channel for the distention medium, while operative flexible hysteroscopes have an additional channel for instrumentation. The outer diameter ranges in size from 3.1 mm to 5 mm. Because of their narrow diameter and flexible tip, introduction into the uterine cavity can often be accomplished without anesthesia, which makes it an attractive office procedure.

## RIGID HYSTEROSCOPES

Rigid hysteroscopes are not flexible and contain a complex optical telescope element (Fig. 35-3). Glass lenses and spacers are precisely aligned between the ocular lens (eyepiece) and objective lens at the distal tip. The diameter of the telescope ranges from 1.9 mm (micro-hysteroscope) to 4 mm. Viewing angles typically range from 0 to 30 degrees. Oblique angle telescopes such as 12- and 30-degree hysteroscopes help visualize uterine cornua and lateral walls and may be useful when a resectoscope is employed or operative procedures such as tubal cannulation are performed. The outer diameter of the hysteroscope sheath ranges from 3 to 8 mm. Initially diagnostic hysteroscopes included only one inflow channel for passage of a distention media. Now, most hysteroscopic systems include at least one discrete inflow and outflow channel. This is particularly important when using fluid media and allows the surgeon to quickly clear even a relatively bloody field to achieve excellent visualization. Rigid, semirigid, or flexible instruments can be passed through the sheath such as scissors, forceps, biopsy instruments, or catheters (Fig. 35-4). They come in various sizes, allowing the combination of different telescope sizes and operative tools.

## RESECTOSCOPES

The hysteroscopic resectoscope is a modification of the urologic resectoscope. Original reports describe the use of the urologic resectoscope for gynecologic procedures.<sup>2–5</sup> The gynecologic resectoscope consists of a rigid hysteroscope, a working element with spring handle, and an inner and outer sheath (Fig. 35-5). The working element can be loaded with various attachments such as resection loops, rollerballs, roller bars, and point electrodes (Fig. 35-6). These tools can be advanced past the sheath of the resectoscope by pushing the working element handle forward. The passive spring mechanism allows for retraction of the tool while it exerts the desired tissue effect. The loop electrodes are used primarily to remove myomas and polyps. The needle electrode can be used for septum resection or lysis of intrauterine adhesions. The barrel or ball electrode is suitable for endometrial ablation. Electrode surface area is inversely proportional to energy density, with thin electrodes producing cutting or vaporizing effects while wide electrodes produce coagulation. Monopolar cautery is typically used, which requires nonconducting distention media and the patient to be grounded. With low viscosity distention media and continuous flow resectoscopes, adequate flushing of the uterine cavity can be achieved, allowing for good visualization and safe surgical technique.

**Figure 35-2 Schematic view of flexible endoscope.** (From Richard Wolf Medical Instrument Company Clinical Resource Manual: Care and Handling of Flexible Endoscopes, p 1.)

A bipolar electrosurgery system has been developed to avoid the risks associated with the use of hypotonic solutions. The VersaPoint system comes with a variety of electrodes. Energy is delivered from the generator to the tissue through an active electrode. The energy then seeks the path of least resistance through the saline distention media to the return electrode and back to the bipolar generator.

## DISTENTION MEDIA

Adequate distention is essential for visualization of the uterine cavity. The minimum amount of pressure necessary to achieve this is 40 to 50 mm Hg. Pressures between 70 and 80 mm Hg routinely produce good visualization for a hysteroscopic survey. The higher the intrauterine pressure, the higher the risk of medium absorption. This can be minimized by not exceeding the patient's mean arterial pressure. A variety of distention media are available. Their advantages and risks are summarized in Table 35-1.

### Carbon Dioxide

Carbon dioxide ( $\text{CO}_2$ ) is a safe<sup>6</sup> gas medium with excellent optical properties. Its low viscosity allows easy flow through the inflow portals of small hysteroscopes and makes it a good choice for diagnostic studies. However, it does not mix with blood, which makes operative hysteroscopic procedures difficult as view-obscuring bubbles form.  $\text{CO}_2$  is delivered through dedicated hysteroscopic insufflators with flow rates of 60 to 80 mL/min and preset pressure between 80 and 100 mm Hg. Laparoscopic insufflators should never be used for hysteroscopy, since high flow rates can cause a  $\text{CO}_2$  pulmonary embolism. Historically  $\text{CO}_2$  was widely used during office hysteroscopy. Now with refined, small-diameter, dual-channel hysteroscopes, many surgeons prefer a liquid medium.

**Table 35-1**  
Comparison of Hysteroscopic Distention Media

Medium	Advantage	Disadvantage	Risks
CO <sub>2</sub>	Safe <sup>6</sup> Easy to use Rapidly absorbed	Poor visibility in the presence of bleeding	CO <sub>2</sub> pulmonary embolism if flow rate exceeds 100 mL/min
Normal saline Lactated Ringer's	Isotonic	Not suitable for monopolar electrosurgery	Fluid overload
Glycine 1.5% Sorbitol Mannitol 5%	Electrolyte free Nonconductive	Hypotonic <sup>7</sup>	Hypotonic fluid overload Hyponatremia
Dextran 32% (Hyskon)	Electrolyte free Nonconductive Immiscible with blood <sup>9</sup>	Highly viscous Difficult to deliver	Hypertonic fluid overload Anaphylactic reaction

### Normal Saline and Lactated Ringer's Solutions

Normal saline and lactated Ringer's solutions are isotonic, which greatly reduces the risk of hyponatremia in the event of intravasation. However, fluid overload can still occur, making it important to keep track of inflow and outflow during the hysteroscopic procedure. Normal saline and lactated Ringer's also are low-viscosity solutions with good optical characteristics. They readily mix with blood and keep the operative field clear when used with a continuous flow instrument. Unfortunately they do not allow electrosurgical operations with monopolar current, since the electrolyte solution will disperse electro-surgical current in the uterine cavity. Because of this shortcoming, a bipolar electrosurgery system was developed. These solutions should be the media of preference for operative hysteroscopic procedures such as adhesiolysis for which electrosurgery is not required.

### Glycine

Glycine is an amino acid mixed as a 1.5% solution in water. This low-viscosity fluid is supplied in 3-L bags, making it economical and convenient for longer operative procedures. It has been used for decades by urologists for transurethral resections of the prostate because of its excellent optical properties and lack of electrolytes. However, it is a hypotonic solution and carries the risk of volume overload with concurrent hyponatremia.<sup>7</sup> Glycine metabolism generates ammonia, with the potential for encephalopathic changes in patients with underlying liver abnormalities, although the risk appears small. There have been instances of transient visual disturbances following surgery but no documented cases of persistent findings.<sup>8</sup> It is believed that glycine acts as a neuroinhibitory substance at the retina, causing these reversible changes.

### Sorbitol and Mannitol

Sorbitol and mannitol are 6-carbon carbohydrates with similar chemical structures. Their solutions in water are electrolyte free and therefore nonconductive. Similarly to glycine, significant hypoglycemia can occur in the event of fluid overload. While

## Minimally Invasive Surgery

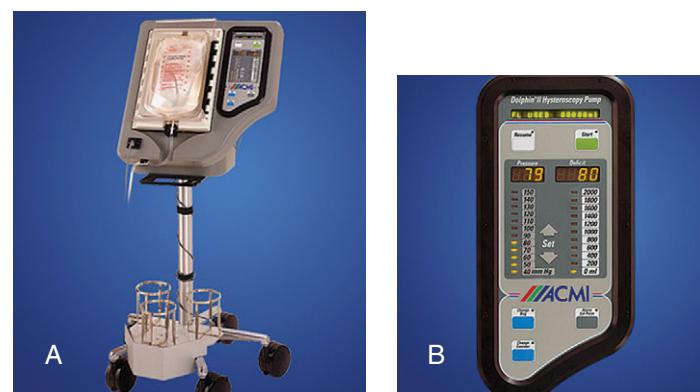

sorbitol is metabolized to glucose and fructose, mannitol is rapidly excreted by the kidney and acts as an osmotic diuretic. This gives it a theoretical advantage for prevention of fluid overload. A concentration of 5% mannitol has been suggested as a close-to-ideal distention medium.<sup>7</sup> It has an osmolarity of 274 mosm/L, similar to that of serum (280 mosm/L).

**Dextran 32% (Hyskon)**

Hyskon is a high-viscosity solution composed of dextran 70 (32% w/v) in 10% dextrose (w/v). It is electrolyte free, non-conductive, and immiscible with blood.<sup>9</sup> Its viscous nature helps prevent loss of fluid through fallopian tubes and cervix. Typically 100 mL is sufficient to distend the uterine cavity. The drawback to its high viscosity is difficult delivery of the solution through the small inflow channels of the hysteroscope. Furthermore, the hysteroscopic instruments must be washed immediately in warm water following procedures to prevent crystallization of the fluid and blockage of stopcocks. There have been reports of allergic reactions, pulmonary edema, and deaths.

**AVAILABILITY OF INSTRUMENTS**

When preparing for hysteroscopic surgery, it may behoove the surgeon to have different types of instruments available. A continuous-flow, small-caliber diagnostic instrument will allow passage in all but the most stenotic of cervixes (Fig. 35-7). Availability of an operative hysteroscope with a larger sheath improves the ability to clear the cavity because of the greater inflow/outflow capacity of the larger bore sheath. It is important that all these instruments have discrete inflow and outflow channels. Multiple instruments should be readily available

**Figure 35-8 ACMI fluid monitoring system.** A and B, Dolphin hysteroscopic fluid management system (ACMI), demonstrating fluid input/output digitally.

including scissors, graspers, and biopsy forceps. When a larger operative hysteroscope is used, these other instruments may be slightly larger and more robust. Finally, a smaller pediatric resectoscope as well as a standard resectoscope (26–28F) should be available in case the surgeon encounters a large polyp, fibroid, and so on. Multiple electrodes are available for these various sized resectoscopes. In this way the surgeon is able to treat any pathology appropriate for hysteroscopic management and to readily switch between instruments.

**FLUID PUMPS AND FLUID MONITORING**

It is critical during operative hysteroscopic or resectoscopic procedures to monitor fluid inflow and outflow. While little risk exists for substantial fluid overload during a diagnostic procedure, such small procedures often change to operative procedures. Simple systems such as a flow sheet to document input and output may be made part of the operative record. A nurse or one of the operating team may be assigned this critical responsibility. At regular timed intervals the values should be reported, and extra vigilance should be paid if there is a discrepancy of more than 500 mL in a healthy patient. More recently, pump systems have been developed that monitor and visually report inflow/outflow and any deficit (Fig. 35-8). This may be helpful to the operating surgeon who will have a continuous sense of fluid status and be able to terminate the operative procedure should the threshold be passed.

# Chapter 36

# Surgical Setup for Minimally Invasive Surgery

Ronald L. Levine, MD, and Resad Pasic, MD, PhD

## KEY POINTS

- Minimally invasive surgery (MIS) requires a different operating room (OR) configuration than that of open surgery.
- Instruments for MIS should be positioned in a standard setup within each hospital OR.
- The OR personnel, including a biotechnician, make up the team that can expedite surgery in the most efficient and cost-effective manner.

MIS has literally become the modus operandi of the practicing gynecologist. However, multiple ORs still have not adapted to routine instrument setups as they have for open abdominal cases, neither for the general surgeons nor for the gynecologists. Similarly many ORs are also not configured for MIS. ORs that are structured for a particular use or specialty can decrease turnover times and increase the efficiency of the personnel, significantly saving costs.<sup>1,2</sup>

Although many articles have been published, mainly by nursing personnel, there are no randomized controlled trials comparing various standardized setups.<sup>3–7</sup> Unfortunately, the setup of instruments and ancillary equipment in the OR varies widely from hospital to hospital, from scrub nurse to scrub nurse and from surgeon to surgeon, depending on their personal routines. In this setting randomized clinical trials are made more difficult.<sup>8</sup>

Previous chapters address the necessary instrumentation utilized in both hysteroscopic and laparoscopic surgery. The question then becomes how to prepare and set up the instruments and the operating suite for the employment of these instruments in the most expeditious manner for the surgeon, the OR nurses, and the patient. Although most scrub personal will adroitly place more than 100 instruments around the back tables of an open case, laparoscopic instruments may often all be in a large pan placed in no discernible order. Another problem that is engendered by endoscopic surgery is the necessity for a large array of electronic equipment and other “gadgets” that are frequently used in this modality. The choice of the instruments also varies greatly from surgeon to surgeon. An additional complicating factor is the plethora of new instruments that become available almost daily as this highly technology driven surgery continues to gain acceptance.

The authors can only give recommendations based on a long anecdotal experience of teaching and performing laparoscopic

surgery over more than 30 years. As equipment changes so must the set-up of the room, to meet the exigencies of the time.

## ROOM SETUP

### Personnel

The overall goal of the OR setup should be to perform safe surgery in the most expeditious manner possible; this can only be achieved by utilizing a team approach. The traditional surgical team present during open surgery remains the same during endoscopic surgery (a circulating nurse and a scrub nurse or technician) with one exception, the addition of a biotechnician. The biotechnician is a relatively new constituent of the operating suite and is becoming a standard fixture in many hospitals. This individual should be trained to address any instrument, video, or electrosurgical problems that may occur. The biotechnician need not be a nurse but should be extremely familiar with all of the multiple complex instruments that are utilized in modern endoscopic surgery. The biotechnician frequently acts as a troubleshooter in the care and assembly of the instruments employed in endoscopic surgery and may act as an assistant to the circulator by obtaining materials that may not be in the OR. This individual can shorten OR time by decreasing downtime that occurs owing to failed instrument function. It is imperative that the biotechnician be trained regarding OR procedures such as antisepsis and the standard rules of OR etiquette and behavior.<sup>9</sup>

The instruments that are used in open surgery are for the most part of simple construction with few if any movable components, whereas in endoscopy, many of the instruments have complex interchangeable parts, connections, and moving pieces, making them more subject to failure of one or more parts. Many surgeons have faced the frustration of a bipolar forceps that does not work at a crucial moment. This can be for multiple reasons: a malfunctioning electrosurgical generator, a poor connection from instrument to generator, a broken component within the forceps, or the forceps not being reassembled correctly after cleaning and sterilization. Although it should be mandatory for the surgeon to know all the instruments and be able to troubleshoot, this is not always the case. Another major problem in gynecologic endoscopy is the plethora of new instruments and energy modalities that are marketed almost daily that make it almost impossible for the surgeon to be knowledgeable of all the changes. The role of the biotechnician is to troubleshoot technical problems in order to reduce OR time. This person therefore is a cost-effective part of the OR team.

## Minimally Invasive Surgery

Many surgical nurses and scrub technicians were trained prior to the current ubiquitous use of endoscopy. It is therefore necessary for these members of the team to receive some type of postgraduate instruction in the complexities of gynecologic endoscopy. An ongoing program of in-service education should be required in a modern endoscopic surgery operating suite.

### Position of Operating Table, Equipment, and Lights for Laparoscopy

Often, little thought is given to the placement of the operating table in relation to the room. Several conditions must be met:

1. The table should be oriented so that the doors of the room are located at the head of the table or at the side of the table so that when the patient is in the lithotomy position she is not exposed to the door opening (Fig. 36-1).
2. The monitors and video equipment are best suspended from ceiling mounts. This avoids clutter and keeps the myriad of wires and connections off the floor (Fig. 36-2). The table has to be placed so that monitors can be positioned for the best view by the surgeon and the assistant. If two monitors are employed, then one may be on each side of the patient's feet, but if only one monitor is used, then it is best located between the abducted legs.

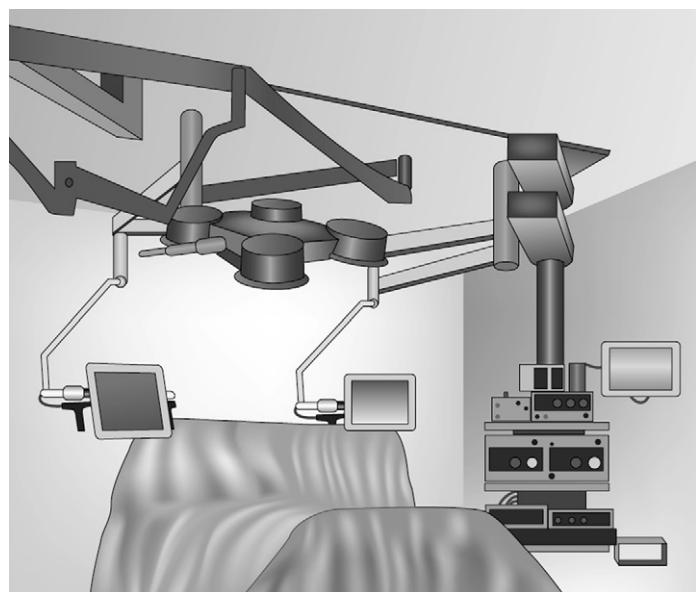

Although the OR lights are usually turned down or off during laparoscopy, they need to be positioned so that one light is over the abdomen for placement of ports and for suturing and another can be directed at the vaginal area (Fig. 36-3).

### Position of Table and Lights for Hysteroscopy

There are only minor differences in positioning from laparoscopy to hysteroscopic surgery. Since all hysteroscopic surgery is performed vaginally, the monitors are placed near the patient's side, or in the case of suspended monitors, a single monitor may be placed just over the abdomen in the midline. In either case, the monitor must be positioned for easy visual access by the hysteroscopist. The OR lights are positioned to illuminate the

**Figure 36-1** The operating table should always be placed so that the entrance to the OR is either at the head of the table or at the side to limit exposure of the patient when the door is opened.

**Figure 36-2** The ideal MIS operating suite utilizes modular units that are suspended from the ceiling and capable of moving to various positions. This keeps the myriad of wires and cables off the floor and reduces both clutter and entanglement while increasing visual acquisition.

vagina, so they should be shining from behind and above the surgeon (Fig. 36-4).

### Position of Surgeons and Staff for Laparoscopy

Traditionally, in laparoscopy prior to the use of cameras and video, the operating surgeon stood at the left side of the patient so that his or her right hand would be free to use the instruments. However, in the modern OR, the surgeon may stand on either side, often depending on which hand is the dominant one. In laparoscopy the surgeon should be able to use either hand

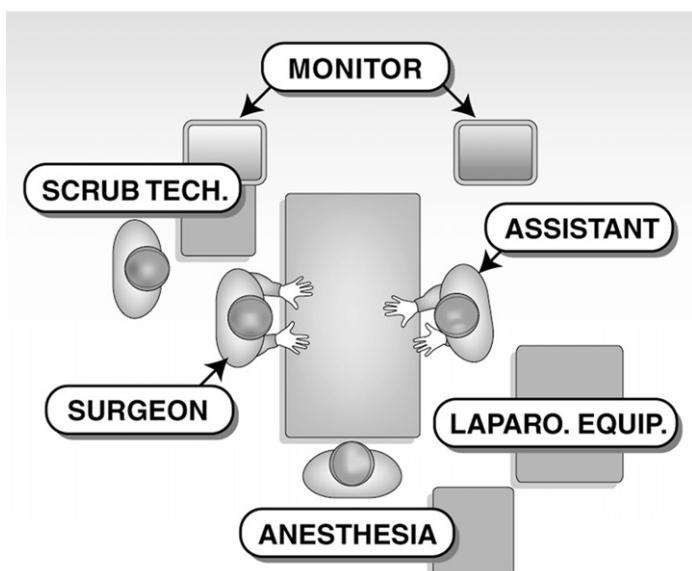

**Figure 36-3** The position of OR lights is important for the expeditious performance of surgery. If the lights are positioned prior to the onset of the operation, it saves time. Note that one light is used for the vaginal portion of the case, while the other is directly over the abdomen for port placement and site closure.

**Figure 36-4** During hysteroscopy the only necessary light is shining into the vaginal area. In this picture, the monitor is part of a modular unit, so it is to the side of the patient, but when only the monitor is suspended, it is best placed over the patient's abdomen directly in front of the surgeon.

effectively, and often the surgeon may switch sides in order to manipulate the instruments in an expeditious manner unless there is an assistant who has similar skills. If the assistant and the surgeon operate as a team, the surgery often is a beautiful ballet of the hands, and it is frequently difficult for an observer watching the screen to discern whose hands are controlling which instruments. This team approach produces the best surgical result.

As noted previously, the assistant usually stands on the opposite side of the surgeon, and the scrub person may be either between the patient's legs or behind the surgeon in the more traditional placement (Fig. 36-5).

**Figure 36-5** If two monitors are available, one should be on each side of the patient's legs. The surgeon and assistant are positioned as described in the text.

### Position of Surgeons and Staff for Hysteroscopy

During hysteroscopy, it is often unnecessary to have a formal assistant, since the scrub person can assist in the holding of instruments. In this case, the scrub person stands alongside the surgeon, who usually is sitting. The necessary instruments may be on a Mayo stand next to the scrub person.

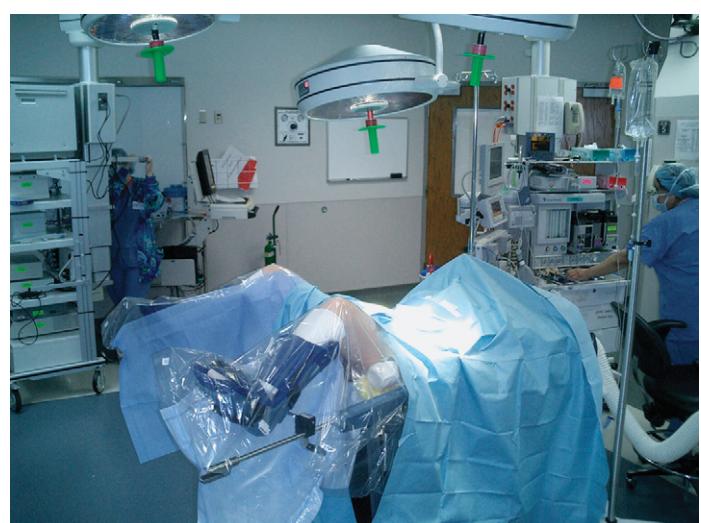

### Position of Patient for Laparoscopy

The laparoscopic surgical patient should be positioned well down on the operating table with her buttocks just over the edge to allow for the placement of a uterine manipulator that can be moved in the most advantageous manner. The feet should be placed in a well-padded boot stirrup that can be adjusted from a position in which there is no flexion of the thigh relative to the abdomen to a position in which the thigh is almost at a 90-degree angle to the abdomen to permit vaginal surgery (Fig. 36-6).

The patient's arms can be tucked in at her sides by utilizing the sides of the lift sheet. Some ORs use a plastic or metal curved shield to hold the arm close to the body. The OR personnel must be careful to protect the patient's fingers from injury when the table end is either dropped or brought back to the full position. This can be accomplished by placing and taping the hand into the bottom portion of a plastic IV bottle that has the top cut off (Fig. 36-7). The goal is to have the arms out of the way of the operating surgeon without injuring the patient. However, especially if the patient is obese, this may be difficult to accomplish and may require the arm with the IV in place to be out on an arm board. It is often possible to bring the arm up over the chest and to secure it in this position so that it is safely out of the way and there is no danger of causing injury to the brachial plexus.

### Position of Patient for Hysteroscopy

The positioning of the patient for hysteroscopy requires placing the patient in the traditional lithotomy position, either using

**Figure 36-6** The legs should be placed in a boot type stirrup that puts the weight of the leg primarily on the sole of the foot. The boot stirrup can be adjusted to either raise up for the vaginal portion of the surgery or drop so that the thigh is virtually even with the abdomen.

**Figure 36-7** The patient's arm may be held close to the body with the use of a metal or plastic shield. The fingers are protected by use of half of a plastic bottle taped in place.

candy cane stirrups or boot stirrups. If candy canes are used, then one must be careful in positioning the lower extremities so as not to place too much stretch on the femoral nerve. Boot stirrups may be preferable for longer operative hysteroscopic cases.

#### Instrument Layout for Laparoscopy

Instruments on the back table for laparoscopy should be set up in relative order of use. They should generally be in a standardized placement for the institution (Fig. 36-8). It is important that the scrub nurse be able to be relieved during an operation by other personnel without causing confusion regarding the location of instruments, particularly in the dimmed light of the OR. Individual surgeons should have a preference card on file, with a plastic-coated copy available in the OR for reference if needed by the scrub personnel (Fig. 36-9).

**Figure 36-8** The instruments on the back table are placed in an orderly fashion that may change from institution to institution.

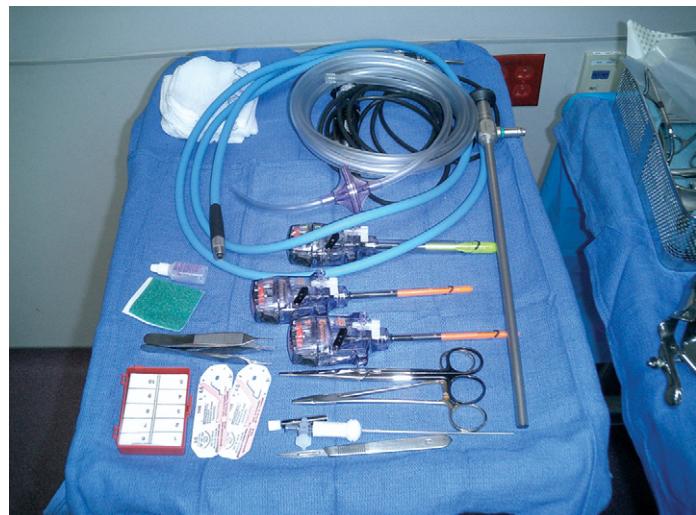

**Figure 36-9** Instruments are placed on the back table or a Mayo stand in the approximate order of use. These instruments are used during the vaginal portion of a case.

A general guide for the order of use of instruments prior to the performance of the pneumoperitoneum is as follows:

1. Vaginal specula: bivalve and weighted
2. Vaginal retractors (side wall)
3. Single-tooth tenaculum
4. Uterine sound
5. Pratt dilators
6. Sponge stick
7. Uterine manipulator

The preceding instruments may be placed in order on a back table. A Mayo stand may hold the following (Fig. 36-10):

1. Light cable
2. Camera head
3. Insufflation tubing

**Figure 36-10** A Mayo stand holds the instruments that are used during the entry phase of the laparoscopy.

4. Scopes (5 mm and 10 mm)
5. Electro-cable (for electrosurgical generator)
6. Veress needle
7. Trocars
8. Suction tubing
9. Scalpel

As stated earlier, there are a great number of laparoscopic surgical instruments and variations among them. They may be placed on the back table in a standard order for the individual OR, but they may be grouped according to use and size.

Five-millimeter instruments:

1. Graspers: traumatic and atraumatic
2. Dissectors
3. Scissors: curved and straight

A similar method can then be used for instruments of other sizes (3 mm or 10–12 mm).

The next group of instruments is those needed for closure of the incisional sites. They may be grouped on the back table. These should include the following:

1. Small S-shaped retractors
2. Needle holders
3. Suture
4. Hemostats
5. Suture scissors

Many surgeons use some newer technology pieces such as harmonic energy instruments or electrosurgery systems that require their own specialized unit to supply the energy. This type of equipment also uses an array of disposable instruments and cables that may require a single Mayo stand to hold all of the supply in one place.

### **Instrument Layout for Hysteroscopy**

Hysteroscopy requires many fewer instruments than laparoscopy. Instruments may be divided into three distinct sets: diagnostic, operative, and global ablative. However, the hysteroscopes may be interchangeable in all three sets unless they are matched or if the OR is lucky enough to have several scopes in each category of viewing angle. Each set minimally needs a 12-degree and a 25- or 30-degree scope.<sup>10</sup>

### **Diagnostic Hysteroscopy**

Diagnostic hysteroscopy requires very few instruments. The tray containing these instruments is Spartan compared with a laparoscopic setup. Often, diagnostic hysteroscopy is accomplished in the office or clinic with a small-caliber flexible hysteroscope using a syringe of saline as the uterine distending mechanism. The same technique may be used in the OR, but a rigid hysteroscope can be substituted for the flexible if needed. Rigid hysteroscopy may require some cervical dilatation, so the setup should include a dilation and curettage set that contains several types of specula (weighted and bivalves of various sizes), a uterine sound, a tenaculum, and cervical dilators.

Diagnostic hysteroscopy can be performed with either CO<sub>2</sub> gas, which requires a specialized insufflator, or with just saline or other physiologic media for fluid distention. The saline may be instilled with 60-mL syringes connected to the scope sheath

**Figure 36-11** The fluid management system should be positioned in easy view of the surgeon. A bag is in place to collect the distention fluid that is returned.

with IV tubing or alternatively as a 500- or 1000-mL bag. The entire setup may be placed on a Mayo stand.

### **Operative Hysteroscopy**

The setup for operative hysteroscopy may entail the use of a resectoscope and also requires fluid monitoring. Many surgeons use a diagnostic setup to begin their operative cases and then proceed to an operative setup. The use of a resectoscope usually requires a fluid collection system placed under the patient's buttocks with tubing that returns all fluid for an accurate accounting of input and outputs (I&Os). Newer fluid management systems may aid the surgeon and operating team in tracking fluid I&Os (Fig. 36-11). The management system should be in close proximity to the patient's side and well within the view of the operator. It is often helpful to have the electrosurgical generator on the opposite side to decrease the amount of tubing, cables, and so on, coming from this area (camera cable, fluid management tubes, electrosurgical cable, suction tubing). The position of the video monitor was described earlier.

### **Global Ablative Surgery**

Currently many global ablative techniques are available, and each has an individualized setup. Some, such as the balloon technology, require very little equipment as they do not require the use of a hysteroscope and a camera. Others, such as the hydro-thermal ablator, need essentially the same setup as required for diagnostic hysteroscopy.

### **SUMMARY**

It is worthwhile to make an effort to standardize both laparoscopic and hysteroscopic setups across obstetrics and gynecology departments. Evaluation of actual use of individual instruments may identify little used instruments or opportunities for surgeons to agree on one instrument or another for their setup. Elimination of redundancy may decrease costs for instrument cleaning, decrease time spent reassembling trays, and decrease cost of eventual instrument replacement after multiple use cycles.

# Chapter 37

# Laparoscopic Procedures

Farr Nezhat, MD, FACOG, FACS, Ali Mahdavi, MD, FACOG, and Tanja Pejovic, MD, PhD

## KEY POINTS

- Diagnostic laparoscopy is the most commonly performed laparoscopic gynecologic procedure. The main indications are infertility, pelvic pain, pelvic inflammatory disease, and suspected pelvic mass or ectopic pregnancy.
- Bipolar coagulation is the most commonly used laparoscopic tubal occlusion method in the United States. Mechanical methods make microsurgical reversal more likely to succeed.
- Laparoscopic linear salpingostomy is the method of choice for surgical management of most tubal pregnancies.
- Although clinical examination and the results of preoperative workup often indicate the benign or malignant nature of an ovarian cyst, only histologic study can provide the absolute diagnosis. Therefore, as clinically indicated for laparoscopic management of adnexal masses, the availability of immediate histologic diagnosis with frozen section is crucial.
- For women who require abdominal hysterectomy, the laparoscopic approach offers the benefit of less postoperative discomfort, shorter hospital stay, and quicker recovery.
- Laparoscopic hysterectomy is not cost effective compared with vaginal hysterectomy.
- Laparoscopic myomectomy is associated with accelerated postoperative recovery compared with laparotomy. The incidence of uterine rupture and recurrence can be slightly higher compared with an open procedure.
- If standard surgical techniques are followed, laparoscopic procedures for stress urinary incontinence and pelvic organ prolapse should have similar outcomes and cure rates compared with an open approach.
- In experienced hands, laparoscopic pelvic and para-aortic lymphadenectomy appears to be a safe, adequate, and feasible procedure, with a low complication rate.
- Surgical therapy is warranted as the first line of treatment for women with endometriosis who have pain symptoms and desire to become pregnant as soon as possible.

Gynecologic applications of laparoscopy have contributed greatly to the popularization of laparoscopic surgery. Laparoscopic gynecologic surgery has many accepted applications, from diagnostic use to facilitation of hysteroscopy and reconstructive

pelvic surgery. Gynecologic oncologists also have embraced laparoscopic techniques that are now being evaluated in prospective randomized trials. According to the American Association of Gynecologic Laparoscopists (AAGL) survey of members regarding patterns in the use of laparoscopic procedures, diagnostic laparoscopy was the most commonly performed laparoscopic procedure.<sup>1</sup>

## INDICATIONS FOR LAPAROSCOPY

The main indications for diagnostic gynecologic laparoscopy include infertility, pelvic pain, pelvic inflammatory disease, suspected pelvic masses, and ectopic pregnancy. The evaluation of pelvic pain and infertility focuses on identification of endometriosis, adhesions, or tubal blockage. Less common indications for diagnostic laparoscopy include evaluation of possible uterine perforation during dilation and curettage, evaluation of early postoperative complications, removal of foreign bodies, and evaluation of pelvic tumors before laparotomy. The workup prior to performing diagnostic laparoscopy for acute pelvic pain should include documentation of the location, severity and duration of symptoms, last menstrual period, pregnancy test, urinalysis, and complete blood count.<sup>2</sup>

## ADHESIOLYSIS

Peritoneal adhesions may cause pelvic pain, infertility, and bowel obstruction. Formation of intra-abdominal adhesions between the operative scar and the underlying viscera is a common consequence of laparotomy. Patients with midline incisions have more adhesions than those with Pfannenstiel incisions.<sup>3</sup> Patients with midline incisions performed for gynecologic indications also have more adhesions than patients with any abdominal incisions for obstetric indications.<sup>4</sup> Adhesions to the bowel are more common after supraumbilical midline incisions.<sup>5</sup>

Impairment of fertility has been a major indication for adhesiolysis, and severity of adhesions is considered an inverse prognostic factor in the success of infertility surgery.<sup>6</sup> After adhesiolysis, pregnancy rates vary according to the extent of adnexal damage and, to a lesser degree, the severity of the adhesions.<sup>7</sup>

### Formation of Adhesions

Normal fibrinolytic activity usually prevents formation of fibrinous attachments during the first 72 to 96 hours after injury. Mesothelial repair starts within 5 days after trauma when a

## Minimally Invasive Surgery

single layer of mesothelium covers the raw area, replacing the fibrinous exudates. However, if the fibrinolytic activity of the peritoneum is suppressed, fibroblasts will proliferate and form adhesions with collagen deposition and vascular proliferation. Factors that suppress fibrinolytic activity and promote postoperative adhesion formation are ischemia, drying of serosal surfaces, excessive suturing, traction of the peritoneum, blood clots in the peritoneal cavity, infection, prolonged surgery, and adnexal trauma.<sup>3</sup>

The current opinion is that operative laparoscopy may be more efficient than laparotomy in treating postoperative adhesions and should be the initial step in their management when clinically appropriate. Several animal and clinical studies compared the formation of postoperative adhesions after fertility-promoting operations by laparotomy and laparoscopy. With few exceptions, laparoscopy resulted in the development of fewer re-formed adhesions and new (*de novo*) adhesions.<sup>8,9</sup>

Decreased adhesion formation after laparoscopic surgery has been attributed to the reduced presence of foreign bodies within the peritoneal cavity that usually stimulate dense and more numerous adhesions. The type of injury to the peritoneum also influences the formation of adhesions. The potential to form adhesions is much higher in visceral than in parietal peritoneum.<sup>10</sup> Transperitoneal laparoscopy induced fewer adhesions than transperitoneal laparotomy. Also, there is a presumed advantage of the extraperitoneal approach in avoidance of adhesion formation because peritoneum remains intact and direct contact with intra-abdominal structures is thereby avoided. However, when the peritoneum is dissected off the abdominal wall, it is partially devascularized, leading to potential scars and adhesions. Interestingly, in a murine model, the totally extraperitoneal approach did not completely prevent the formation of adhesions.<sup>11</sup>

Three or four abdominal puncture sites are necessary to perform adequate adhesiolysis: an infraumbilical site for the video-laparoscope and two lower quadrant and one suprapubic trocar for the instruments. Through the lateral trocar at the assistant's side, an atraumatic grasping forceps is inserted to hold the adhesion, stretch it, and identify its boundaries and avascular planes. The opposite trocar is used for scissors or the suction-irrigation probe. Adhesions are cut close to the involved organ at both ends and may be removed from the abdominal cavity if possible. Vascular adhesions are coagulated with laser or micro-electrodes before being cut. Intestinal adhesions may be cut first, followed by parovarian and peritubal adhesions. This approach allows for progressive exposure of the pelvic structures. Grasping forceps are essential for applying traction to the ovary, tubes, bowel, and the abdominal wall to identify a free plane of dissection. Whenever possible, either the adhesions or the ovarian ligaments are grasped rather than the ovarian cortex to reduce trauma to the ovary. Once the ovaries are mobilized, the peritubal adhesions are freed. Adhesions can be safely coagulated and incised with a CO<sub>2</sub> laser, superpulse (40 W) laser, ultrapulse (20–80 W and 25–200 mJ) fiber laser (15–25 W), or micro-electrode (15–20 W in cutting mode).<sup>3</sup> In the case of dense adhesions, hydrodissection with a suction-irrigator may be useful to create tissue planes before dissection. Once the pelvic structures are freed, the cul-de-sac is filled with lactated Ringer's solution and the adnexa are allowed to float. Filmy adhesions

become visible and can be removed from their attachments by microdissection. Fimbrial folds also float and disperse in the fluid, and their adhesions become visible and amenable to dissection with fine scissors or the ultrapulse laser. Laser beams other than ultrapulse are greater than 1 mm and therefore too wide for these adhesions. Thermal damage may occur with electrosurgery or the fiber laser and thus may not be optimal in these delicate procedures.

## STERILIZATION

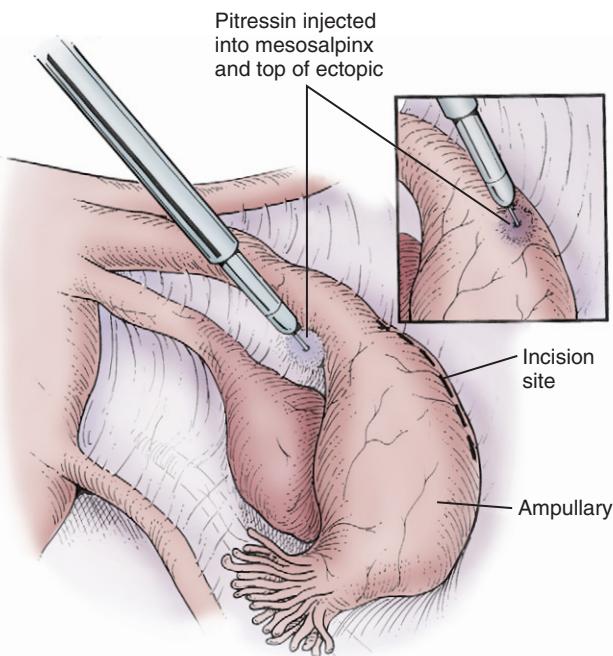

The use of laparoscopy as a safe outpatient sterilization technique has contributed greatly to the popularity of laparoscopy in gynecology. Single, double, and triple puncture techniques have been described. Techniques for tubal occlusion have included electrocoagulation, mechanical methods, and ligation methods. Bipolar coagulation is now the most commonly used laparoscopic occlusion method in the United States.<sup>12</sup> To maximize the effectiveness of bipolar coagulation, at least 3 cm of the isthmic portion of the fallopian tube must be completely coagulated by use of sufficient energy (25 W) delivered in a cutting waveform. Use of a current meter, rather than a visual endpoint or a defined period, has been suggested to indicate complete coagulation. Mechanical occlusion devices commonly used in the United States include the silicone rubber band (Falope ring), the spring-loaded clip (Hulka-Clemens clip), and the titanium clip lined with silicone rubber (Filshie clip). Mechanical methods have no associated risk of electrical burn and destroy less of the fallopian tube (5 mm for clips and 2 cm for rings), making microsurgical reversal more likely to succeed. The silicone band can only be applied to a fallopian tube that is sufficiently mobile to allow it to be drawn into the applicator; tubal adhesions or a thickened or dilated fallopian tube increase the risk of misplacement and subsequent failure. Techniques for laparoscopic ligation and resection of portions of both tubes have also been described.

The 5-year and 10-year pregnancy rates, respectively, for different methods are as follows<sup>13</sup>: bipolar coagulation: 16.5 and 24.8 per 1000 procedures, silicone band methods: 10 and 17.7 per 1000 procedures, and spring clip: 31.7 and 36.5 per 1000 procedures.

The risk of ectopic pregnancy varies substantially with the method and timing of sterilization. Based on CREST (U.S. Collaborative Review of Sterilization) study data,<sup>13</sup> bipolar coagulation had the highest cumulative probability of ectopic pregnancy (17.1/1000), and postpartum partial salpingectomy had the lowest cumulative probability (1.5/1000).

## ECTOPIC PREGNANCY

The treatment of ectopic pregnancy has been dramatically changed over the last 15 years by the use of operative laparoscopy and chemotherapy (see Chapter 15). Initially the management included salpingo-oophorectomy; thereafter, salpingectomy by laparotomy. With the development of laparoscopic techniques, linear salpingostomy became the method of choice for surgical management of an unruptured tubal pregnancy. Tubal salvage has been further improved by the use of methotrexate in selected hemodynamically stable patients.<sup>14</sup> Today, ruptured tubal pregnancies are treated successfully by endoscopy if the bleeding has

**Figure 37-1** Injection of vasopressin into the mesosalpinx and the incision site.

ceased or is stopped adequately. A 10-mm suction instrument quickly cleanses the abdominal cavity. Forced irrigation with lactated Ringer's solution dislodges clots and trophoblastic tissue from the serosa with minimal trauma.

For unruptured tubal pregnancies, the tube is identified and mobilized. To reduce bleeding, 5 to 7 mL of diluted vasopressin (20 units in 100 mL normal saline) is injected with a 20-gauge spinal or laparoscopic needle into the mesosalpinx and over

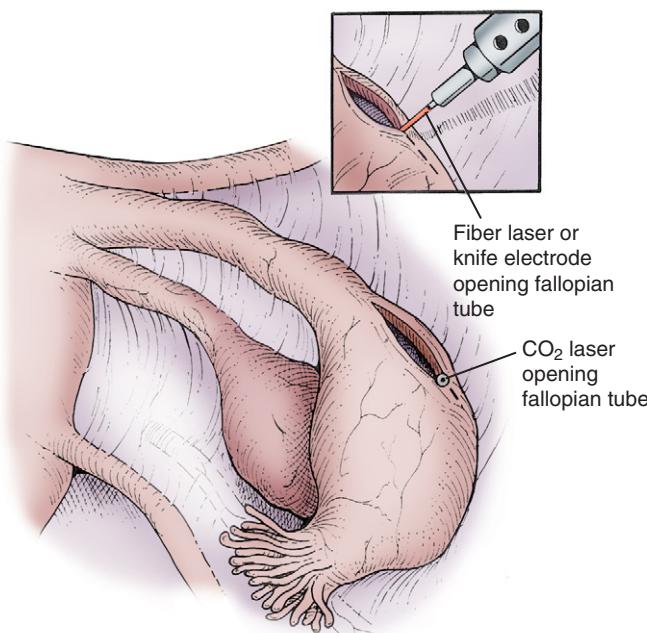

the antimesenteric surface of the tubal segment containing the gestational products (Fig. 37-1). With a laser, microelectrode, or scissors, a linear incision is made on the antimesenteric surface extending 1 to 2 cm over the thinnest portion of the tube containing the pregnancy (Fig. 37-2). The gestational products usually protrude through the incision and slowly slip out of the tube; it is then removed by use of hydrodissection or laparoscopic forceps (Figs. 37-3 and 37-4). Oozing from the tube is common but usually ceases spontaneously. Occasionally, coagulation is necessary with a defocused laser beam or an electrocoagulator. Salpingectomy is preferable to salpingostomy in the presence of uncontrolled bleeding, tubal destruction, or a recurrent pregnancy in the same tube.<sup>15</sup>

Salpingectomy is done by progressively desiccating and cutting the mesosalpinx, beginning with the proximal isthmic portion and progressing to the fimbriated end of the tube (Figs. 37-5 to 37-7). The isolated segment containing the gestational tissue is removed intact or in sectioned parts through the 10-mm trocar sleeve. Products of conception can be placed in an endoscopic bag (endo-bag) and removed. Adhesions or other pathologic processes such as endometriosis are treated after removal of the tubal pregnancy. The pelvic cavity should be irrigated and washed to entirely remove the gestational tissue, since reimplantation of this tissue can occur. Usually, the patient is discharged home subsequently on the day of surgery.

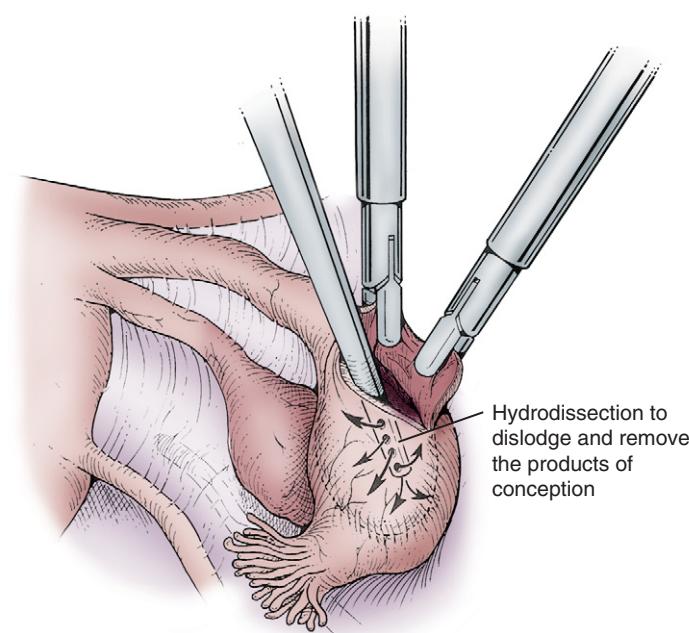

## FALLOPIAN TUBE SURGERY

Tubal abnormalities cause infertility in 20% of infertile couples. Pelvic inflammatory disease (PID), previous pelvic operations, ruptured appendix, and endometriosis are the principal causes.

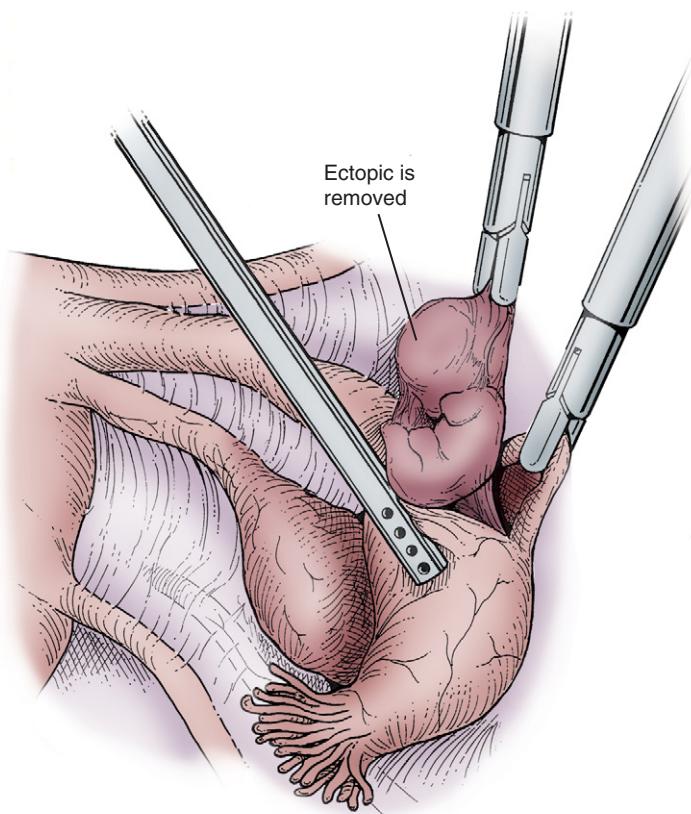

Diagnostic laparoscopy is routinely used to diagnose acute PID in Europe.<sup>16</sup> Laparoscopic procedures to treat pelvic abscesses have been described by several authors.<sup>17,18</sup> The abscesses are

**Figure 37-2** Salpingostomy is made with a CO<sub>2</sub> laser, knife electrode, or fiber laser.

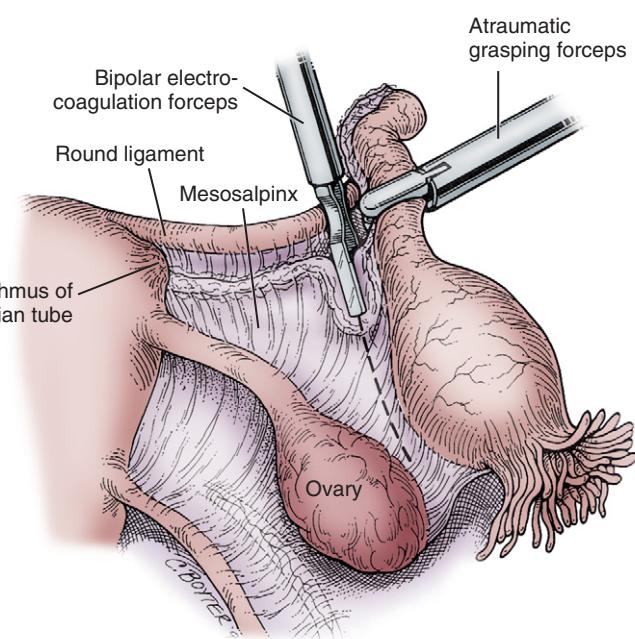

**Figure 37-3** Hydrodissection is performed to dislodge the ectopic pregnancy.

**Figure 37-4** The ectopic pregnancy is removed from the tube.

separated by means of a combination of sharp and blunt dissection and hydrodissection. After the abscess is mobilized, it is drained.<sup>19</sup> Its walls are removed in sections by the use of 5-mm graspers. The upper abdomen is also irrigated, and the remainder of the fluid is aspirated with the patient in a reverse Trendelenburg position. In contrast to the adhesions associated with an acute abscess, chronic tubo-ovarian abscesses have

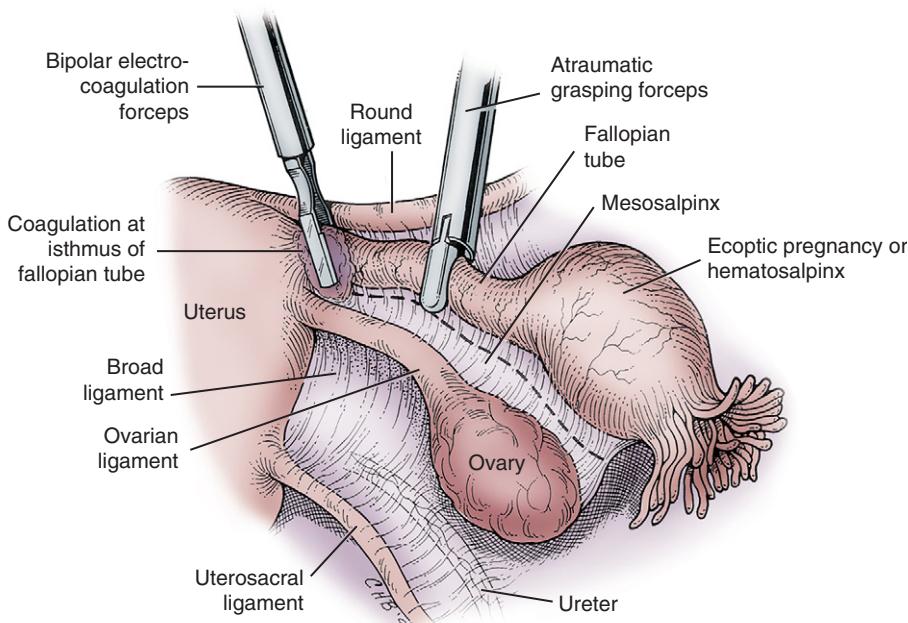

**Figure 37-6** The tube is separated from the uterus.

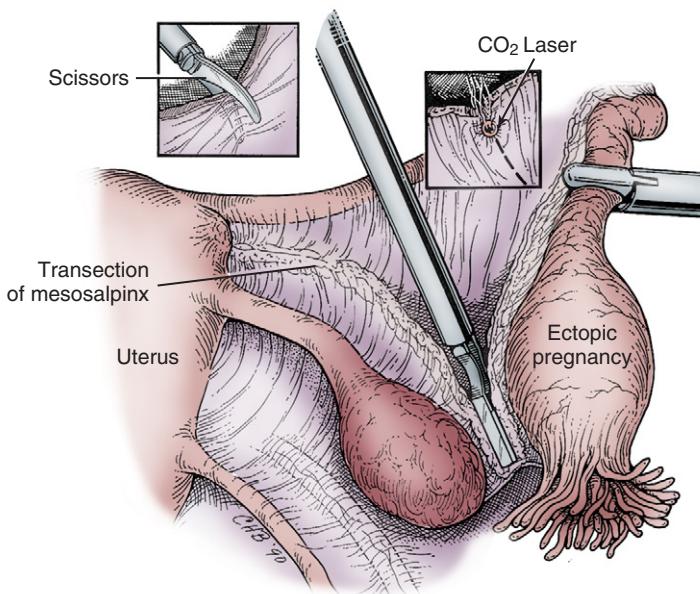

dense walls. The bowel often adheres to pelvic organs and is dissected with difficulty. The adnexa may appear as a dense mass, making it difficult to distinguish between the pyosalpinx and the ovary. In these cases, adhesiolysis is technically difficult and associated with a high risk of complications.<sup>20</sup>

Distal tubal obstruction has been treated with microsurgical techniques with pregnancy rates of 20% to 30%, 2 years post-operatively.<sup>21</sup> Fimbrioplasty and lysis of peritubal and parovarian adhesions result in the best outcome (Figs. 37-8 and 37-9).

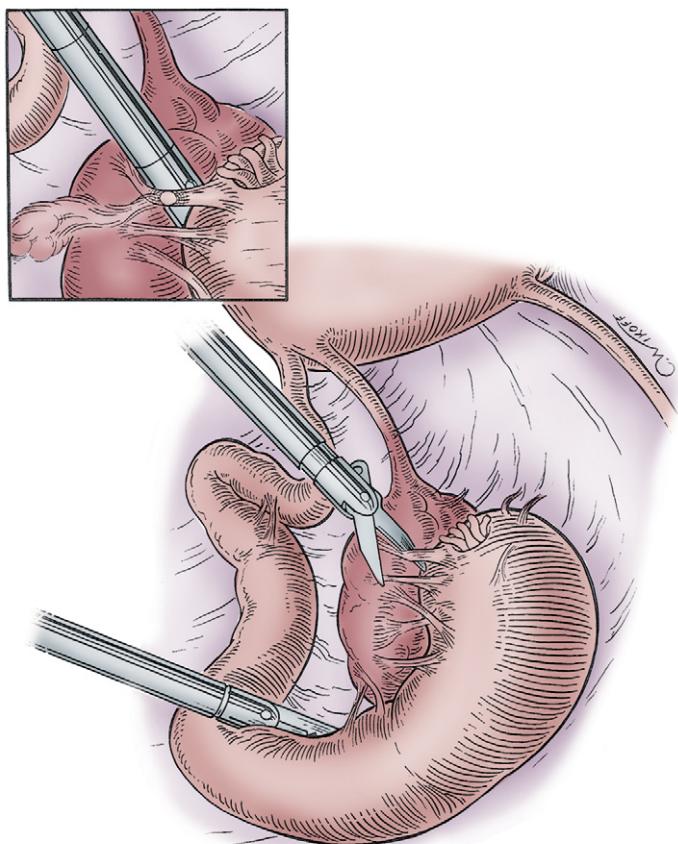

A hydrosalpinx results from distal tubal occlusion and is characterized by a dilated tube filled with clear fluid. The presence of numerous fixed adhesions and thick tubal wall are associated with poor pregnancy rates and therefore are

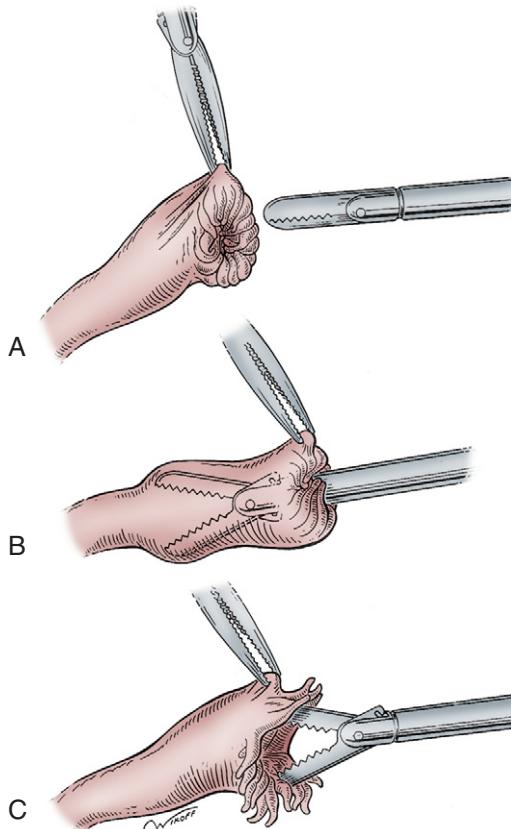

**Figure 37-5** Coagulation of the mesosalpinx is performed for complete salpingectomy. Inset shows transection of mesosalpinx with scissors or CO<sub>2</sub> laser.

**Figure 37-7** The procedure continues.

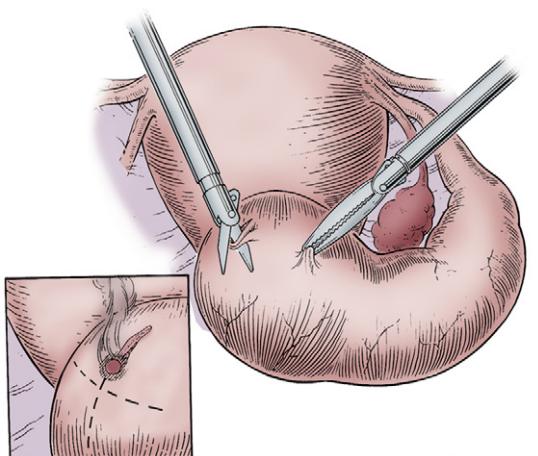

**Figure 37-8** Sharp microscissors or an ultrapulse CO<sub>2</sub> laser is used for fimbrioplasty. The tube is under traction.

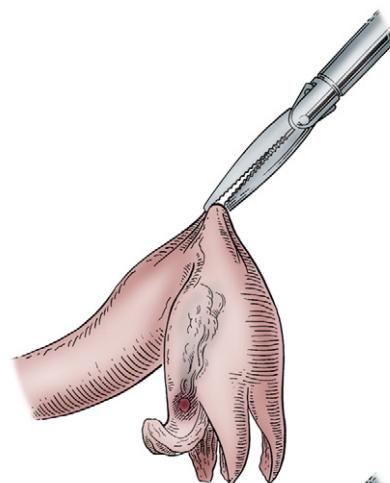

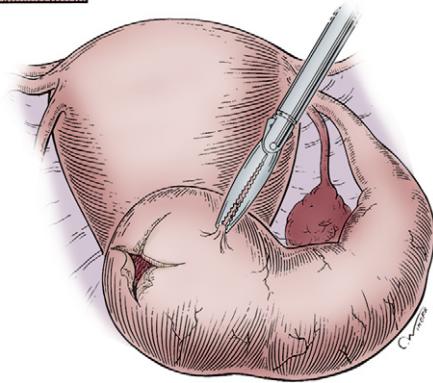

**Figure 37-9** Steps in performing fimbrioplasty. *A*, Introduction of grasping forceps. *B*, Opening the forceps. *C*, Withdrawing the forceps.

contraindications to tuboplasty. For neosalpingostomy, after the adhesions surrounding the tubes and ovaries are released, the distal portion of the tube is manipulated into position with the grasper and the uterine fundus is used as a shelf.<sup>19</sup> Fluid distention of the tube with chromoperturbation allows identification of the avascular central point that is the thinnest portion of the tube. A cruciate incision using the CO<sub>2</sub> laser or scissors creates several flaps (Fig. 37-10). The edges are flared back by use of the defocused laser (10 W) (Fig. 37-11). If the tube is thick and does not flare back with the laser, the edges are sutured to the tubal serosa by use of 4-0 to 6-0 polydioxanone. Tubal patency is confirmed by injection of diluted indigo carmine through the uterine cannula.

The goal of fimbrioplasty is to expose the fimbria to restore normal function. Tubal phimosis results from fimbrial agglutination and adhesions that bind the fimbriated end to the ovary or cover the distal end. Chromoperturbation distends the tube. If adhesions cover the ostia, they are incised with scissors and separated with a CO<sub>2</sub> laser, microscissors, a fiber laser, or a fine electrode tip (see Fig. 37-8). The tube is immobilized by using the uterus as a shelf or by steadyng its position with a blunt probe. To lyse adhesions around the fimbria, a closed 3-mm forceps is inserted into the fallopian tube through the phimotic opening. The jaws of the forceps are opened within the tube; the opened forceps are withdrawn (see Fig. 37-9). This procedure is repeated until satisfactory deglutination of the fimbria is obtained. Gentle manipulation decreases the chance of bleeding.

**Figure 37-10** Cruciate incisions in distal end of the tube. Sharp microscissors or an ultrapulse CO<sub>2</sub> laser is used.

**Figure 37-11** Ends of the tube are everted using a defocused laser beam.

The selection of patients who can benefit from tubal reconstructive operations is mostly based on the results of a preoperative hysterosalpingogram (HSG) and the laparoscopic appearance of the tubes. Although mucosal folds can be seen on HSG, the correlation between radiologic studies and endoscopy in assessing the tubal mucosa has been poor in many instances. Henry-Suchet et al,<sup>22</sup> in a study of 231 tubes during tubal microsurgery, demonstrated that salpingoscopy was more accurate in detecting tubal mucosal abnormalities than was HSG. Laparoscopic salpingoscopy permits detailed examination of the ampullary endosalpinx. The surgeon should examine and decide on treatment of the contralateral tube in a woman with tubal pregnancy.

With advances in laparoscopic microinstruments, refinement of three-dimensional video cameras, and further improvement of surgical skills, microsurgical tubal anastomosis has become possible entirely by laparoscopy. Robotic assistance may facilitate laparoscopic tubal anastomosis by filtering tremors, reducing the surgeon's fatigue, and scaling the maneuvers.<sup>23</sup>

## ADNEXAL MASS

### Etiology

Suspected ovarian neoplasm is a common clinical problem affecting women of all ages. Although the majority of adnexal masses in reproductive-age women are due to benign processes,

the primary goal of the diagnostic evaluation is the exclusion of malignancy. Extrapolating from the data of ovarian cancer, it can be estimated that approximately 5% to 10% of women in the United States will undergo a surgical procedure for a suspected ovarian neoplasm during their lifetime.

The most common adnexal masses in reproductive-age women are benign functional cysts of the ovaries, and these tend to regress spontaneously. These include follicular cysts, corpus luteum cysts, theca-lutein cysts, and polycystic ovaries. The other benign conditions include endometriosis (with ovarian endometriotic cysts), inflammatory enlargements of the fallopian tubes and ovaries (hydrosalpinges, tubo-ovarian abscess) due to pelvic infection, ectopic pregnancy, and trophoblastic disease.

True benign ovarian neoplasms can also cause adnexal enlargement. These include serous or mucinous cystadenoma and benign cystic teratomas. It is unclear whether these are precursors of malignant neoplasms, although some changes may represent true ovarian intra-epithelial neoplasia. Other neoplastic processes include parovarian cysts, pedunculated fibroids, and ovarian and fallopian tube cancers. In certain instances, the mass is clinically indeterminate and may be due to nongynecologic causes such as full bladder, stool in colon, distended cecum, peritoneal cyst, appendiceal abscess, diverticular abscess, Crohn's disease, ectopic kidney, urachal cyst, abdominal wall tumor, lymphoma, retroperitoneal sarcoma, metastatic tumor to the ovaries, and malignant diseases of the gastrointestinal system.

### Clinical Presentation and Evaluation

The majority of patients have symptoms related to compression of the pelvic organs. Less commonly, an ovarian mass is discovered during a routine pelvic examination. In patients with a malignant process, the most common clinical symptom is abdominal discomfort due to ascites. In several surgical series, the reported incidence of ovarian malignancy in patients with a preoperative diagnosis of ovarian mass ranges from 13% to 21%. The most important predictor of malignancy is the age of the patient. In fact, the risk that an ovarian neoplasm is malignant increases 12-fold from ages 12 to 29 and 60 to 69.

The evaluation of a woman with a suspected adnexal mass consists of a clinical history, including a gynecologic history and family history of ovarian or breast cancer. The physical examination should include an abdominal, pelvic, and rectovaginal examination. However, physical examination alone is often inaccurate in determining whether an adnexal mass is benign or malignant, unless there are associated findings of disseminated disease. Imaging studies are usually required for further evaluation.

There are no universally accepted criteria for the sonographic description of ovarian disease. No single gray-scale or Doppler sonographic feature allows distinction between benign and malignant adnexal masses. Although most comparison studies have found that gray-scale is superior to Doppler sonography or that Doppler offers no significant improvement over gray-scale sonography, a minority of studies report Doppler features to be superior. Sassone et al<sup>24</sup> evaluated an ultrasound scoring system to predict ovarian malignancy. Transvaginal sonographic pelvic images of 143 patients were correlated with surgicopathologic findings. The variables in the scoring system included the inner wall structure of the adnexal cyst, wall thickness, presence and thickness of septa, and echogenicity. The scoring system was useful in distinguishing benign from malignant masses, with specificity of 83%, sensitivity of 100%, and positive and negative predictive values of 37% and 100%, respectively. Subsequently, Alcazar and Jurado<sup>25</sup> developed a logistic model to predict malignancy based on menopausal status, ultrasound morphology, and color Doppler findings in 79 adnexal masses. The authors derived a mathematical formula to estimate preoperatively the risk of malignancy of a given adnexal mass in a simple and reproducible way. When this formula was applied prospectively, 56 of 58 (96.5%) adnexal masses were correctly classified.

In general, a CT scan is not indicated routinely for the evaluation of the adnexal mass. However, it is probably indicated in the evaluation of a patient with a hard, fixed, lateralized mass; ascites; abnormal liver function tests; or a palpable abdominopelvic mass.

### Tumor Markers

Serum tumor markers for malignant germ cell tumors, lactic dehydrogenase (LDH), beta human chorionic gonadotropin ( $\beta$ -hCG), and  $\alpha$ -fetoprotein should be obtained in the young patient with a cystic-solid or solid adnexal mass. Serum CA 125 and carcinoembryonic antigen (CEA) should also be obtained in patients suspected of gynecologic or GI cancer, respectively. However, in premenopausal women, CA 125 is elevated in a variety of benign conditions and may cloud, rather than clarify, the differential diagnosis of ovarian mass.

### Management

The crucial decisions regarding management of a premenopausal woman with an adnexal mass are 2-fold: to observe the patient or proceed with surgical removal of the mass, and if surgical removal is indicated, when is a laparoscopic approach justified?

During the reproductive years, cystic adnexal masses that are less than 8 cm in diameter may be followed expectantly in the asymptomatic patient, since 70% of these masses will resolve spontaneously. The patient should undergo repeat physical examination and pelvic ultrasound at a specified time interval. A common practice is to suppress ovulation with the oral contraceptive pill, but the value of this strategy remains unproved. Indications for surgery include persistence of the mass, change in ultrasonic characteristics to a more complex appearance, solid enlargement, or evidence of ascites. However, if the mass remains less than 8 cm, is simple in ultrasound appearance, and causes no symptoms, continued follow-up is a reasonable option. In the reproductive-age woman with an adnexal mass greater than 8 cm in diameter, solid appearance on ultrasound, bilaterality, and presence of ascites, surgical evaluation is indicated.

Once surgery is decided upon, keep in mind the goal of the operation: for most patients, it is the exclusion of ovarian malignancy. If a malignant ovarian neoplasm is discovered, the current standard of care is the performance of a comprehensive surgical staging procedure, followed in most cases by adjuvant chemotherapy.

Many surgeons now use the laparoscopic approach for the management of the adnexal mass in reproductive-age women. In a 1990 survey by the American Association of Gynecologic Laparoscopists,<sup>26</sup> operative laparoscopy was accomplished in most patients and there were only 53 cases of unsuspected ovarian cancer in 13,739 cases (0.04%). The benefits of laparoscopic surgery include shorter length of hospital stay, decreased post-operative pain and recovery time, and probably reduced cost. However, there are understandable persisting concerns about the laparoscopic management of adnexal masses. These include the failure to diagnose ovarian malignancies, tumor spillage, inability to proceed immediately with a staging procedure, and delay in therapy. On balance, laparoscopic surgery can be attempted for selected reproductive-age women requiring operative treatment of an adnexal mass provided there is no evidence of metastatic disease, frozen section diagnosis is available, and the patient has signed consent for comprehensive surgical staging for ovarian cancer, including laparotomy. Post-operatively, the patient should follow up with the physician to determine the need for further therapy based on the results of full pathologic evaluation of the surgical specimen. Future studies in reproductive-age women should focus on decreasing the number of patients undergoing a surgical procedure, and in patients who require surgery, further evaluation of laparoscopy as a safe, cost-effective means of treatment.

### ENDOMETRIOSIS

Endometriosis is a progressive disease that affects 10% to 15% of women of childbearing age. It is the second most frequent gynecologic disorder, with leiomyomas, affecting one third of women in their reproductive years, being more frequent. Endometriosis is the presence of the glands and stroma of the lining

## Minimally Invasive Surgery

of the uterus in an aberrant location. The etiology of endometriosis is uncertain and may involve retrograde menstruation, metaplasia, vascular dissemination, genetic predisposition, and immunologic factors. The etiology, diagnosis, and treatment are discussed in Chapter 13.

**LAPAROSCOPIC MYOMECTOMY**

Uterine leiomyomas are the most common tumor of the female reproductive tract. Although traditionally noted in 20% of women over the age of 35, leiomyomas have been noted in 50% of women at time of autopsy examination. Myomas develop from benign transformation and proliferation of smooth muscle cells and can develop in any area with smooth muscle cells of müllerian origin.

**Clinical Features**

Uterine myomas can cause abnormal uterine bleeding, abdominal and pelvic pain and pressure, urinary symptoms, and constipation. The severity of these symptoms is dependent on the number of tumors, their size, and their location. Although not primarily the cause of infertility, myomas have been linked to fetal wastage and premature delivery.

**Diagnosis and Preoperative Evaluation**

It is imperative to know the size, location, and number of uterine myomas. This is especially important in a laparoscopic approach to myomectomy, since tactile feedback is diminished. Ultrasonography is the most commonly used imaging technique in the preoperative assessment. In cases in which ultrasound results are suspect, magnetic resonance imaging also can be used to map the myomas. Before the procedure or at the time of myomectomy, the endometrial cavity must be evaluated by hysterosonogram, hysteroscopy, or hysterosalpingogram.<sup>27</sup> Before surgery, hematologic status must be evaluated. The use of gonadotropin-releasing hormone (GnRH) analogs is an option for anemic patients because it may restore a normal hematocrit, decrease the size of the myoma, and reduce the need for transfusion. Patients should be counseled about the potential for intraoperative and postoperative bleeding and the possible need for blood transfusion, conversion to laparotomy, and chance of hysterectomy.

**Treatment and Surgical Technique**

If myomas are thought to be unrelated to reproductive dysfunction or if they are asymptomatic, no treatment is indicated. The indications for myomectomy are summarized in Table 37-1.

**Table 37-1**  
**Indications for Myomectomy**

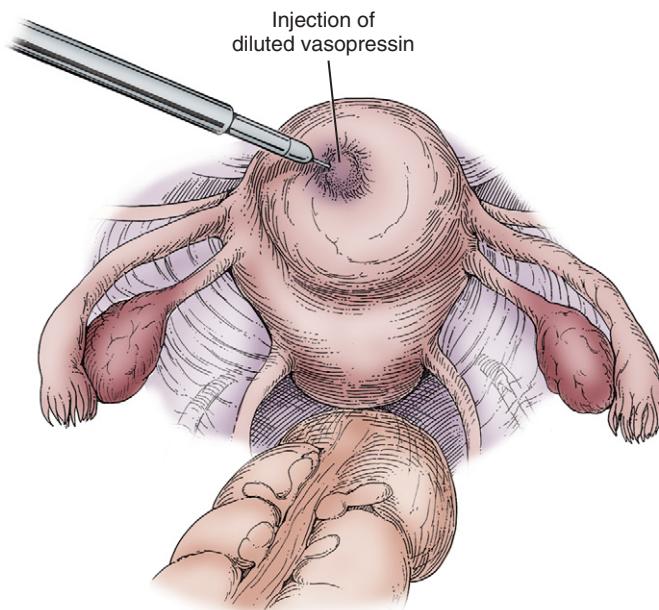

1. Iron deficiency anemia
2. Abnormal uterine bleeding (most frequently menorrhagia)
3. Rapid growth of myoma or growth after menopause
4. Infertility or recurrent pregnancy loss
5. Abdominal or pelvic pain or pressure symptoms
6. Urinary tract symptoms or obstruction

Laparoscopic myomectomy (LM) has recently gained wide acceptance. This procedure remains technically demanding, and concerns have been raised regarding the prolonged time of anesthesia, increased blood loss, and possible higher risk of postoperative uterine rupture of the pregnant uterus. However, in carefully selected cases, LM is a safe and efficient alternative to myomectomy by laparotomy.

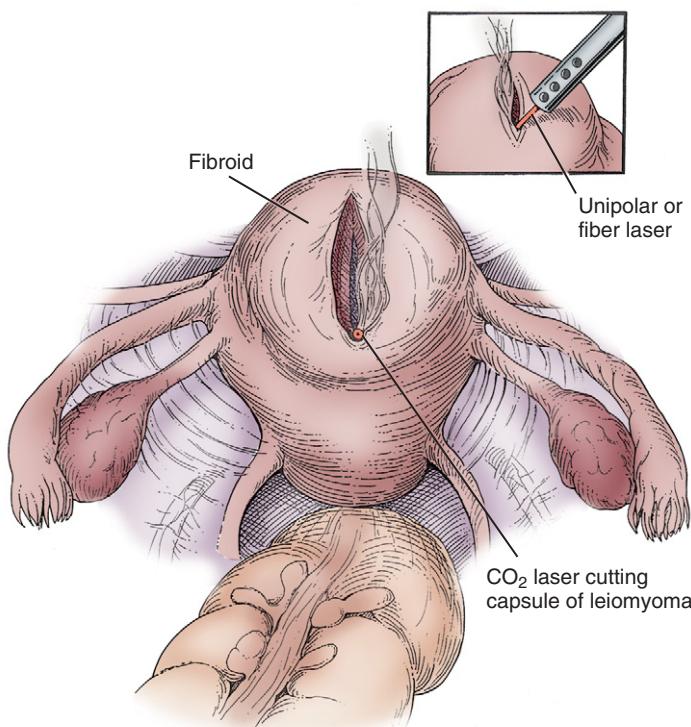

The required instruments for LM include CO<sub>2</sub> or fiber laser, unipolar electrode or harmonic scalpel for cutting, bipolar Kleppinger forceps for achieving hemostasis, and clawed grasping forceps.

In cases of pedunculated subserosal myoma, dilute vasopressin (20 units in 50 mL normal saline) is injected at the base of the stalk. The myoma is removed by coagulating and cutting the stalk. For subserosal and intramural myomas, dilute vasopressin is injected in multiple sites between the myometrium and the fibroid capsule (Fig. 37-12). An incision is made on the serosa overlying the leiomyoma, using a CO<sub>2</sub> laser, monopolar electrode, fiber laser, or harmonic scalpel (Fig. 37-13). The incision is extended until it reaches the capsule. The myometrium retracts as the incision is made, exposing the tumor. The suction-irrigator is used as a blunt probe to shell the myoma from its capsule. Traction is applied using a myoma screw that is inserted into the tumor (Fig. 37-14). Bleeding points are controlled with electrocoagulation, and the uterine defect is irrigated. The edges of the uterine defect are approximated by suturing. If the defect is deep or large, the myometrium and serosa are approximated (Fig. 37-15). After repair, the uterine surface is irrigated. Myomas can be removed from the abdominal cavity by means of an electromechanical morcellator, through a posterior colpotomy, or via minilaparotomy.<sup>28</sup>

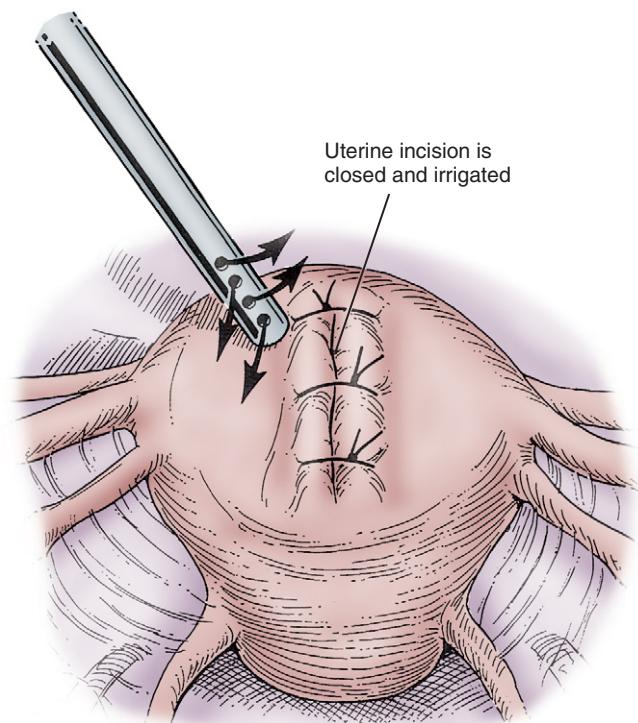

Laparoscopically assisted myomectomy (LAM) is a safe alternative to LM and is less difficult and less time consuming.<sup>29</sup> LAM can be used for large (>8 cm), multiple, or deep intramural myomas. By means of a combination of laparoscopy and a

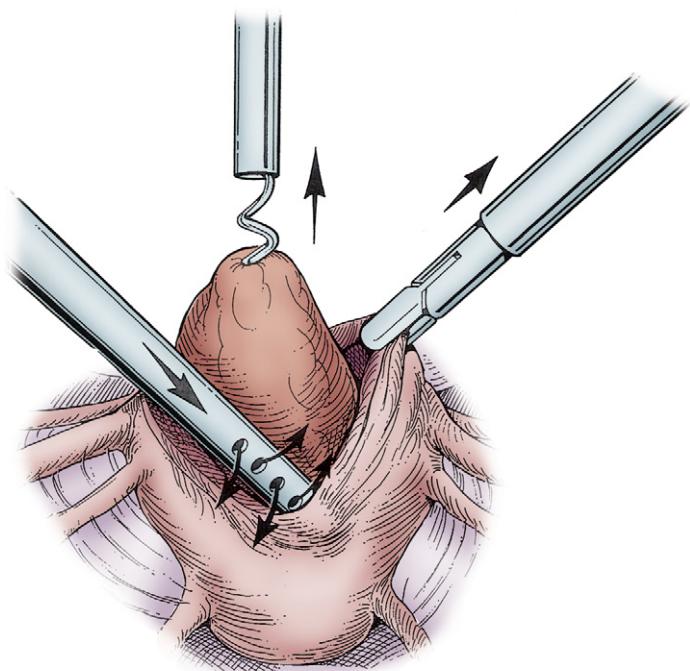

**Figure 37-12** The serosa overlying the myoma is injected with dilute vasopressin.

**Figure 37-13 Incision of the myometrium to remove an intramural myoma.**

**Figure 37-15 Uterine incision is closed and irrigated.**

**Figure 37-14 Myoma removal using the suction-irrigator as a blunt probe and also for hydrodissection.**

2- to 4-cm abdominal incision, the uterine defect can be closed in two or three layers to reduce the risk of uterine dehiscence and fistula and adhesion formation.

Following LM or LAM, most patients are observed in an outpatient unit and discharged the morning after the operation. Women who desire future fertility and require myomectomy for an intramural tumor may benefit from LAM to ensure proper closure of the myometrial incision. Cesarean delivery is recommended in patients who have deep intramural or multiple intramural myomas even if the endometrial cavity is not entered.

#### Pitfalls and Controversies

Four aspects of LM make it technically more difficult compared with an approach by laparotomy<sup>27</sup>:

1. Finding a deep intramural myoma may be difficult with laparoscopy due to lack of tactile sensation.
2. Enucleation of a myoma is sometimes difficult in the laparoscopic setting.
3. Laparoscopic suturing is technically more difficult and time consuming than laparotomy suturing.
4. Myoma extraction adds to the complexity of LM.

Laparoscopy is associated with a reduction in adhesion formation. Since fertility preservation is a primary goal of myomectomy, the potential reduction of adhesion formation by LM may provide an advantage over laparotomy.<sup>30</sup>

The incidence of uterine rupture after LM is unknown, since the procedure is relatively new. However, the incidence was estimated to be approximately 1% (95% CI 0.0–5.5) in a follow-up study of 100 cases by Dubuisson et al. In another study,<sup>31</sup>

## Minimally Invasive Surgery

spontaneous uterine rupture was not noted during pregnancy in any of the 40 women with a history of LM.

The recurrence of myomas has been reported to be higher after laparoscopic surgery in some studies, but not all. Nezhat et al<sup>33</sup> reported a recurrence rate of 33% after a mean interval of 27 months after LM. They concluded that although LM was associated with less morbidity than removal by laparotomy, the recurrence of myomas might be higher with a laparoscopic approach. The reported recurrence after a randomized clinical trial<sup>34</sup> between laparoscopy and laparotomy was the same at approximately 21%. In this study, the operative time was not significantly different between the two groups; postoperative morbidity was less and recovery was faster in the laparoscopy group. Pregnancy rates, abortion rates, preterm delivery, and the use of cesarean section were similar between the two groups. No uterine rupture was reported. Several recent studies further address these issues. In one randomized clinical trial,<sup>35</sup> operative time was significantly longer for LM; however, the laparoscopic approach was associated with faster postoperative recovery compared with laparotomy.

In a recent case-control study, Silva et al<sup>36</sup> compared laparoscopic with abdominal approaches to myomectomy. Median length of hospital stay (30.5 vs 65.0 hours) and duration of postoperative intravenous narcotic use (14.8 vs 24.0 hours) were significantly shorter for laparoscopic group. The laparoscopic cases required a longer median operative time; however, no difference was detected in estimated blood loss from surgery.

### Summary

Two randomized clinical trials and many observational studies have shown that LM is associated with an accelerated post-operative recovery compared with laparotomy. In the hands of skilled surgeons, the incidence of uterine rupture and recurrence may be the same as with an open procedure. There are no specific limitations regarding the size or number of myomas, but clinical judgment and experience should determine the surgeon's personal limits.

## LAPAROSCOPIC HYSTERECTOMY

Hysterectomy is a common operation, with up to 550,000 and 100,000 procedures undertaken annually in the United States and United Kingdom, respectively. The advent of laparoscopic approaches to hysterectomy offers the prospect of improved outcomes and gains in cost effectiveness through reduced severity of convalescence and shorter length of hospital stay. The main indications for hysterectomy for nonmalignant disease in the United States include fibroids (35%), abnormal uterine bleeding (22%), and chronic pelvic pain (18%). For women who require hysterectomy, the appropriate route of surgery is determined by anatomic considerations, the type of pathologic condition expected, patient preference, and physician experience and training.

### Laparoscopically Assisted Vaginal Hysterectomy

#### **Definition and Indications**

The term *laparoscopically assisted vaginal hysterectomy* (LAVH) has been applied to various operations that include portions of the procedure performed vaginally. In this procedure, the uterine

vessels are ligated either vaginally or laparoscopically. According to an American College of Obstetricians and Gynecologists (ACOG) criteria set,<sup>37</sup> LAVH is indicated to assist in the performance of a vaginal hysterectomy in situations in which an abdominal approach might otherwise be indicated. These conditions include previous pelvic surgery, endometriosis or pelvic inflammatory disease requiring lysis of adhesions, ligation of the infundibulopelvic ligaments for ovarian removal allowing completion by vaginal hysterectomy, and presence of a pelvic mass and malignancies that require evaluation.

#### **Risks, Benefits, and Possible Complications**

In the first randomized clinical trial, Nezhat et al<sup>38</sup> compared the perioperative and postoperative courses for 10 women who underwent total abdominal hysterectomy and 10 who underwent LAVH. Although LAVH took longer (160 vs 102 min), the women undergoing it had a shorter duration of hospitalization (2.4 vs 4.4 days), more rapid recuperation (3 vs 5 weeks), and fewer complications. They concluded that in the hands of experienced surgeons, LAVH is preferable to abdominal hysterectomy for selected candidates.

A multicenter randomized clinical trial<sup>39</sup> compared intraoperative and postoperative outcomes between LAVH and abdominal hysterectomy among patients who were not eligible for vaginal hysterectomy. Sixty-five women at three institutions underwent LAVH ( $n = 34$ ) or abdominal hysterectomy ( $n = 31$ ). Three patients in the laparoscopic group required conversion to abdominal hysterectomy. Mean operating time was significantly longer for LAVH (179.8 vs 146 min). There were no differences in blood loss or incidence of intraoperative complications. There was a higher incidence of wound complications in the abdominal hysterectomy group, but no significant difference in the frequency of other postoperative complications. LAVH required a significantly shorter mean hospital stay (2.1 days) and convalescence (28 days) than abdominal hysterectomy (4.1 days and 38 days, respectively). There were no significant differences in mean hospital charges between the study groups (laparoscopic \$8161, abdominal \$6974).

A prospective randomized clinical trial<sup>40</sup> of LAVH ( $n = 24$ ) versus abdominal hysterectomy ( $n = 24$ ) was carried out in a tertiary care setting. The LAVH group had longer operative times (180 vs 130 min), lower requirement for postoperative intravenous analgesia, shorter length of hospital stay (1.5 vs 2.5 days), and quicker return to work. Both procedures had similar hospital costs.

A randomized clinical trial<sup>41</sup> showed that LAVH took longer (120 vs 64 min) and had higher cost (\$7905 vs \$4891) compared with vaginal hysterectomy. There was no difference in complications, length of stay, and postoperative recovery between the two groups. The authors concluded that the vaginal approach should be preferred for hysterectomy whenever feasible.

Kovac<sup>42</sup> conducted a prospective cohort study in 1427 women who underwent abdominal hysterectomy, LAVH, or vaginal hysterectomy. Length of stay was longer after abdominal hysterectomy than for LAVH or vaginal hysterectomy ( $P < 0.001$ ), hospital charges were lower for vaginal hysterectomy than for either LAVH or abdominal hysterectomy ( $P < 0.001$ ), and postoperative complications were higher for

abdominal hysterectomy ( $P < 0.001$ ). He concluded that the vaginal route of hysterectomy should be considered when disease is confined to the uterus and estimated uterine weight is less than 280 g.

The frequency and cause of aborted LAVH were studied in a retrospective cohort study<sup>43</sup> of 78 patients. Of the aborted LAVH procedures, 11.1% were converted to abdominal hysterectomy, the most frequent reason for conversion being large uterine size followed by significant intraperitoneal adhesions and intraoperative bleeding.

## Total Laparoscopic Hysterectomy

### **Definition and Indications**

In total laparoscopic hysterectomy (TLH), all vascular pedicles and uterine attachments are ligated and excised laparoscopically. The vaginal cuff may be repaired laparoscopically or vaginally.

TLH is indicated when vaginal hysterectomy is not possible because of little or no vaginal access to uterine vessels or presence of intraperitoneal pathology. Contraindications to TLH include a uterine mass suspicious for cancer that cannot be removed intact, medical conditions that prohibit surgery such as severe cardiac and pulmonary diseases, and inadequate training and experience in advanced laparoscopic surgery on the part of the staff.

### **Risks, Benefits, and Possible Complications**

In two parallel randomized clinical trials, one comparing laparoscopic with abdominal hysterectomy and the other comparing laparoscopic with vaginal hysterectomy in 1346 patients, Garry et al<sup>44</sup> showed that TLH was associated with higher rate of major complications than abdominal hysterectomy (11.1% vs 6.2%) and also took longer to perform (84 vs 50 min) but was less painful and resulted in shorter hospital stay after the operation (3 vs 4 days). In the vaginal trial, they found no evidence of a difference in major complication rates between TLH and vaginal hysterectomy (9.8% vs 9.5%). LH took longer to perform (72 vs 39 min) and was associated with a higher rate of detection of unexpected pathology.

A Finnish prospective cohort study<sup>45</sup> compared the operation-related morbidity and postoperative complications of abdominal, vaginal, and total laparoscopic hysterectomies. In a total of 10,110 hysterectomies, infection and hemorrhagic events were similar in the three groups. However, ureteral injuries were more frequent in the laparoscopic group (RR = 7.2) compared with the abdominal group, whereas bowel injuries were most common in the vaginal group (RR = 2.5). Surgeons who had performed more than 30 laparoscopic hysterectomies had a significantly lower incidence of ureter and bladder injuries (0.5% and 0.8%, respectively) than those who had performed fewer than 30 operations (2.2% and 2.0%, respectively). A decreasing trend of bowel complications was also seen with increasing experience in vaginal hysterectomy.

When a retrospective comparative study<sup>46</sup> evaluated the frequency of complications of TLH performed in the first and then more recent years of surgeons' experience, they found substantial decreases in major complication rates in the more recent group (1.3% vs 5.6%). It was concluded that LH was safe, effective, and reproducible after training and with current technique had a low rate of complications.

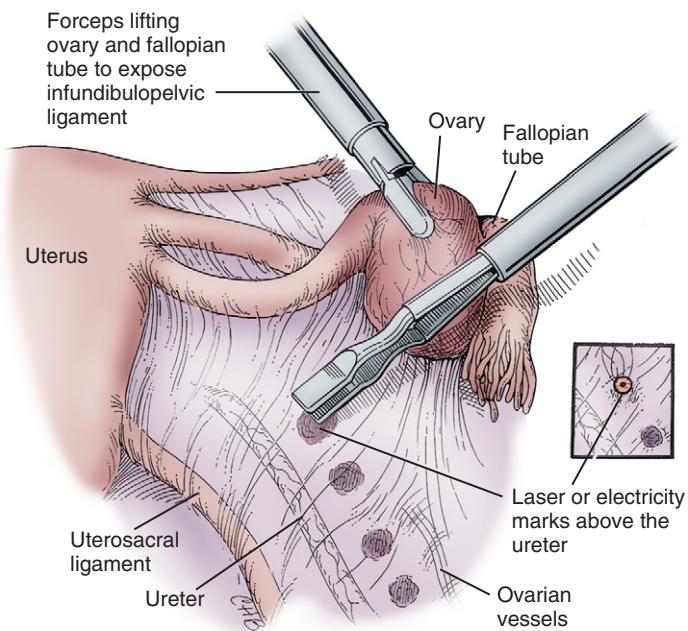

Recently, Sculpher and colleagues<sup>47</sup> assessed the cost-effectiveness (U.S. dollars) of LH compared with conventional abdominal and vaginal hysterectomies in the United Kingdom. LH cost an average of \$708 more than vaginal hysterectomy and \$328 more than abdominal hysterectomy. They concluded that LH was not cost effective relative to vaginal hysterectomy and was comparable to abdominal hysterectomy.

### **Preoperative Evaluation**

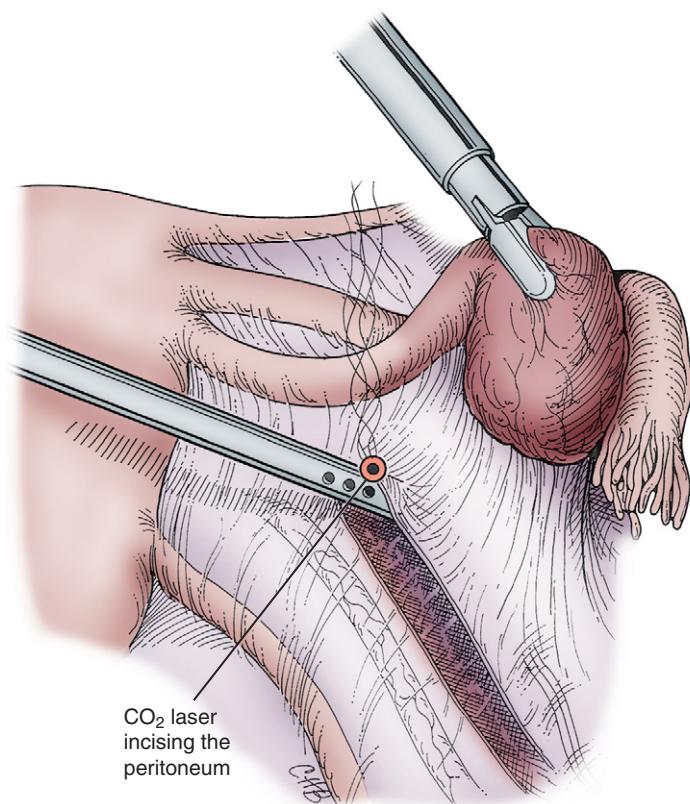

Routine preoperative tests may include complete blood count, serum electrolytes, and blood type and antibody screen. More comprehensive blood studies, electrocardiogram, chest x-ray and endometrial biopsy are performed as indicated. A mechanical or sometimes antibiotic bowel preparation is advised depending on the clinical situation. A GnRH analog may be considered if anemia is present. Informed consent is obtained after a thorough explanation of the procedure, its potential risks and benefits, the possibility of laparotomy, and therapeutic alternatives.

### **Surgical Technique**

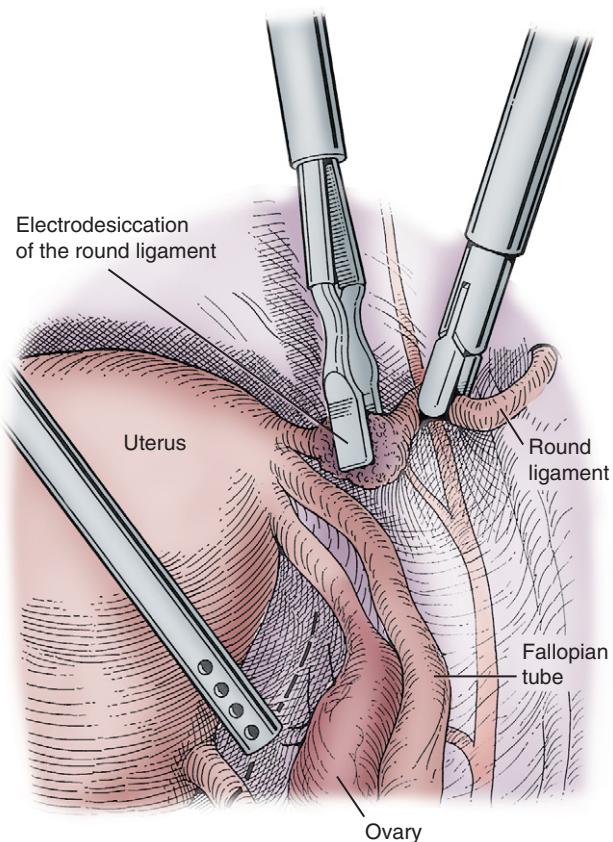

The patient is placed in a dorsolithotomy position with the buttocks extended over the end of the table. We prefer Allen universal stirrups with thighs in a flexed (120-degree) position to allow instrument manipulation. An oral gastric tube is inserted for decompression of the stomach prior to instrumentation of the abdomen. After insertion of a Foley catheter, a uterine manipulator is placed into the cervix and uterine cavity to properly manipulate the uterus during the procedure. A 5- or a 10-mm trocar is inserted infraumblically and two to four accessory trocars are positioned suprapubically or as needed depending on the anatomy. After exploration of the abdominal and pelvic cavities and treatment of any associated pathology such as endometriosis or adhesions, the direction and location of both ureters are identified from pelvic brim to the cardinal ligaments and their locations are marked lateral to the uterosacral ligaments (Fig. 37-16). If needed, the peritoneum is opened above the ureter and hydrodissection is carried out (Fig. 37-17). With the ureters retracted laterally, the uterosacral ligaments can be dissected at their connections to the back of the cervix at this time or later. If adnexitomy is indicated, after electrocoagulation and cutting of the round ligament 2 to 3 cm from the uterus (Figs. 37-18 and 37-19), the infundibulopelvic ligament is isolated and electrode desiccated. Using hydrodissection, the anterior leaf of the broad ligament is opened toward the vesicouterine fold and the bladder flap is developed (Fig. 37-20). The anterior leaf of the broad ligament is grasped, elevated, and dissected from the anterior lower uterine segment. After the bladder is dissected from the anterior cervix, the uterine vessels are identified, desiccated, and cut to free the lateral borders of the uterus (Fig. 37-21). At the base of the cardinal ligaments, the ureter and descending branches of the uterine artery are close to one another and the cervix. Once the ureter is displaced laterally, the cardinal ligament tissue closest to the cervix is desiccated (Fig. 37-22). A folded wet gauze in a sponge forceps or the tip of a right-angle retractor marks the anterior and posterior vaginal fornix. The vaginal wall is tented and transected horizontally (Fig. 37-23). The uterus is removed through the vagina or abdominally using an electromechanical morcellator. The vaginal cuff is closed vaginally or laparoscopically. To ensure

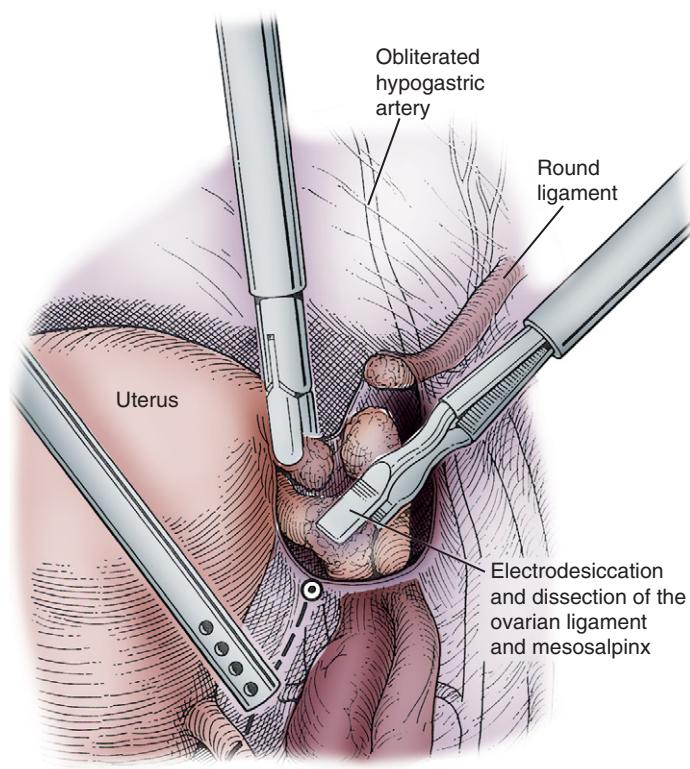

**Figure 37-16** Marking the direction and location of the ureter by making a superficial peritoneal coagulation above it.

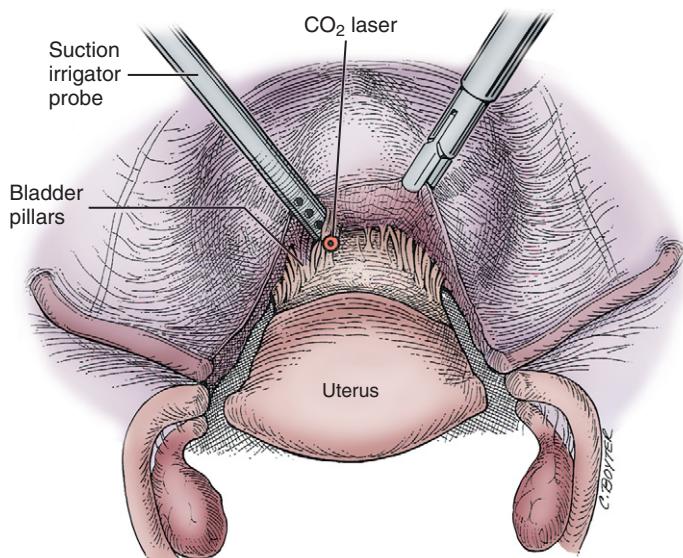

**Figure 37-17** Ureter dissection. With the suction irrigator probe used as a backstop, an opening is made above the ureter with a CO<sub>2</sub> laser. Using blunt dissection and hydrodissection, the ureter is dissected from the pelvic brim to the back of the bladder.

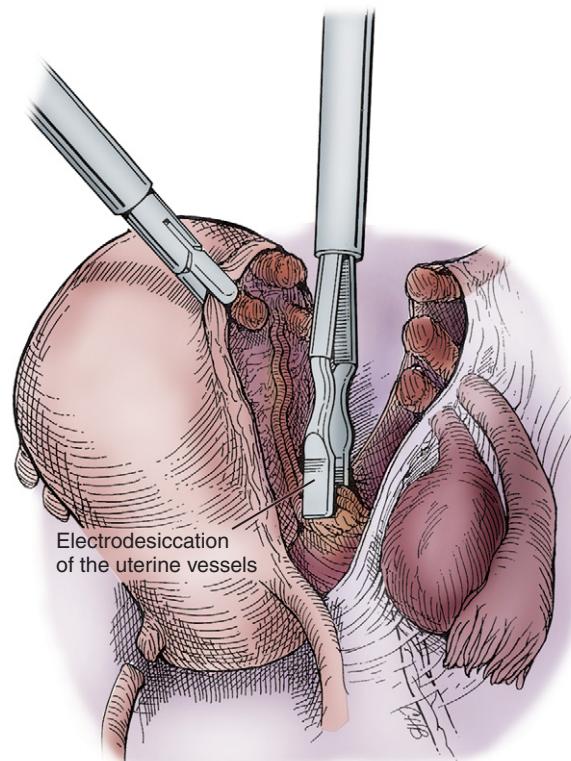

**Figure 37-18** The round ligament is electrodesiccated and cut 2 to 3 cm lateral to the uterus.

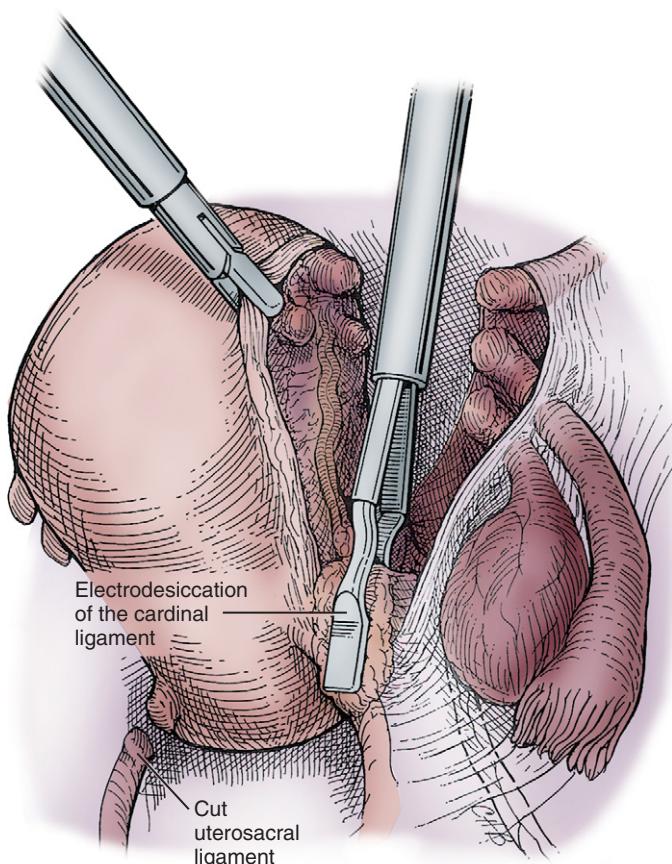

**Figure 37-19** The proximal tube, mesosalpinx, and utero-ovarian ligament are electrodesiccated and cut.

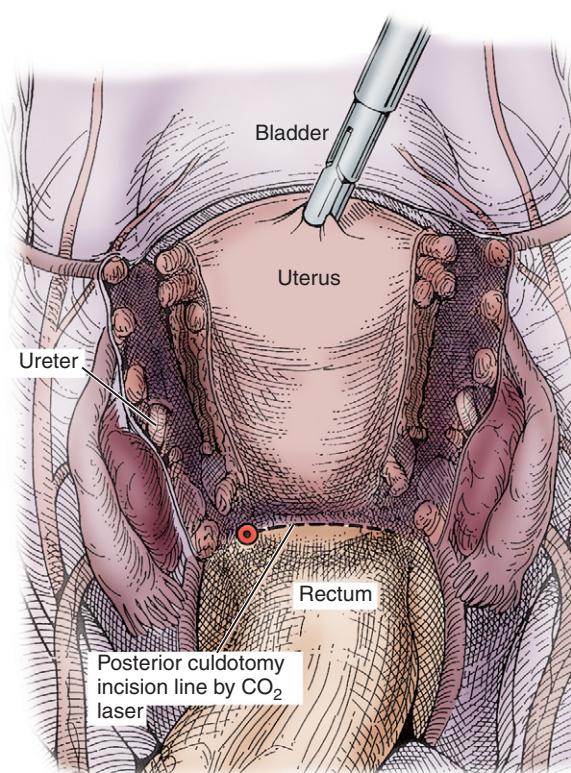

**Figure 37-20** The bladder pillars are identified and cut close to the cervix with a CO<sub>2</sub> laser.

**Figure 37-21** While the ureter is kept under observation, the uterine vessels are skeletonized, electrodesiccated, and cut.

**Figure 37-22** While the uterus is pulled to the opposite side, the cardinal ligament is electrodesiccated and cut. The ureter must be observed to ensure its integrity.

**Figure 37-23** The uterus is elevated, and as the assistant identifies the posterior fornix, laparoscopic posterior culdotomy is performed. The surgeon must ensure that the correct location is selected and that the rectum is not involved.

## Minimally Invasive Surgery

hemostasis, the pelvis is partially filled with lactated Ringer's solution and the vaginal cuff is viewed by submerging the laparoscope under water. If indicated, cystoscopy may be performed to ensure ureteral patency and bladder integrity.<sup>48</sup>

### Laparoscopic Supracervical Hysterectomy

Laparoscopic supracervical hysterectomy (LSH) may be offered to patients in whom hysterectomy is indicated and the following conditions are ruled out: endometrial or cervical cancer or recent cervical dysplasia, pelvic floor relaxation, and severe endometriosis of the uterosacral ligaments as well as in any patient who cannot be expected to continue cytologic surveillance. The real risk of cervical disease is no greater than in patients with an intact uterus, but the patient should be counseled concerning the importance of continued Papanicolaou (Pap) smear screening.

Milad et al<sup>49</sup> performed a prospective cohort analysis comparing 27 patients who underwent LSH with 105 who underwent LAVH. Patients undergoing LSH had significantly shorter operating times (181 vs 220 min), briefer hospital stays (1 vs 2 days) and less blood loss (125 vs 400 mL). None of the patients submitted to LSH experienced morbidity as compared with a 13% morbidity rate for those who underwent LAVH. They concluded that the practice of routine cervicectomy at laparoscopic hysterectomy should be reconsidered.

A retrospective study<sup>50</sup> of 70 patients assessed the long term outcome of LSH. Seventeen women (24.3%) reported symptoms related to the cervical stump, and all required further surgery. The cervical stump was removed in 16 (22.8%). Histologic analysis showed normal cervical tissue in six (35.3%), endometriosis in four (23.5%), residual endometrium in another four, and chronic cervicitis, CIN I, and a mucocele in three patients. They concluded that symptoms related to the cervical stump requiring further surgery frequently occurred following LSH. Discussion of possible complications should be included in the preoperative counseling.

Overall, data on LSH are equivocal. It may be considered in cases where there is difficult dissection, distorted anatomy, compromised medical conditions, and patient desire to preserve the cervix. Careful evaluation to rule out any cervical dysplasia is required prior to LSH.

### Laparoscope-Assisted Radical Vaginal Hysterectomy

Advanced operative laparoscopy in gynecologic oncology developed after advances in laparoscopic retroperitoneal surgery, particularly pelvic and para-aortic lymphadenectomy. The radical vaginal hysterectomy (Schauta) was historically associated with a reduction in postoperative mortality compared with abdominal radical hysterectomy. However, with the popularization of complete pelvic lymphadenectomy in the surgical management of cervical cancer, the Schauta operation became less popular. Dargent is credited with reviving this operation through a combined laparoscopic retroperitoneal lymphadenectomy and radical vaginal hysterectomy. Abu-Rustum<sup>51</sup> summarized 11 reports on 382 laparoscope-assisted radical vaginal hysterectomies (LARVs) and pelvic and para-aortic lymphadenectomies. The operative time was 225 to

380 minutes with 4 to 5 days of hospital stay. Intra- and postoperative complications included 4% to 5% cystotomy, 1% to 2% ureteral and 1% to 2% vascular injuries, 1% to 2% abscess and 1% to 2% hematoma formation, and 6% to 7% transfusion. These results appear to be comparable to those of standard open technique.

### Total Laparoscopic Radical Hysterectomy

Total laparoscopic radical hysterectomy (TLRH) with pelvic and para-aortic lymph node dissection was first reported by Nezhat et al in 1992.<sup>52,53</sup> No randomized trials are available yet comparing TLRH with abdominal radical hysterectomy; however, more than 150 patients have so far been reported, with encouraging results. Abu-Rustum<sup>51</sup> has recently reviewed eight reports on 146 patients who underwent TLRH with pelvic and para-aortic lymphadenectomy. The mean operative time was 300 minutes with hospital stay of 4 days. Complications included 3% to 4% conversion to laparotomy, 2% to 3% cystotomy, 2% to 3% ureteral injury, and 1% to 2% transfusion. It appears that the overall complication rate is acceptable with no compromise in outcome. However, randomized clinical trials are needed before the role of laparoscopy in gynecologic oncology is well established.

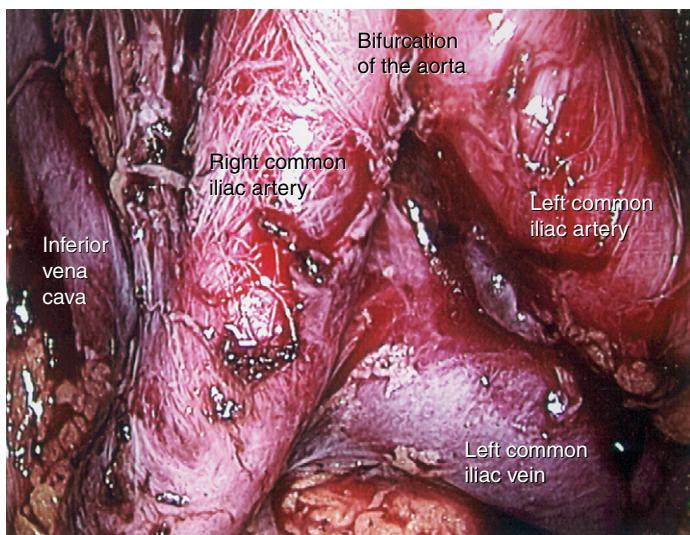

## RETROPERITONEAL LYMPHADENECTOMY

Since the initial report by Dargent and colleagues<sup>54</sup> in the late 1980s, laparoscopic lymphadenectomy has been utilized in the management of gynecologic and urologic malignancies as well as of some lymphomas. Nezhat et al<sup>52</sup> described the first para-aortic lymphadenectomy performed laparoscopically for cancer of the uterine cervix. Over recent years, the literature has been expanding regarding outcomes and complications of laparoscopic lymphadenectomy.

Lymph node status is the most important prognostic factor in gynecologic cancer, and surgical removal of pelvic or para-aortic lymph nodes for histologic assessment is an integral part of staging for gynecologic malignancies. Additionally, removal of the bulky lymph nodes may have therapeutic benefit.

### Surgical Technique

Pelvic lymphadenectomy performed either laparoscopically or by laparotomy begins with identification of the ureter, coagulation and cutting of the round ligament, and opening of the posterior peritoneum and the pelvic side wall. The common iliac and external iliac nodes are dissected with care taken to avoid the genitofemoral nerve, which lies medial on the psoas muscle. The nodes are dissected from the common iliac artery bifurcation to the circumflex iliac vein caudally (Fig. 37-24). After development of the paravesical space between the obliterated hypogastric artery and external iliac artery and vein, the obturator space is opened and the obturator nerve and vessels are identified (Fig. 37-25). Although the majority of patients have both the obturator artery and vein dorsal to the obturator nerve, 10% will have an aberrant obturator vein arising from the external iliac vein. The obturator lymph nodes are

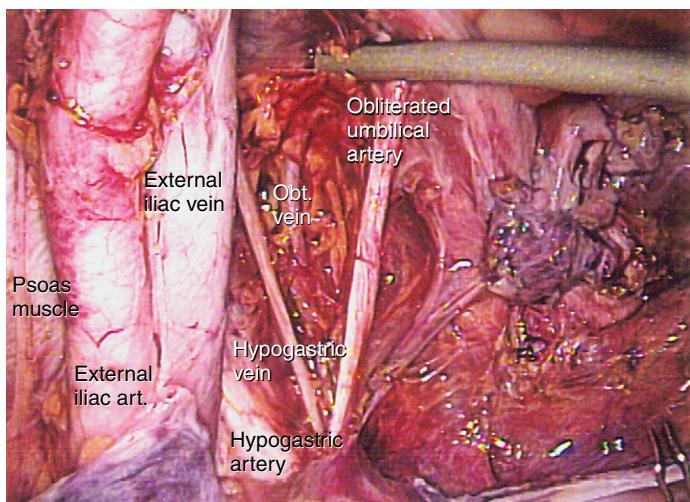

**Figure 37-24** Anatomic relationships during pelvic lymphadenectomy on the left side.

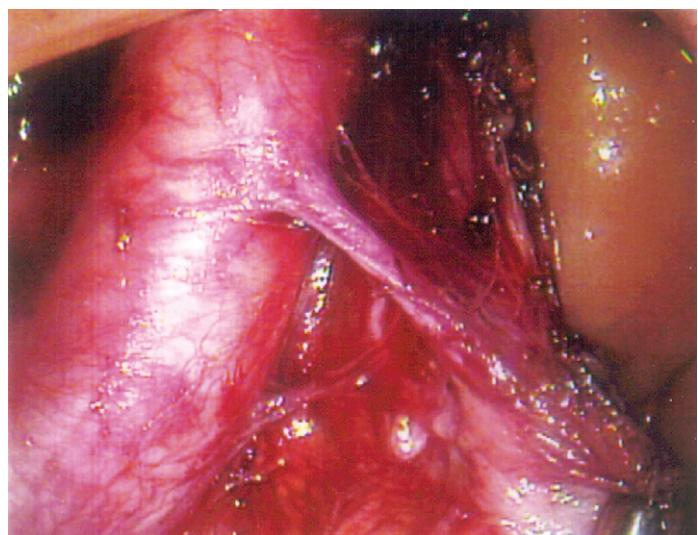

grasped just under the external iliac vein and traction is applied medially. The node chain is thereby separated from the obturator nerve and vessels and the nodes are dissected cephalad to the hypogastric artery. Finally, the hypogastric lymph nodes are removed up to the common iliac artery with care to avoid injury to hypogastric vein. For the para-aortic dissection, the peritoneum is incised over the sacral promontory or right common iliac artery with the right ureter in view. This incision is extended up to the inferior mesenteric artery or up to the left renal vein in cases of ovarian or fallopian tube carcinoma. The lymph node packages are retrieved along the common iliac vessels, along the aorta and vena cava with careful attention to the ovarian vessels, ureters, renal vessels, and inferior mesenteric artery (Fig. 37-26).

### Risks, Benefits, and Possible Complications

Technically there are multiple benefits of the laparoscopic approach to pelvic and para-aortic lymphadenectomy. The

**Figure 37-25** Anatomic relationships of the aorta and inferior vena cava.

**Figure 37-26** Anatomic relationships of the lower para-aortic region.

laparoscope provides 7- to 10-fold magnification of the operative field, allowing identification of small tributary vessels. Additionally, the pneumoperitoneum facilitates the development of pelvic spaces and decreases venous oozing, thereby maintaining a clean operative dissection with good visualization of nodal bundles.

Complications of laparoscopic lymphadenectomy belong in two general categories. The first includes the complications that are intrinsic to laparoscopy, regardless of the specific procedure being performed. These include complications such as subcutaneous emphysema or laceration of the abdominal wall and trocar injuries to inferior epigastric vessels, the bowel, or major retroperitoneal vessels. The second group of complications includes those that are intrinsic to the procedure regardless of the method by which it is performed. These include the following:

#### Vascular Injury

Vascular injuries related to lymphadenectomy are potentially life-threatening. In a series of laparoscopic lymphadenectomies,<sup>55</sup> seven of nine vascular complications occurred as the result of trocar injury to the anterior abdominal wall vasculature. Potential vascular compromise specific to pelvic lymphadenectomy includes injury to the obturator, internal iliac, external iliac, or common iliac vessels. Vessels at risk for injury during para-aortic lymphadenectomy include the aorta and vena cava, as well as the common iliac, inferior mesenteric, lumbar, ovarian, and renal vessels. In one of the largest studies<sup>56</sup> of more than 300 pelvic lymphadenectomies, injury to major pelvic vessels was a rare event. The vessel most likely to be injured was the aberrant obturator vein emerging from the obturator canal, across the nodal bundle, to empty into the external iliac vein. Laparoscopic management of vascular injuries varies according to the type (artery or vein) and the size of the vessel injured. The modalities utilized in managing these vascular injuries include pressure, monopolar and bipolar electricity, clips, and sutures. Depending on the caliber of the injured vessel, any of these modalities may achieve hemostasis satisfactorily.

**Genitourinary Injury**

Cystotomy during trocar insertion, adhesiolysis, or dissection with endoscopic scissors with or without electrocautery has been described as a complication of laparoscopic lymphadenectomy, although it is not specific to this procedure. Cystotomy can occur when the paravesical and pararectal spaces are opened if the obliterated umbilical artery is not retracted medially. Ureterovaginal and vesicovaginal fistulae, as well as injury to the patent urachus, are other potential complications. Pelvic lymphadenectomy places the ureter at risk for sharp, crush, and thermal injury. The lumbar portion of the ureter is at risk during para-aortic lymphadenectomy. If such an injury is recognized intraoperatively, it can be managed laparoscopically. A transurethral stent is placed, the ureteral defect is oversewn, and a retroperitoneal drain is placed laparoscopically. Though it is an area of current investigation, there is no proven role for prophylactic ureteral stent placement prior to laparoscopic lymphadenectomy.

**Neurologic Injury**

Genitofemoral nerve injury can occur during removal of the lateral pelvic lymph nodes. Such an injury results in medial thigh numbness but is otherwise of little clinical consequence. It is arguably the most common injury encountered by the gynecologic oncologist. Injury of the obturator nerve is a rare complication of laparoscopic pelvic lymphadenectomy. It manifests as adductor weakness and decreased sensation of the anteromedial thigh.

**Abdominal Wall Metastases and Peritoneal Tumor Dissemination**

Abdominal wall metastases, also called port or wound site metastases, have been reported after both laparoscopy and laparotomy. The incidence has been 1% after laparotomy and 1% to 3% after laparoscopy.<sup>57</sup> Port sites are contaminated during tumor extraction or withdrawal of contaminated ports. The risk of contamination is higher if abdominal insufflation is lost during tumor extraction or port withdrawal. Although port site recurrences may be disfiguring and difficult to treat, there is no prospective evidence that port site metastases worsen prognosis. To prevent this complication, removal of all specimens using an endo-bag, removal of all ports while the abdomen is still insuffed, immediate local treatment of the contaminated ports with a cytotoxic agent, and closure of the peritoneum and fascia of all trocar sites is highly recommended.

**Complications Requiring Laparotomy**

Complications resulting in laparotomy have been related to damage to the ureter, bladder, bowel, and vascular structures. The incidence of conversion to laparotomy in 150 cases reported by Passover et al<sup>58</sup> was 2.7% (see also Chapter 38).

**Adequacy of Node Retrieval**

Lymphadenectomy is primarily performed to evaluate for micrometastasis in the setting of a malignancy. It is therefore essential that the lymph node dissection achieve adequate node retrieval by laparotomy or laparoscopy. The gynecologic oncology group (GOG) protocol 9207 examined laparoscopic para-aortic lymph node sampling and therapeutic pelvic

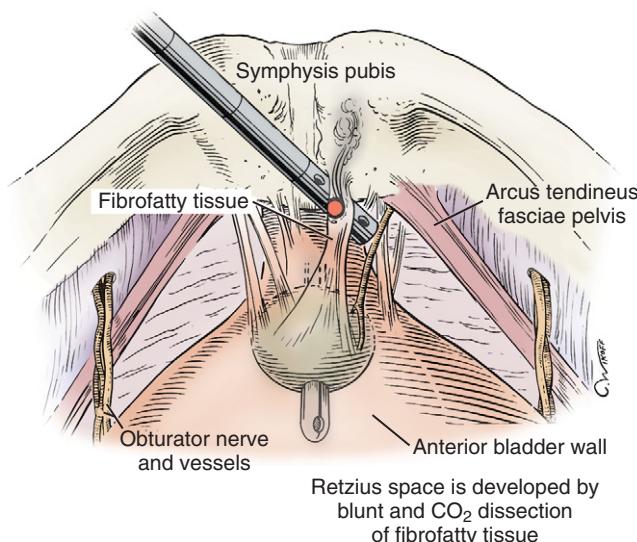

lymphadenectomy in women with stages IA, IB, and IIA cervical cancer. In 69 patients, across seven institutions, the average lymph node retrieval was up to 70 (mean of 32) for pelvic nodes, and up to 37 (mean of 12) for para-aortic nodes. The complication rate was 10% for vascular injury and 1.4% for ureteral injury. The study concluded that laparoscopic approach is a feasible alternative for retroperitoneal lymphadenectomy by laparotomy.

**Summary**

Laparoscopic lymphadenectomy is an evolving technique that may play an increasingly important role in the management of gynecologic malignancies. Laparoscopic pelvic and para-aortic lymphadenectomy appears to be a safe, adequate, and feasible procedure, with a low complication rate. The risks include those traditionally attributed to laparoscopy as well as those inherent in open lymphadenectomy. The use of simple preventive measures allows the patient to benefit from this technique while diminishing the likelihood of complications.

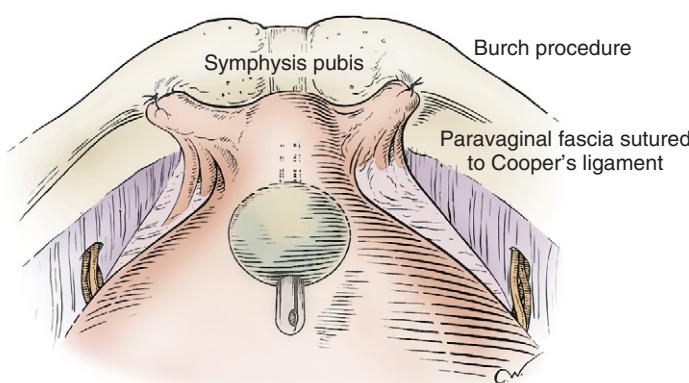

**PELVIC RECONSTRUCTIVE PROCEDURES**

Laparoscopic approach to pelvic reconstructive procedures has been made possible by recent advances in minimally invasive surgery. Laparoscopy allows better visualization of the retropubic space because of magnification, insufflation effects, and better hemostasis. The laparoscopic technique for Burch urethropexy is identical to the open approach. After induction of general anesthesia, the patient is placed in the lithotomy position using Allen stirrups, and a Foley catheter is inserted. A 5- or a 10-mm videolaparoscope is introduced intraumbilically, and three 5-mm accessory cannulas are inserted. The middle cannula is 5 to 6 cm above the pubic symphysis, and the other two cannulas are 3 cm medial to and above the anterior superior iliac spines. After the intraperitoneal cavity is thoroughly inspected for any pelvic disease, the anterior abdominal wall peritoneum, 5 to 6 cm above the pubic symphysis, is pulled down by means of grasping forceps and a transverse incision is made with a laser, scissors, or harmonic scalpel. The midline cannula entry and anatomic landmarks, including the round ligament and the internal ring, are used to avoid injury to the bladder. The retropubic space is dissected mostly bluntly. The incision should remain close to the back of the pubic bone to drop the anterior bladder wall, vaginal wall, and the urethra downward (Fig. 37-27). Dissection is limited over the urethra in the midline to approximately 2 cm lateral to the urethra to protect its delicate neuromusculature. An assistant does a vaginal examination with one finger on each side of the catheterized urethra, elevating the lateral vaginal fornix. The overlying fibrofatty tissue is cleared from the anterior vaginal wall under laparoscopic magnification. The thin-walled venous plexus is identified and protected from trauma. The pubic symphysis, urethrovesical junction, obturator neuro-muscular bundle, Cooper's ligament, and arcus tendineus fasciae pelvis are visualized bilaterally. If paravaginal wall defects are present, the lateral margins of the pubocervical fascia will be detached from the pelvic side wall at the arcus tendineus fasciae pelvis (white line). Unilateral or bilateral defects may be present. It is recommended to complete the paravaginal repair prior to the Burch colposuspension. To repair the paravaginal defect,

**Figure 37-27** The space of Retzius is developed by means of blunt and sharp dissection of fibrofatty tissue. Care is taken to avoid obturator nerve and vessel injury.

2-0 nonabsorbable sutures are placed sequentially along the paravaginal defects from the ischial spine toward the urethrovesical junction. By performing the paravaginal defect repair first, normal anatomical support of the anterior vaginal segment is recreated, reducing the chance of overelevation of the paraurethral Burch sutures and subsequent voiding dysfunction. With elevation of the vaginal fingers, the Burch sutures are placed in the vaginal wall excluding the vaginal epithelium, 2 cm lateral to the urethrovesical junction. No. 0 nonabsorbable suture is placed in a figure-of-eight stitch incorporating the entire thickness of anterior vaginal wall. The suture is then passed through the ipsilateral Cooper ligament and tied with either intracorporeal or extracorporeal knots (Fig. 37-28). A second suture is placed at the level of the mid-urethra. The procedure is repeated on the opposite side. In tying the sutures, the surgeon should not reapproximate the vaginal wall to Cooper's ligament or place too much tension on the vaginal wall. A suture bridge of 1.5 to 2 cm is common. Cystoscopy is performed to assess ureteral patency and integrity of the bladder wall. A suprapubic or an indwelling

**Figure 37-28** Sutures are tied, extracorporeally or intracorporeally, elevating the urethrovesical angle.

bladder catheter is placed, and the peritoneum of the retropubic space may be closed with a running absorbable suture. Voiding trials begin on the first postoperative day. The suprapubic tube is clamped when the patient is awake. The patient voids with urge or every 3 hours. The patient is allowed to unclamp the suprapubic tube at night. Once the patient has voided 80% of total bladder volume during two serial attempts (voids must be greater than 150 mL), the catheter is removed. Patients are instructed to refrain from having sexual intercourse and from lifting objects greater than 10 pounds for at least 6 weeks.

If the laparoscopic technique parallels the open retropubic urethropexy, the laparoscopic procedure should have similar cure rates. Buller and Cundiff<sup>59</sup> reviewed 50 papers that collectively included 1867 patients who underwent laparoscopic surgery for the treatment of genuine stress incontinence. At a mean follow-up of 17 months, a cure rate of 89% was observed. Only 30.8% of studies reported objective outcome data, and a wide variety of laparoscopic techniques were used. Three prospective, randomized clinical trials have compared open and laparoscopic retropubic urethropexies. Burton<sup>60</sup> showed lower objective and subjective cure rates for laparoscopic colposuspension, which decreased from 1 year (73% vs 97%) to 3 years (60% vs 93%). The use of absorbable suture in this study must be questioned. Su and colleagues<sup>61</sup> showed a lower 1-year objective cure rate for laparoscopic Burch colposuspension (80.4%), compared with the open group (95.6%); however, only one suture was placed bilaterally in the laparoscopic group, compared with two or three sutures placed bilaterally in the open group. Summitt et al<sup>62</sup> subsequently found similar objective cure rates for laparoscopic and transabdominal Burch procedures at 3 months (100% vs 97%) and 1 year (92.8% vs 88.2%). Two stitches were placed bilaterally in all patients using permanent sutures.

The indications and surgical techniques for laparoscopic enterocele, vaginal apex prolapse, and rectocele repair are not new; it is the route by which they are performed that differs. The choice of laparoscopic route is determined by surgeon and patient preference and the laparoscopic skill of the surgeon. There are a small number of reports of laparoscopic repair of vaginal apex prolapse. Nezhat et al<sup>63</sup> reported a series of 15 patients who underwent laparoscopic sacral colpopexy in whom the mean operative time was 170 minutes and mean blood loss was 226 mL. The mean hospital stay was 2.3 days, excluding a case converted to laparotomy for presacral hemorrhage. The cure rate for apical prolapse was 100% at 3 and 40 months. Ross<sup>64</sup> evaluated 19 patients with posthysterectomy vaginal apex prolapse who underwent laparoscopic sacral colpopexy, Burch colposuspension, and modified culdeplasty. The cure rate at 1 year was 100% for vaginal apex prolapse and 93% for genuine stress incontinence, although two patients were lost to follow-up.

## UTEROSACRAL TRANSECTION AND ABLATION AND PRESACRAL NEURECTOMY

Laparoscopic uterosacral nerve ablation (LUNA) can be performed in patients with chronic pelvic pain in whom laparoscopy reveals either no pathology or mild endometriosis; however, reported long-term relief with this procedure is variable. The

## Minimally Invasive Surgery

Lee-Frankenhauser sensory nerve plexuses and parasympathetic ganglia in the uterosacral ligaments carry pain from the uterus, cervix, and other pelvic structures. Interruption of these nerve trunks by LUNA may alleviate the pain. However, the balance between benefits and risks has not been reliably assessed, and many surgeons no longer perform this surgery because of the controversy regarding its indications.

Presacral neurectomy is indicated for patients who have disabling midline dysmenorrhea and pelvic pain who have not responded to appropriate and adequate management. The success rate is difficult to predict, although the operation is likely to relieve pain in 50 to 75% of patients.<sup>65,66</sup> Primary dysmenorrhea or dysmenorrhea caused by endometriosis may be an indication for endoscopic corrective procedures followed by presacral neurectomy. In most patients, dyspareunia is decreased and chronic pain is alleviated.<sup>65,66</sup>

## CONCLUSION

Recent advances in endoscopic surgery have revolutionized our approach to gynecologic surgery. Most reproductive operations can be done by laparoscopy. It appears that laparoscopic gynecologic surgery, when performed by an experienced endoscopist, is feasible and effective and provides the patient with benefits of less postoperative pain, faster recovery, and better cosmesis.

## KEY POINTS

- Blind curettage captures less than 50% of polyps.
- Tamoxifen increases the risk of endometrial polyps in premenopausal and postmenopausal patients.
- Sonohysterography is an effective method for evaluating the extent of intracavitary involvement of submucous myomata.
- During resection of submucous myomata, myometrial contractions will cause the intramural portion of a fibroid to move to a level above the endometrium.
- Resection of submucous myomata is an effective method of treating menorrhagia, with acceptable long-term recurrence rates.
- Fundal and cornual myomata are the most difficult to resect.
- If a myoma is on a stalk within the cavity, this should be excised last.
- Magnetic resonance imaging is an excellent imaging technique for use in patients with müllerian abnormalities.
- Reproductive outcome after hysteroscopic metroplasty is comparable to that achieved through traditional laparotomy and Tompkins or Jones procedures.
- Obstetric curettage is the most common antecedent event prior to Asherman's syndrome.
- A high percentage of patients with Asherman's syndrome will present with menstrual abnormalities that will be corrected after surgery.
- Successful term pregnancy inversely correlates with extent of intrauterine adhesions.
- Approximately half of patients treated for Asherman's syndrome will require more than one procedure to free the majority of the cavity from adhesions.
- Hysteroscopic sterilization with the Essure device is 99% effective when the device is successfully placed and is shown to be present on follow-up hysterosalpingogram (HSG).
- A primary advantage of hysteroscopic sterilization is that it avoids entry via the abdominal cavity.
- Transcervical catheters may be used hysteroscopically or fluoroscopically for patients with proximal tubal occlusion.
- Approximately one quarter of patients found on initial HSG to have proximal occlusion will have at least one open tube on reevaluation.
- Hysteroscopic endometrial resection may be the most difficult technique to perform and does not generate higher rates of success than coagulation ablation or global ablation techniques.
- One third of patients undergoing endometrial ablation may require further intervention, with one quarter requiring hysterectomy.
- Although controversy remains regarding whether fluid hysteroscopy causes more dissemination of endometrial cells than dilation and curettage (D&C), there appears to be no impact on overall mortality.

Hysteroscopy has evolved over the past several decades to become the gold standard for diagnosing and treating abnormalities of the endometrial cavity. Many procedures previously requiring laparotomy, such as removal of uterine septa or submucous myomata, are now able to be performed hysteroscopically, saving the patient from undergoing major surgery as well as the morbidity and expense associated with such surgery. This chapter focuses on the various procedures that are now possible with the hysteroscope.

## DIAGNOSTIC HYSTEROSCOPY

Diagnostic hysteroscopy has supplanted D&C as the standard for evaluating the endometrial cavity and ultimately obtaining tissue for biopsy. Few D&Cs are performed in modern gynecology other than for obstetric purposes. Ultrasound and

sonohysterography (SHG) are extremely useful tests for evaluating the uterus and pelvic organs (see Chapter 8), but only hysteroscopy allows concomitant treatment if an underlying abnormality is identified.

Multiple types of hysteroscopes are available in the marketplace today (see Chapter 35). An ideal operating room setup includes a small-diameter hysteroscope (approximately 3 mm) with sheaths that allow continuous inflow and outflow. A larger 4-mm hysteroscope should also be available with operative channels; finally, a resectoscope should be available. Use of small diagnostic hysteroscopes allows the surgeon to pass through small-diameter endocervical canals. They are also useful in the office setting to decrease patient discomfort.

For many years we have chosen to use fluid media, even for office and diagnostic evaluation. A small bag of 250 to 500 mL normal saline solution is attached to large-bore tubing, which is

## Minimally Invasive Surgery

then connected to the hysteroscope. A small pressure bag may be used if necessary to allow adequate distention of the cavity because with diagnostic and basic operative cases there is less concern regarding fluid overload. The patient should be examined before starting the procedure to ascertain the position of the uterus. Generally the cervix is stabilized with a tenaculum, which also allows the endometrial canal to be straightened, although some authors have reported successful hysteroscopic examinations without the use of a tenaculum.<sup>1</sup> The media should be run through the tubing and the hysteroscope to decrease air in the line as well as subsequent bubbles in the endometrial cavity. The hysteroscope is then placed into the external os under direct visualization and is used to first examine the endocervical canal, identifying the internal os and carefully entering the endometrial canal. We attempt not to sound the uterus or dilate the cervix unless cervical stenosis precludes this, preferring direct visualization instead. Use of a fore-oblique hysteroscope with 12- or 30-degree offset easily allows the entire cavity to be visualized. This also allows the surgeon to rotate around the axis of the endometrial canal and avoids overmanipulation and torque of the instrument, which may cause patient discomfort as well as overdilation of the cervix. The ostia should be readily visible; with rotation the anterior, posterior, and sidewalls are easily inspected.

Various options exist for anesthesia when performing diagnostic hysteroscopy. Often, use of nonsteroidal anti-inflammatory agents alone is adequate for analgesia for simple office cases in a parous patient; more difficult cases or those that may become operative are best performed in an operative setting with general anesthesia readily available.

## THERAPEUTIC HYSTEROSCOPY

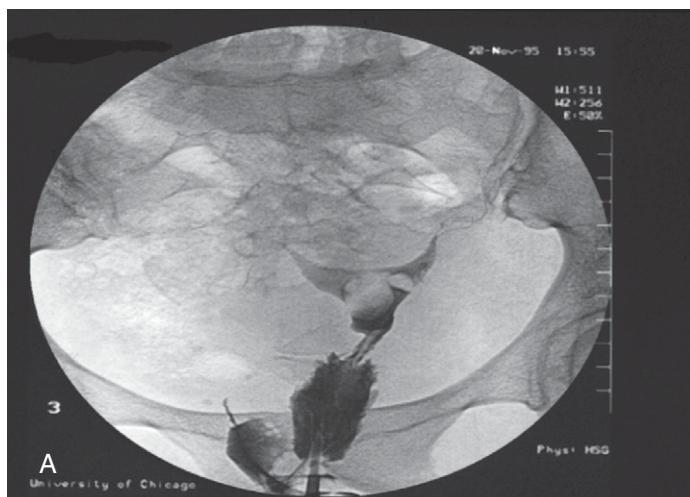

## Polypectomy

Endometrial polyps are commonly identified in patients with abnormal bleeding as well as infertility. SHG or hysterosalpingogram (HSG) readily identifies a discrete intrauterine mass, although on occasion small myomata may be mistaken for

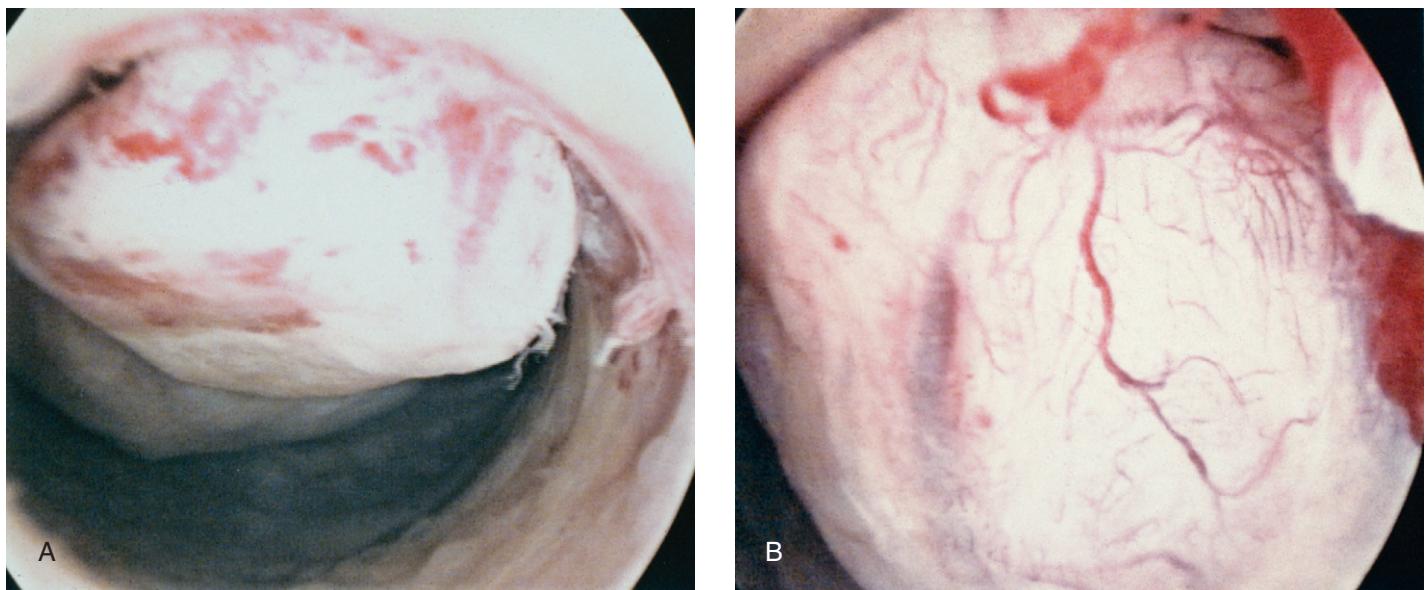

a polyp (Fig. 38-1). The patient's symptoms may range from nonexistent to menorrhagia. Polyps may also range in size from very tiny and of limited clinical significance to very large. Tamoxifen has been implicated as causing endometrial polyps, some of which may be quite large (Fig. 38-2).

Once diagnostic hysteroscopy has identified the polyp(s), if necessary the surgeon needs to change to an operative instrument with at least one operating channel. An alternative is to use polyp forceps after identification, although reevaluation of the cavity with hysteroscopy should occur to ensure that the lesion has been removed in its entirety. Hysteroscopic scissors may be used to incise the base of the polyp or stalk until only a small portion remains to anchor the lesion. At this point, the scissors may be exchanged for a grasping instrument, which can grasp the lower portion of the lesion. The distention media should be turned off and the lesion slowly removed at the same time as the hysteroscope. This method allows even large polyps to be removed through an undilated cervix. Unless the operating channel is large or the polyp is small, attempting to bring the polyp into the operative channel will cause it to be lost from the jaws of the grasper. If the entire lesion is incised and released into the cavity, it can become difficult to grasp while floating in the fluid media. An alternative to use of the operative hysteroscope is use of a resectoscope to excise the polyp. In one of the largest series published to date, Preutthipan and Herabtya retrospectively evaluated 240 premenopausal and postmenopausal women who underwent polypectomy.<sup>2</sup> They noted a higher recurrence rate with use of forceps versus the resectoscope to perform the polypectomy. They also noted no differences in reproductive outcome when small (<2.5 cm) versus large (>2.5 cm) polyps were removed. Complete extraction of the polyp or lesion is likely more important than the particular methodology employed for removal. However, even when lesions are removed in their entirety, patients may still return with a recurrence and new lesion.

Gebauer and colleagues prospectively evaluated postmenopausal patients who presented with an abnormal ultrasound or bleeding.<sup>3</sup> Patients initially underwent hysteroscopy,

**Figure 38-1** A, Hysterosalpingogram demonstrates intracavitary abnormality. Note: only a small amount of dye, which readily outlines the lesion, has been injected at this point. B, On hysteroscopy, the lesion is easily seen as a polyp.

**Figure 38-2** A, Patient on tamoxifen who presented with postmenopausal bleeding. Hysteroscopy demonstrates a small lesion near the endocervix. B, Once the two smaller polyps were removed, a large polyp remains. These were all benign.

then a second blinded team performed curettage and passage of Randall polyp forceps; a repeat hysteroscopy was then performed with removal of any remaining polyps. They noted that curettage revealed the polyp in only 43% of cases, and the addition of the polyp forceps significantly improved the yield. However, use of hysteroscopy was found to be superior, especially in patients with thickened endometrium. Tjarks and Van Voorhis evaluated patients who had presented with abnormal bleeding and an abnormal SHG suggestive of endometrial polyp and found polypectomy with or without concomitant endometrial ablation or myomectomy significantly decreased bleeding and led to patient satisfaction<sup>4</sup> (Table 38-1). Chalas and colleagues evaluated the benign gynecologic conditions in patients from the large Breast Cancer Prevention Trial that compared the use of tamoxifen versus placebo for breast cancer prevention.<sup>5</sup> They noted that tamoxifen increased the risk not only of endometrial

polyps in premenopausal and postmenopausal patients, but also of leiomyomata and procedures such as curettage and hysterectomy (Table 38-2).

### Myomectomy

Uterine fibroids may be very amenable to hysteroscopic treatment, depending on depth of penetration into the endometrial cavity. Figure 38-3 demonstrates the natural evolution of a myoma from intramural to partly intracavitory to completely intracavitory to prolapsing.

Often, as endometrial distortion increases, menorrhagia will ensue and the patient may be significantly anemic. SHG is an excellent preoperative method for ascertaining what amount of the myoma is intracavitary versus intramural. It also allows an assessment of overall size as well as allowing the physician to determine if other myomata exist within the uterus. Leone and

**Table 38-1**  
Patient Satisfaction with Treatment

Procedure	n	Mean age (year)	Mean Length of Follow-up (mo)	Satisfaction Score*	Satisfied (%)	Percentage Having Another Procedure
Polypectomy	26	52 ± 12	12 ± 5	3 (0–4)	65	15
Polypectomy with ablation	8	47 ± 4	12 ± 4	4 (0–4)	63	0
Polypectomy with myomectomy	8	46 ± 6	15 ± 2	3.5 (0.4)	63	13
Hysterectomy	7	45 ± 12	14 ± 5	4 (3–4)	100	0
Medical treatment	7	48 ± 10	14 ± 5	2 (1–3)	43	14

\*Satisfaction rating: 0 = very dissatisfied, 1 = dissatisfied, 2 = neither satisfied nor dissatisfied, 3 = satisfied, 4 = very satisfied. Satisfaction scores are reported as the median value with the range in parentheses.

colleagues found that using a strict SHG methodology, they were able to as effectively evaluate the extent of intramural versus submucous involvement of the myoma with SHG as with hysteroscopy.<sup>6</sup> Figures 38-4 and 38-5 demonstrate the SHG appearance of various types of myomata and how the authors evaluated the amount of endometrial extension. Figure 38-6 demonstrates the hysteroscopic appearance of a G2 type myoma, with only a portion of the myoma seen protruding into the cavity.

The surgical technique for removal generally involves the use of the resectoscope, although historically lasers and other devices were used. Loffer described the process of resection, whereby the active electrode is placed behind the myoma and strips of myoma are removed as the electrode is brought toward the resectoscope (Fig. 38-7).<sup>7</sup> If a portion of the myoma is

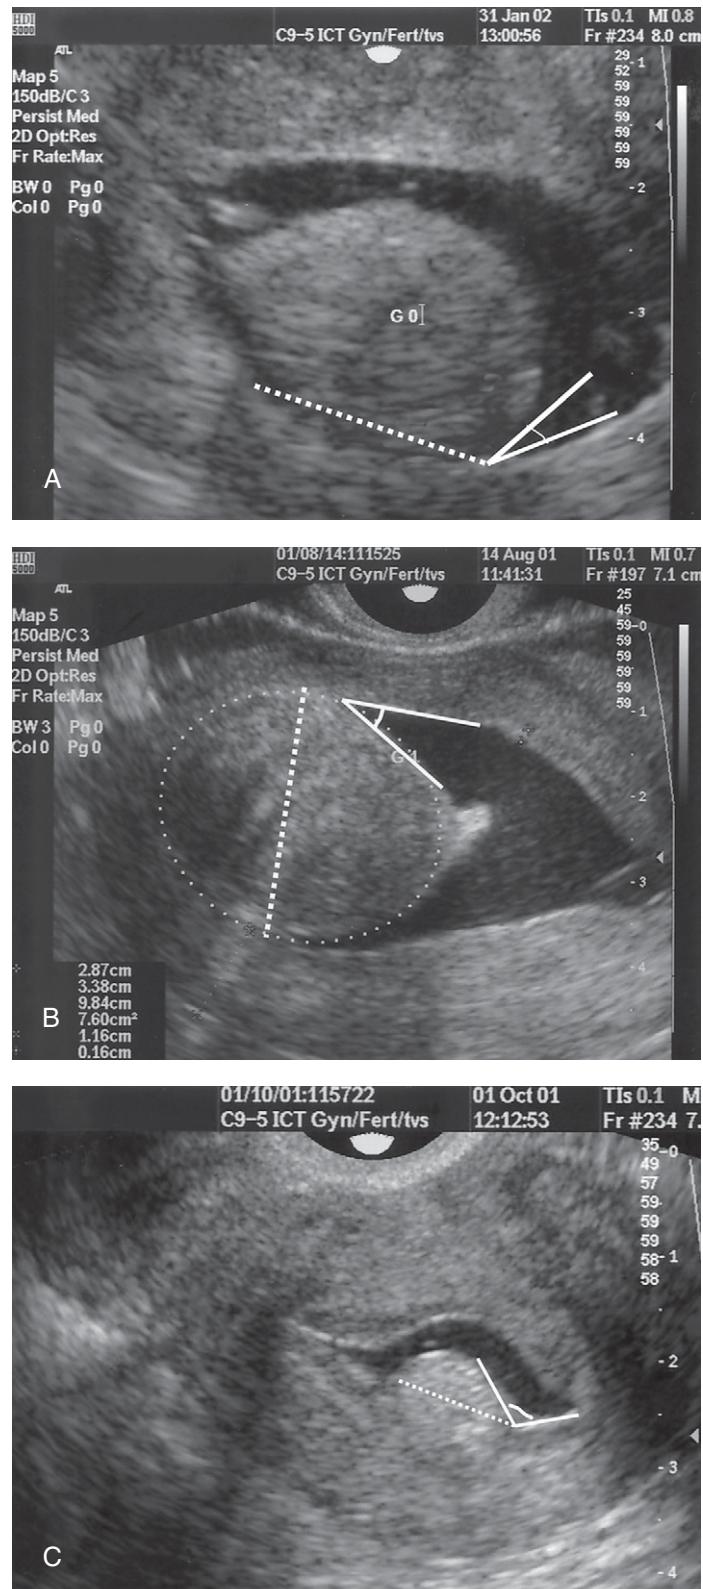

**Figure 38-3** Demonstration of the evolution of a myoma from intramural (A), to partly intracavitory (B), to completely intracavitory with a sessile base (C), to pedunculated intracavitory myoma (D), to prolapsing myoma on a thin pedicle (E). (From Bieber EJ, Maclin VM [eds]: Myomectomy. Boston, Blackwell Science, 1998, chap. 7, fig. 1.)

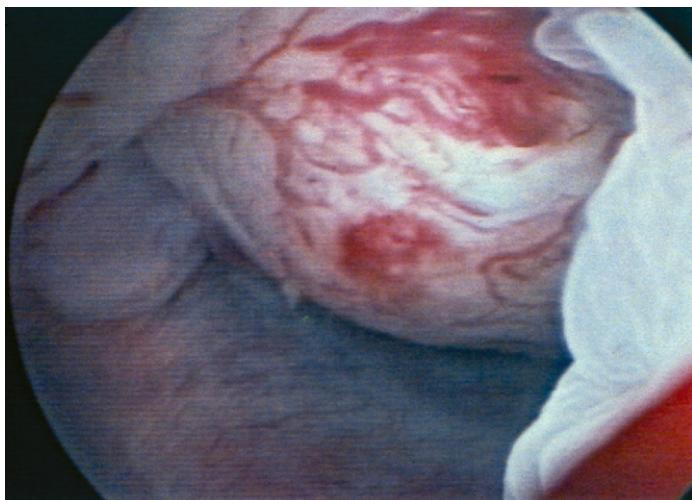

**Figure 38-4 Schematic drawing of the sonographic criteria.** The white dotted line depicts the line joining the two myoma–endometrial edges of the myoma, which allows the percentage of intracavitary and intramural portions of the myoma to be determined. The black lines show the angle between the endometrium and the circumference of the fibroid on the same plane. (From Leone FP, Lanzani C, Ferrazzi E: Use of strict sonohysterographic methods for preoperative assessment of submucous myomas. *Fertil Steril* 2003;79:998–1002.) Copyright 2003. Reprinted with permission from the American Society for Reproductive Medicine.

intramural, as the resection proceeds myometrial contractility will “push” the intramural portion of the myoma toward the cavity, allowing more of the myoma to be removed (Fig. 38-8). Generally, we do not resect below the level of the endometrium. This same technique may be applied to polyps or other intrauterine abnormalities such as adenomyomata (Fig. 38-9), which would otherwise be impossible to remove. As myoma chips accumulate and obscure vision, they are removed and retained to send for pathology. Fluid input and output is always important to observe during any operative hysteroscopy. The process of resecting myomata may quickly open large vessels, which then

**Figure 38-5 Submucous myomas.** A, Submucous myoma classified as G0 on sonohysterogram (SHG). B, Submucous myoma classified as G1 on SHG. C, Submucous myoma classified as G2 on SHG. (From Leone FP, Lanzani C, Ferrazzi E: Use of strict sonohysterographic methods for preoperative assessment of submucous myomas. *Fertil Steril* 2003;79:998–1002.) Copyright 2003. Reprinted with permission from the American Society for Reproductive Medicine.

**Figure 38-6** A partly intracavitary myoma is seen on hysteroscopy in a patient who presented with anemia and menorrhagia. The majority of the myoma is intramural.

will allow fluid extravasation and quick loss of media, so vigilance during these procedures is especially important. Figure 38-10 demonstrates a patient who had presented with significant bleeding and had been placed on high-dose oral contraceptives for an extended period. An entirely intracavitary myoma is seen with underlying striations of musculature and a very thin endometrium from use of the oral contraceptives. Figure 38-11 demonstrates a patient who presented with profound anemia and an intracavitary myoma. With removal of the intrauterine mass her menorrhagia resolved completely.

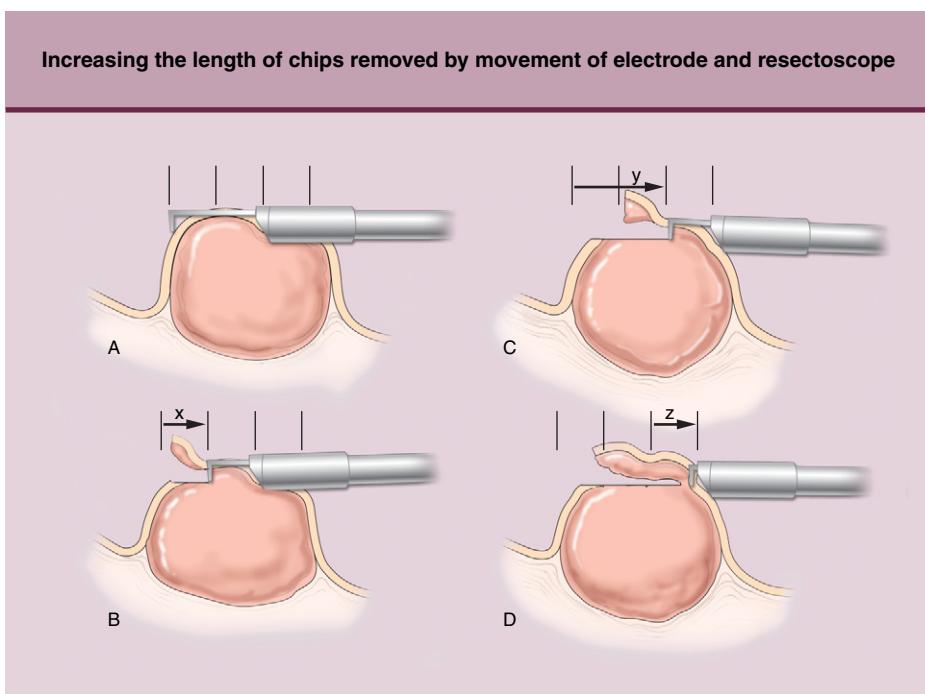

A newer alternative to this technique is the use of bipolar instrumentation, which allows vaporization of a portion of the

myoma.<sup>8</sup> In this situation, normal saline may be used as a distending media. A portion of the myoma should still be retained for pathology.

Resectoscopic myomectomy appears to have an excellent success rate in patients presenting with menorrhagia. More than 90% of patients will experience immediate relief after these procedures. Vercellini and colleagues evaluated results in 108 women who underwent hysteroscopic myomectomy, finding a 3-year recurrence rate of 34% and a return of menorrhagia at 3 years of 30%.<sup>9</sup> They found that extent of intramural extension was correlated with need for additional procedures for complete removal but did not influence long-term success. In a larger case series, Emanuel and colleagues reported on 285 patients who underwent hysteroscopic myomectomy.<sup>10</sup> Median follow-up was 46 months, with 14.5% of patients having a repeat surgery. Both uterine size and number of submucous myomata were independent prognosticators for recurrence, with 90.3% of patients with an initial normal size uterus and two or fewer myomata recurrence-free.

Results after hysteroscopic myomectomy in infertility patients are less well investigated but appear to have similar results to open myomectomy. Vercellini and colleagues reported a 3-year cumulative pregnancy rate of 49%, 36%, and 33% in patients with pedunculated, sessile, and partly intramural myomata, respectively.<sup>9</sup>

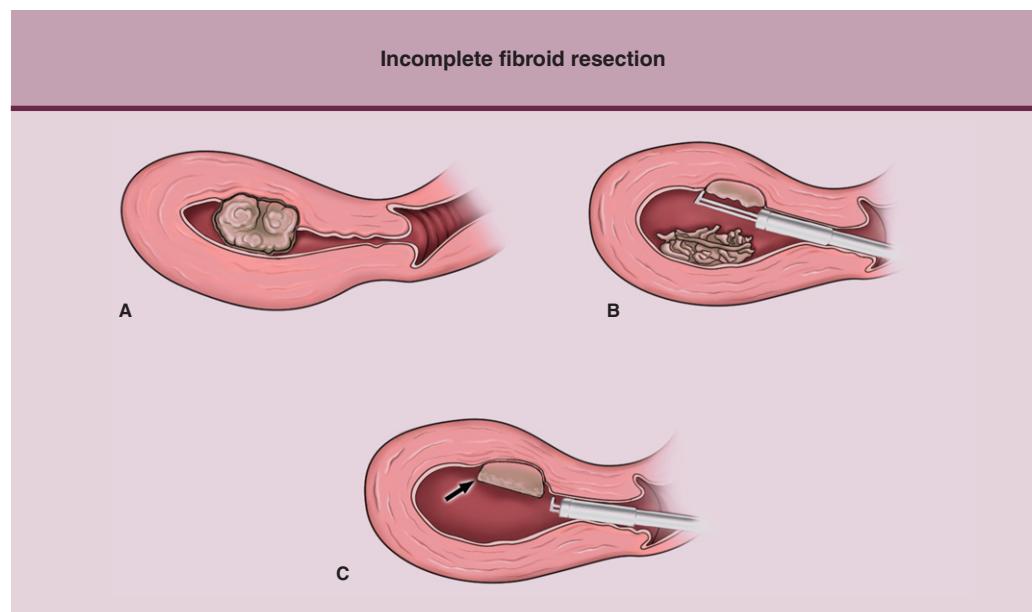

Limitations of hysteroscopic myomectomy may include the size of the submucous myoma, with myomata greater than 4 cm being somewhat difficult to remove in a single operative session. In addition, risk of fluid overload may increase with increasing myoma size. Another difficult situation is when the myoma has begun to prolapse through the cervix making distention impossible (Fig. 38-12). In these settings, if the myoma is on a stalk, rotating the myoma repetitively may allow it to be freed from its underlying attachment. Care must also be exercised

**Figure 38-7** Increasing the length of chips removed by movement of both the electrode and the resectoscope. *A*, The loop is placed fully extended. *B*, The loop is partially closed resecting a portion (*x*) of the chip. *C*, The resectoscope is then withdrawn without further closing of the loop thus enlarging the length of the chip to *y*. *D*, Finally, the loop is closed into the resectoscope completing the formation of a long chip by resecting to *z*. (From Bieber EJ, Loffer FD [eds]: Hysteroscopy, Resectoscopy and Endometrial Ablation. New York: Parthenon, 2003, p 102, fig. 4.)

**Figure 38-8 Incomplete fibroid resection**

**resection.** A, A sessile myoma before partial removal is prevented from becoming pedunculated by counterpressure from the opposite uterine wall. B, The myoma is shaved flush with the uterine wall during the resectoscope procedure. C, After the uterine cavity is emptied of distending medium to retrieve the chips, the uterine muscle fibers beneath the myoma contract and push the myoma out of its base so that a lip of the myoma visibly protrudes beyond the level of the uterine cavity (arrow). (From Loffer FD: Removal of large symptomatic intrauterine growths by the hysteroscopic resectoscope. *Obstet Gynecol* 1990;76:836-840 fig. 1.)

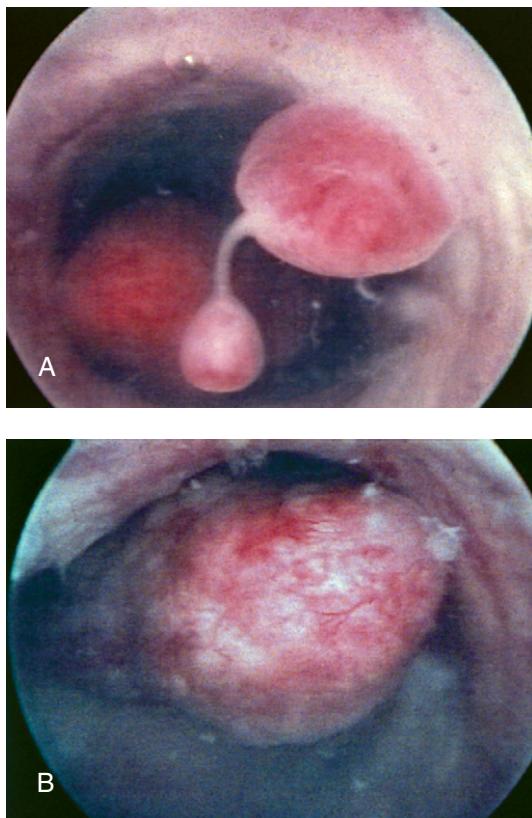

when resecting myomata that are either fundal or near the cornua. When resecting near the fundus, it may be difficult to move the electrode toward the instrument effectively; it may require a back-and-forth motion. When resecting near the cornua, care must be taken because this area may be thin and

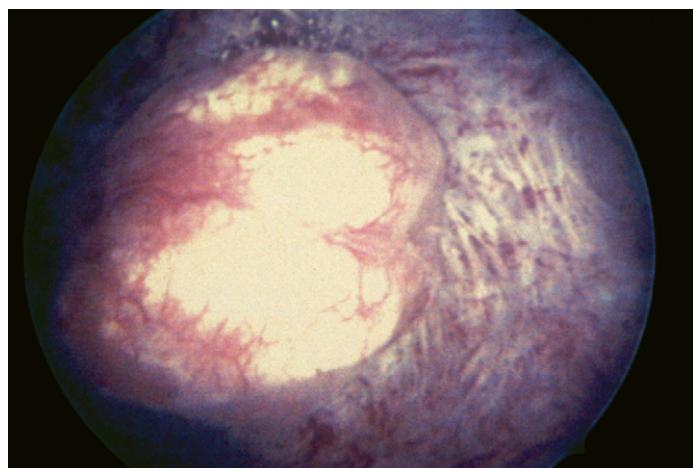

thus predisposed to perforation. Consideration may be given to concomitant laparoscopy in selected cases, although in many cases it will not be required.

#### Resection/Incision of Uterine Septum

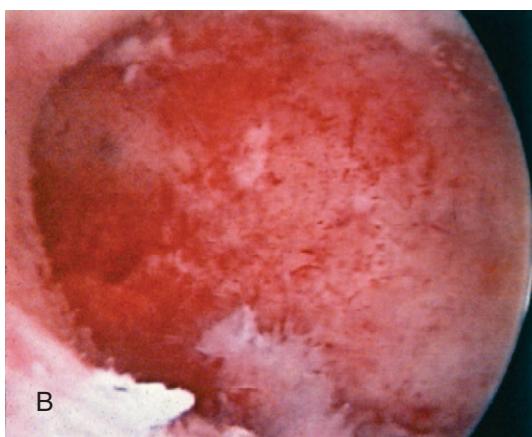

Historically, the septate uterus had been managed with a laparotomy and Tompkins or Jones metroplasty. These procedures required inpatient hospitalization and the morbidity of a laparotomy, with concern regarding formation of adhesions, as well as the need for subsequent mandatory cesarean section should pregnancy ensue. Fortunately, the advent of hysteroscopy has allowed effective transcervical treatment of this müllerian abnormality. Patients may present with habitual pregnancy loss or infertility and are generally identified on SHG or HSG. The clinician must determine that the abnormality is not a bicornuate uterus, a condition not amenable to hysteroscopic management.

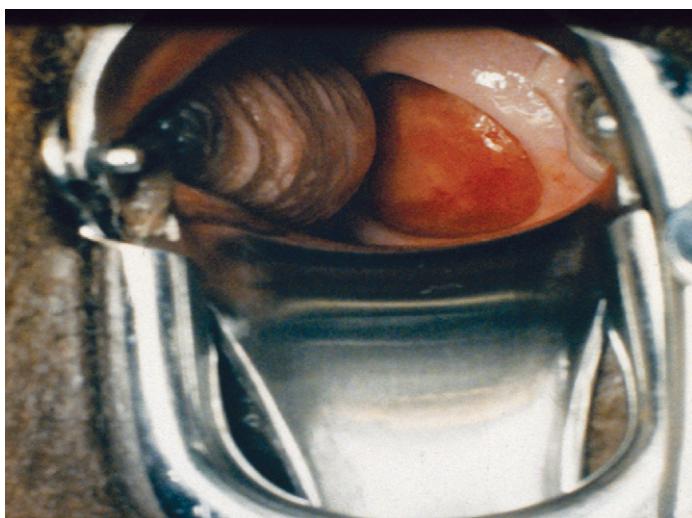

**Figure 38-9** A, A small bizarre-looking polyp is seen in the lower uterine segment. B, Beyond this polyp a large adenomyoma is present in a patient who presented with menorrhagia.

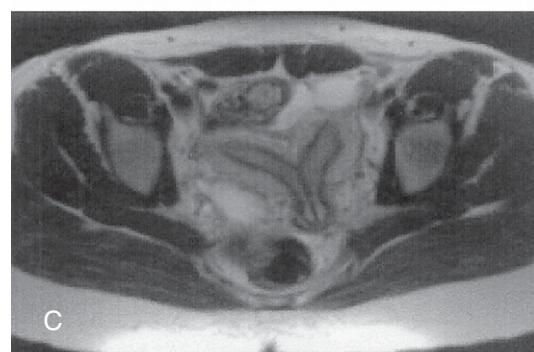

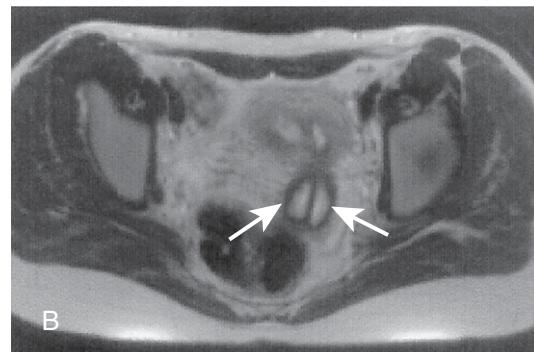

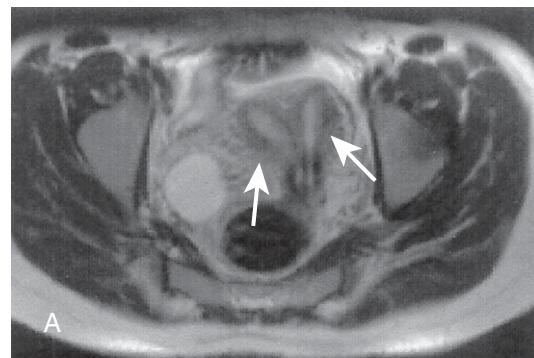

**Figure 38-10** An entirely intracavitory myoma is seen in a patient who had been treated with extended high-dose oral contraceptives. Little endometrium is identified and underlying myometrial striations are seen.

**Figure 38-11** Patient who had prior laparotomy myomectomy who presented with profound anemia. A, A discrete intracavitary myoma is identified. B, A normal cavity after resection of the myoma. The patient resumed normal menses following the surgery.

**Figure 38-12** Patient with dilated cervix and myoma beginning to prolapse through the cervix. (From Bieber EJ, Maclin VM [eds]: Myomectomy. Boston, Blackwell Science, 1998.)

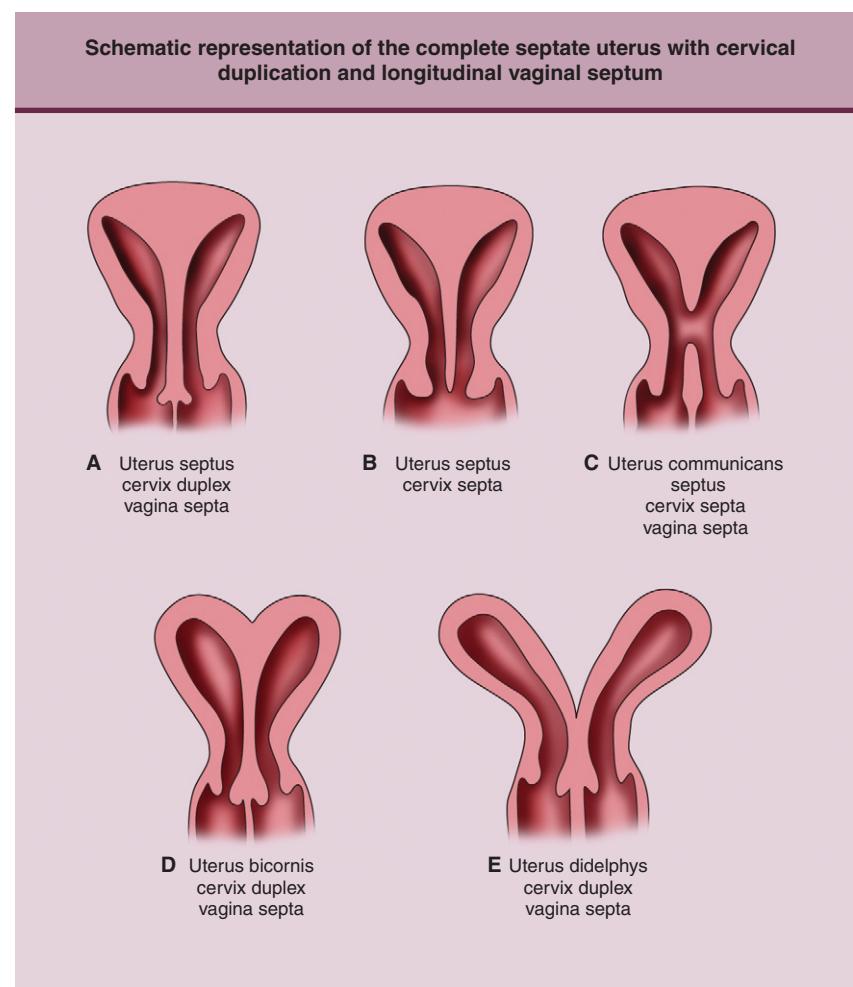

**Figure 38-13** A, High-resolution, T<sub>2</sub>-weighted axial MRI, demonstrating a normal uterine contour, a uterine septum, two separate endometrial cavities (arrows), and two cervices. Incidental note is made of a right ovarian cyst. B, T<sub>2</sub>-weighted axial MRI of same patient, which further demonstrates two distinct cervices (arrows). C, High-resolution T<sub>2</sub>-weighted MRI of another patient, demonstrating a mixed müllerian anomaly with partial uterine septum, fused uterine horns, small indentation at the fundus, and two distinct cervices. (From Chang AS, Siegel CL, Moley KH, et al: Septate uterus with cervical duplication and longitudinal vaginal septum:a report of five new cases. Fertil Steril 2004;81:1133–1136.) Copyright 2004. Reprinted with permission from the American Society for Reproductive Medicine.

Magnetic resonance imaging studies may be useful in this regard (Fig. 38-13).<sup>11</sup> If the patient has presented with habitual pregnancy loss, a complete workup should be performed before surgery even if an abnormality is seen early on in the evaluation on HSG. Many variations of uterine septa exist, ranging from small septa to complete septation to the cervix or even an associated vaginal septum (Fig. 38-14).

Interestingly, most uterine septa do not require excision but instead require incision. Multiple different devices and energy modalities have been used to accomplish incision, including

**Figure 38-14 Complete septate uterus with cervical duplication and longitudinal vaginal septum and other uterine anomalies for which it may be mistaken.**

A, Schematic representation. B, Complete septate uterus with single cervix. C, Complete septate uterus and single cervix with midseptal perforation (atrium communicans) and vaginal septum; D, Bicornuate uterus with double cervix and longitudinal vaginal septum. E, Didelphic uterus. (From Patton PE: The diagnosis and reproductive outcome after surgical treatment of the complete septate uterus, duplicated cervix, and vaginal septum. Am J Obstet Gynecol 2004;190:1669–1678.)

laser, scissors, knife or point electrodes, or the resectoscope with a 180-degree loop. Each has different pros and cons, and no one modality has been found to be more effective than another.

The surgical technique involves identification of the extent of the septum and evaluation of the two subcavities that it separates. If a vaginal septum is present, this may need to be incised prior to the hysteroscopic portion of the procedure. The ostia should be identified in each of the cavities. Concomitant laparoscopy is often employed both to ascertain that the anomaly is amenable to hysteroscopic treatment and to evaluate the extent of incision. The chosen modality is then used to begin to incise the septum. As this occurs the cavity begins to open. It is important to stay in the center of the septum and not cut toward the anterior or posterior wall because bleeding may ensue. Incising small amounts of the septum at a time will optimize this. Care should be taken not to overextend the incision into the uterine fundus because this may weaken the area and allow subsequent perforation during pregnancy (see Chapter 39). If a laparoscope is in place, the surgeon may be able to access the remaining fundal thickness by turning the laparoscope illumination to a low level and viewing the transmission of light from the hysteroscope through the uterine fundus.

Postoperatively various regimens have been used to decrease the formation of intrauterine adhesions in the denuded area of

the septal incision. Few good studies exist to determine if any of these, including use of an antibiotic, intrauterine device (IUD), or estrogens, have value.<sup>12</sup> Nawroth and colleagues evaluated a small number of patients who underwent septal resection and were placed on no therapy, cyclical hormone replacement therapy (HRT) and IUD, or HRT alone and noted no improvement with either of the active treatments.<sup>13</sup> Given the limited data, in a patient with no contraindications, we generally place the patient on unopposed estrogen for a month followed by progestin withdrawal. Fortunately, few patients will form adhesions and the area appears to heal quickly. After several cycles the cavity should be reassessed by HSG or hysteroscopy. On occasion, a small fundal indentation may still exist where the larger septum was lysed. These appear to have little clinical consequence when smaller than 1 cm.

Reproductive outcome after lysis of uterine septa is very good and comparable to that achieved through the successful but more invasive open procedures. It is generally believed that while a uterine septum may interfere with the ability to sustain a pregnancy, it may have a limited impact on fertility. Unfortunately, to date no well-performed randomized, controlled trial exists regarding treatment of a uterine septum. Valle reported on a case series of 124 patients with partial or complete uterine septa who had 299 pregnancies, of which 87% were miscarried and 10% were delivered prematurely.<sup>14</sup> After hysteroscopic

## Minimally Invasive Surgery

removal of the septum, 81% of patients achieved pregnancy, with 83% delivered at term, 7% preterm, and 12% first-trimester losses. Homer and colleagues evaluated a number of case series and found that collectively the 658 patients with recurrent loss had an 88% miscarriage rate prior to metroplasty, which was decreased to 14% after surgery.<sup>15</sup> Smaller case series by Valli and colleagues and by Vertuoli and colleagues found similar improvements.<sup>16,17</sup>

Lavergne and colleagues retrospectively evaluated patients with uterine anomalies and noted a lower rate of implantation that improved when patients with a uterine septum were treated.<sup>18</sup> Many surgeons who initially would not treat patients until they had one or more miscarriage have reevaluated this paradigm and will now treat patients desiring fertility prior to any losses. Indeed, it is recommended that patients pursuing in vitro fertilization have uterine septa lysed before beginning treatment with assisted reproductive technology. Hopefully, in the future randomized, controlled trials will provide similar compelling information regarding the efficacy of septolysis as the multitude of case series have suggested.

### **Lysis of Intrauterine Adhesions (Asherman's Syndrome)**

Hysteroscopy has also revolutionized the treatment of intrauterine adhesions. Historically the clinician simply performed a D&C with the hope of breaking apart the adhesive bands and preventing them from re-forming. Modern hysteroscopy allows a more rationale approach to this difficult surgery.

Patients typically present with amenorrhea having undergone an antecedent procedure such as D&C for a missed abortion or postpartum. However, the range of presentations also includes patients with hypomenorrhea or eumenorrhea who may only present with infertility. Valle and Sciarra reported that in 183 of 187 patients with intrauterine adhesions, these adhesions were associated with a prior obstetric curettage.<sup>19</sup> Westendorp and colleagues prospectively evaluated 50 patients who had undergone curettage for placental remnants more than 24 hours after delivery or a repeat curettage after D&C for incomplete abortion.<sup>20</sup> Hysteroscopy performed 3 months later demonstrated that 20 of 50 (40%) patients had adhesions ranging from mild to severe.

Typically, HSG will document an abnormal cavity that may be small, misshapen, or filled with discrete intracavitory abnormalities consistent with adhesions. The fallopian tubes may or may not be patent on HSG; adhesive disease can range from a single adhesion to an entirely obliterated cavity.

Surgery for Asherman's syndrome may be the most difficult hysteroscopic procedure, with the highest level of concomitant risk of complications (see Chapter 39). Unless the case is deemed to be simple with a small number of adhesions, laparoscopy may be considered and performed during the hysteroscopic portion of the procedure on a separate video monitor. During the initial phase of the hysteroscopy we prefer a small-size hysteroscope. The endocervical canal is evaluated first and then exploration of the uterine cavity is begun (if possible). Visualization of the ostia may or may not be possible but when seen they provide excellent landmarks. Adhesions are identified and transected in the middle. Again, various modalities have been used, including laser, resectoscope, and various electrodes. It is believed that avoiding

energy sources that may cause lateral thermal damage offers an advantage, although no trials exist to demonstrate the superiority of one modality over another. Zikopoulos and colleagues reported on a 10-year experience using either the resectoscope or the Versapoint system and found similar rates of success.<sup>21</sup> We prefer scissors placed through the operative hysteroscope with a large enough sheath to allow adequate pressures for distention and outflow should any bleeding be encountered. If distention is inadequate, it may be more difficult to appreciate the origin and insertion of the adhesive bands. This process is continued until the adhesive bands are freed and the uterus attains a reasonably normal configuration. At this point, if tubal patency was not initially visible, it should be reevaluated.

Postoperatively most surgeons treat with unopposed estrogen for a period followed by progestin withdrawal unless contraindicated. Others have used IUD (nonmedicated) as an alternative or in addition to estrogen. Unfortunately, little information exists on what postoperative treatments (if any) optimize success and limit the re-formation of adhesions. Ultimately HSG, hysteroscopy, or both should be performed to reevaluate the cavity for the possibility of adhesion reformation.

Valle and Sciarra reported one of the first large series of hysteroscopic intervention in patients with Asherman's syndrome.<sup>19</sup> Only 9.6% of patients initially had normal menses, but after intervention 89% reported normal menstrual function. Successful term pregnancy correlated with extent of adhesions, with 81% of patients successful with mild adhesions but only 32% success with severe adhesions. Katz and colleagues specifically evaluated patients who had a minimum of two prior pregnancies with a prior early loss or a preterm delivery with subsequent loss who underwent hysteroscopic adhesiolysis.<sup>22</sup> Prior to intervention, only 18% of pregnancies were delivered at term, with 62% first-trimester losses. After adhesiolysis, success was seen in 64% of pregnancies. Capella-Allouc and colleagues reported on hysteroscopic adhesiolysis in patients with severe Asherman's syndrome.<sup>23</sup> In 15 of 31 cases, two, three, or even four procedures were required to free the cavity and at least one ostia area. A live birth rate of 32% was ultimately achieved, although success was higher (62.5%) in patients younger than age 35.

Patients undergoing these surgeries should understand the potential need for further surgery to attain a cavity with a normal configuration and that in some cases, this may not be possible. In addition, subsequent pregnancies may have placental abnormalities such as placenta accreta, which may cause significant bleeding at the time of delivery and even necessitate hysterectomy.<sup>19,21,23</sup>

### **Hysteroscopic Sterilization**

For a number of years, multiple clinical trials have evaluated hysteroscopic methodologies for sterilization. In November 2002 one of these methods became available in the United States. Multiple technical issues made the development of such a device quite difficult, including the need to easily place the device in uteri of different shapes as well as the need for occlusion in all patients.

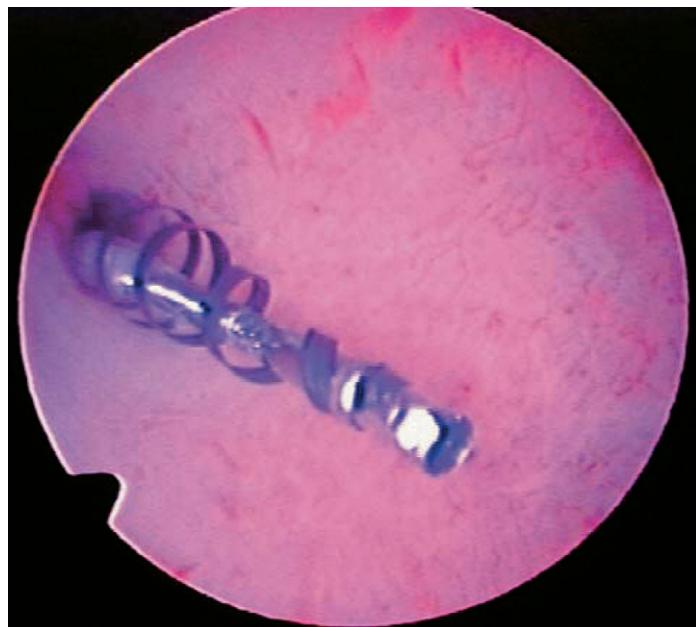

The Essure device that is presently available is made of polyethelyne (PET) fibers in a coil (Fig. 38-15). The device is delivered through the operative channel of the hysteroscope and

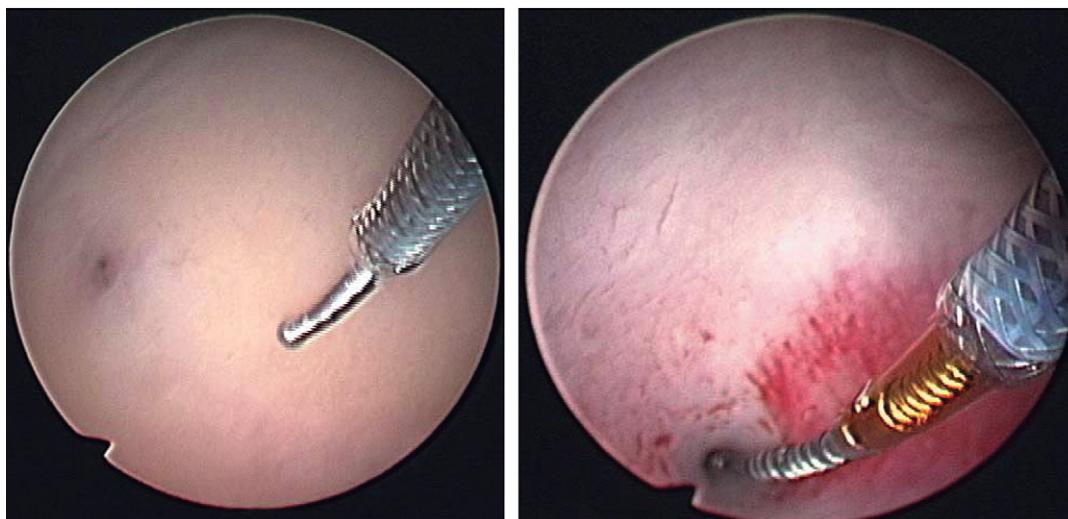

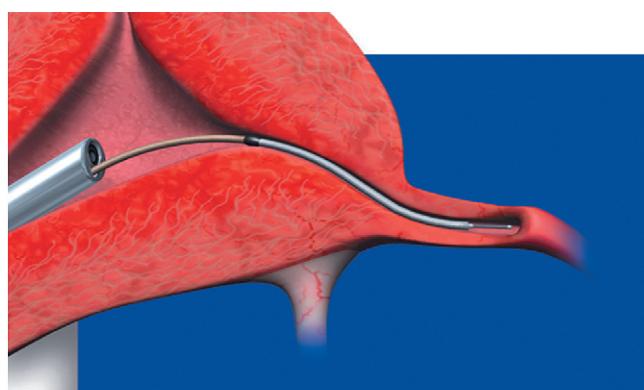

**Figure 38-15 An Essure insert.** (Courtesy of Conceptus, Inc., Mountain View, CA.)

is placed within the ostia. Release of the device allows the coils to unwind, anchoring them at the level of the uterotubal junction (Fig. 38-16). When ideally placed a small number of coils are visible within the uterine cavity while the majority of the coils are located within the tubal lumen (Fig. 38-17). The PET fibers cause a local inflammatory response with subsequent occlusion of the tubal lumen. Patients are recommended to use a reliable form of contraception for the next 3 months and then undergo subsequent HSG to document tubal occlusion (Fig. 38-18). Some authors have suggested that a follow-up ultrasound may be adequate for assessing the location of the inserts.<sup>24</sup>

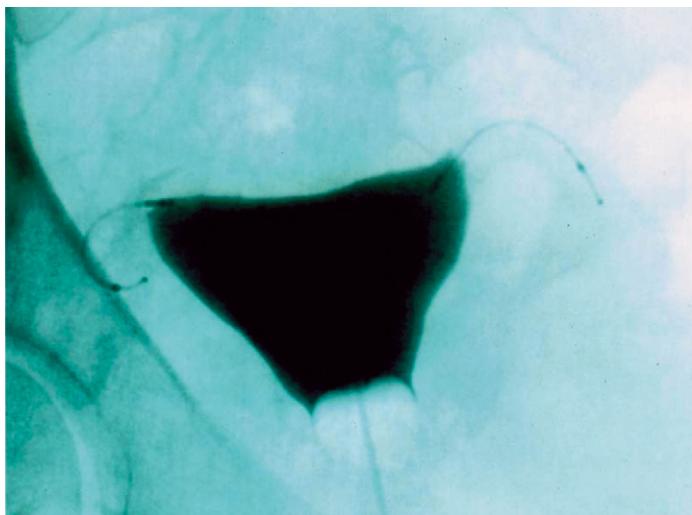

Data from the pivotal trial of the Essure device as well as ongoing evaluation document an effectiveness of more than 99% in patients who have the devices placed appropriately and have evidence of tubal occlusion at follow-up evaluation. Patients do need to be aware that the implants may be extruded, perforation may occur, and uterine or tubal abnormalities may preclude placement. If placement of the device is unsuccessful, some patients will opt for laparoscopic tubal sterilization.

**Figure 38-17 Essure coils visible in the ostia after hysteroscopic placement.** (Courtesy of Conceptus, Inc., Mountain View, CA.)

**Figure 38-16 An Essure device being placed into the fallopian tube.** (Courtesy of Conceptus, Inc., Mountain View, CA.)

**Figure 38-18 Hysterosalpingogram (HSG) demonstrates tubal occlusion with both Essure devices visible at the uterotubal junctions.**

In the Phase III clinical trial, the microinserts were able to be bilaterally placed in 92% of patients and at 3 months tubal occlusion was confirmed in 92%.<sup>25</sup> In this study, 449 of 518 (87%) patients were able to rely on this device for permanent contraception. In another report 98% of patients at 2 years after surgery reported their tolerance of the microinsert as very good or excellent.<sup>26</sup> Follow-up studies have documented significant satisfaction with the procedure and quick recovery with little morbidity. No significant change in menstrual function has been seen to date.

The significant advantage of a hysteroscopic approach for sterilization is the avoidance of entry into the abdominal cavity, which may be very relevant for patients with prior surgery as well as obese patients or those at higher surgical risk for laparoscopy. The Essure device should not be placed in persons who are allergic to nickel. Clinical investigations are ongoing into other methods of hysteroscopic sterilization, which may become available in the future.

#### Treatment of Proximal Tubal Occlusion

Proximal tubal occlusion may be seen in patients seeking fertility treatment with up to 15% of HSGs demonstrating tubal occlusion. Historically these patients were treated with laparotomy and resection and reanastomosis or reimplantation of the affected tube. Hysteroscopic treatment allows a much less invasive technique with similar rates of patency and pregnancy. At HSG, a false-positive finding of tubal occlusion may occur with tubal spasm. When Sulak and colleagues evaluated sections of tube excised for a diagnosis of proximal tubal occlusion, they noted that in 11 of 18 cases no occlusion could be demonstrated and in 6 cases amorphous material was contained within the tubal lumen that they called "plugs."<sup>27</sup>

Novi and colleagues reported on use of a transcervical catheter and inner flexible guidewire placed either via hysteroscopy or fluoroscopy to treat proximal tubal occlusion.<sup>28</sup> Hysteroscopy and concomitant laparoscopy allow documentation that proximal occlusion is present and that concomitant distal disease is not present. An operative hysteroscope is then used to introduce

the initial catheter, which has an angulation that allows it to preferentially come in proximity with the ostia. At this point methylene blue may be reintroduced in direct proximity to the ostia to again document that proximal tubal occlusion exists. Once reconfirmed, the inner wire is inserted through the initially placed catheter in an attempt to break through the area of blockage. The use of concomitant laparoscopy facilitates viewing the lateral passage of the inner catheter through the tube as well as helping the surgeon avoid perforation of the tube if the blockage is severe. If the catheter passes through the blockage, methylene blue is again used to document that tubal patency has been restored.

Another alternative to this technique has been the performance of the procedure using similar catheter systems with radiographic assistance. Similar rates of success have been reported in the literature. A potential limitation of the fluorographic technique is that, without documentation of the normality of the distal tube, an abnormal tube that would not have been operated on endoscopically and that would instead have prompted the gynecologist to recommend in vitro fertilization could be opened. In reality, both techniques appear effective.

Al-Jaroudi and colleagues evaluated 7 years of data on patients presenting for bilateral tubal occlusion at a single institution.<sup>29</sup> On reevaluation, they noted that over 14% of patients had bilateral patent tubes and 12% had at least one patent tube. Using fluoroscopic techniques, they were able to recannulize at least one tube in 61% of patients, with an overall pregnancy rate of 31.9%. This data is consistent with a review of 1079 patients by Thurmond and colleagues demonstrating a crude pregnancy rate of 30%.<sup>30</sup>

#### Endometrial Ablation/Resection

DeCherney and Polan first reported on use of the resectoscope to treat critically ill patients with abnormal uterine bleeding.<sup>31</sup> Since this first report, thousand of patients have undergone endometrial ablation with a multitude of technologies. Initial reports used either the laser, or ball, barrel, or loop electrodes to cause endometrial destruction. More recently, global methodologies have supplanted hysteroscopic endometrial ablation. These technologies include cryoablation, microwave ablation, bipolar ablation, thermal balloon ablation, hysteroscopic thermal ablation, and other rapidly developing devices.

Hysteroscopic endometrial ablation remains a viable alternative for some patients. In a patient with an enlarged or abnormally shaped uterus, this option may be preferable to a global technology. Patients may be pretreated with medical agents before endometrial ablation. The most recent Cochrane review suggests that use of gonadotropin-releasing hormone analogs may improve operating conditions and short-term outcomes.<sup>32</sup> Unfortunately, little information is available regarding long-term outcomes or use of agents with global techniques.

Most surgeons use a small ball electrode with a standard resectoscope. This requires use of a nonelectrolyte-containing media such as glycine unless bipolar technology is used. Initially the cornua are ablated, followed by the fundus, anterior, and sidewalls and finally the posterior uterus. If the uterus has been well prepared before surgery, there should be little tissue present. Variation exists among surgeons regarding the use of a pure cutting current versus coagulation or blended current. Visual

feedback during the ablation suggests whether an adequate effect is being achieved. An alternative to use of a ball electrode is endometrial resection, in which a loop electrode is used to remove a large portion of the endometrium. Interestingly, this technique seems to be favored in Europe whereas coagulation ablation is the favored technique in the United States.

Rauramo and colleagues performed a 3-year open randomized trial of endometrial resection versus the levonorgestrel intrauterine system (IUS) for long-term treatment of menorrhagia.<sup>33</sup> They found both markedly reduced menstrual bleeding and noted a 63% continuation rate in the IUS group. Zupi and colleagues randomized 180 patients to endometrial resection or laparoscopic supracervical hysterectomy and found decreased operative time in the hysteroscopic group but greater patient satisfaction in the hysterectomy group.<sup>34</sup> Pellicano and colleagues evaluated endometrial resection versus thermal ablation and noted thermal ablation to have a higher satisfaction rate, with a decreased operative time, blood loss, and need for reintervention.<sup>35</sup> Interestingly, Boujida and colleagues evaluated 120 women with menorrhagia who had undergone endometrial ablation via coagulation or resection and found no difference in frequency of complications between the groups.<sup>36</sup> However, only 15% of patients subsequently failed their ablation and underwent hysterectomy, while another 15% underwent a second endometrial ablation. Similar reductions in blood loss and patient satisfaction were also noted in both groups. In a case series of 240 women undergoing roller ball endometrial ablation, Dutton and colleagues reported that the probability of no hysterectomy at 5 years was 71% and that repeat ablation and ablation at a younger age were risk factors for failure.<sup>37</sup> Confirming the significant and sustained reduction in blood loss, Teirney and colleagues evaluated menstrual blood loss after roller ball ablation.<sup>38</sup> Using alkaline hematin technique, they reported a decrease in menstrual bleeding from 90 mL before surgery to 3.8 mL at 3 months, 1.8 mL at 6 months, and 3.3 mL at 5 to 6 years after endometrial ablation.

Endometrial ablation has been compared to hysterectomy in several trials, including one conducted by the Aberdeen Endometrial Ablation Trials Group.<sup>39</sup> They randomized 204 women to hysterectomy or endometrial ablation; patients were followed for a minimum of 4 years. Of women randomized to the endometrial ablation group, 38% required further surgery, with 24% undergoing hysterectomy. Both groups had overall high patient satisfaction—80% for endometrial ablation and 89% for hysterectomy. When all factors were considered, ablation was still less expensive, but over time this difference had narrowed from initially after surgery. A 2000 Cochrane review of endometrial resection versus hysterectomy for menorrhagia suggested that improvement in heavy menstrual bleeding and overall satisfaction up to 4 years after surgery was weighted toward hysterectomy.<sup>40</sup> They did state that major and minor adverse events were more likely after hysterectomy, although these differences were markedly diminished on discharge to home.

These data suggest that endometrial ablation remains an appropriate therapy in selected patients with menorrhagia. Up to one third of these patients may require further intervention, with one quarter or more likely to undergo subsequent hysterectomy when viewed over a number of years. It appears that global methods of performing endometrial ablation are as

successful as the more difficult hysteroscopic procedures but may not be applicable to all patients; in addition, overall there is less long-term data related to them. Endometrial resection is a more complicated procedure to perform, although in experienced hands it appears to produce good results. Consideration may be given to alternatives such as the levonorgestrel-containing IUS if appropriate or even hysterectomy if definitive treatment is preferable.

### Endometrial Cancer

Hysteroscopy has been used for several decades as an adjuvant to D&C in the evaluation of patients with abnormal or postmenopausal bleeding. An advantage of hysteroscopy is that the surgeon may identify a lesion, which may then be directly sampled. Figure 38-19 demonstrates complex hyperplasia with atypia with numerous abnormal vessels, which contained a discrete lesion that was a well-differentiated adenocarcinoma. Clark and colleagues, in a review of the literature, found

A

B

**Figure 38-19** A, Patient with postmenopausal bleeding who is seen to have markedly abnormal vessels and tissue, which was atypical hyperplasia with atypia. B, Same patient; focus of well-differentiated adenocarcinoma within the endometrial hyperplasia.

## Minimally Invasive Surgery

hysteroscopy to have 86% sensitivity and 99% specificity for endometrial cancer.<sup>41</sup> They noted that hysteroscopy had high diagnostic accuracy for endometrial cancer and moderate accuracy for endometrial disease (endometrial cancer and hyperplasia). Litta and colleagues also found hysteroscopy to be of value in evaluating postmenopausal bleeding and differentiating benign lesions such as polyps and myomata.<sup>42</sup> They suggest the synergistic value of transvaginal ultrasound along with hysteroscopy and endometrial biopsy in clearly obtaining a diagnosis.

A persistent question has been the issue of dissemination of endometrial cancer cells during the performance of hysteroscopy, especially with the use of fluid media. Bradley and colleagues retrospectively evaluated 256 charts from patients who had endometrial cancer and found positive peritoneal cytology in 6.9% of patients who initially underwent endometrial biopsy or D&C versus 13.5% in those who underwent hysteroscopy.<sup>43</sup> Sainz de la Cuesta and colleagues randomly assigned patients to hysteroscopy immediately before laparotomy for endometrial cancer or to no hysteroscopy and found a small increase in risk of positive peritoneal cytology in the fluid hysteroscopy group but no change in prognosis.<sup>44</sup> In contrast, multiple authors have reported no increase in incidence of positive peritoneal washings or change in prognosis.<sup>45,46</sup> Further prospective studies may help to address the question of whether hysteroscopy actually increases the dissemination of cells more than standard D&C and if this is clinically relevant for disease prognosis.

## CONCLUSION

Hysteroscopy remains the most efficient technology for both evaluating and treating intrauterine disease. In modern gynecologic surgery, hysteroscopy has supplanted many of the gold standard procedures. Rarely today are there indications for Jones or Tompkins metroplasty or laparotomy for proximal tubal disease. Even standard laparoscopic tubal ligation may give way to less invasive hysteroscopic sterilization.

# Chapter 39

# Laparoscopic and Hysteroscopic Complications

Eric J. Bieber, MD, MHCM

## KEY POINTS

- Operative laparoscopy has an overall 1% to 2% complication rate.
- The majority of complications in laparoscopy occur during attempted entry with Veress needle or trocar.
- Even under direct visualization, placement of ancillary trocars may still cause injuries.
- Patients with prior midline surgery have a 60% chance of midline adhesions.
- Alternative sites, such as the left upper quadrant, may be used to gain abdominal entry in selected cases.
- No one method of entry (closed, direct, open) has been demonstrated to be better or safer.
- The inferior epigastric vessels have a dual blood supply.
- A Foley catheter may be placed through a trocar sleeve to tamponade bleeding from epigastric vessels.
- Instill dilute methylene blue to document integrity of bladder if there is a question of perforation.
- The ureter is in close proximity to the infundibulopelvic ligaments.
- The right and left pelvis are not mirror images.
- Increasing abdominal/pelvic pain more than 48 hours after surgery should raise suspicion regarding injury.
- If significant vascular injury occurs during laparoscopy, consider midline laparotomy.
- Approximately 50% of hysteroscopic complications are entry related.
- Track input and output throughout all operative hysteroscopies.
- Stop the hysteroscopic procedure once the threshold for fluid deficit has been reached.
- Be aware of risks of air embolism during hysteroscopy.
- Endometrial ablation is not a sterilization procedure.
- Diagnostic hysteroscopy has a much lower rate of complications than operative hysteroscopy.
- Lysis of intrauterine adhesions, hysteroscopic myomectomy, and septal lysis have the highest risk of hysteroscopic complications.

Laparoscopic and hysteroscopic complications may occur in even the simplest of cases. This chapter reviews the various risks associated with these gynecologic endoscopic procedures and offers suggestions for avoidance and treatment when complications occur (Tables 39-1 and 39-2). It has been stated that even

the best surgeon on the best day may have a complication. Thus, preparation for managing complications when they inevitably occur is critical. This may begin as early as the initial visit to discuss surgery and the informed consent process and continues into the operating room and subsequent postoperative care.

Few good studies exist from which to glean information regarding likelihood of risk. However, multiple salient points begin to emerge from analysis of published data that may be useful in preparing for endoscopic surgery.

## LAPAROSCOPIC COMPLICATIONS

### General Background Information

Chapron and colleagues reported on almost 30,000 laparoscopic cases performed in seven busy French centers.<sup>1</sup> This case series included all laparoscopic cases and found a low overall complication rate of 0.464% and a low conversion rate to laparotomy of 0.32%. Importantly, 29% of complications were not diagnosed intraoperatively. They also noted a trend, over the 9 years of case collection, of decreasing bowel injuries but increasing bladder injuries.

In another large case series, Jansen and colleagues reported on 25,764 laparoscopies performed at 72 hospitals.<sup>2</sup> They noted a complication rate of 0.57%, which included two patient deaths, and a 0.33% conversion to laparotomy. They noted increasing complication rates commensurate with difficulty of surgery, with diagnostic laparoscopy at 0.27%, laparoscopic sterilization at 0.45%, and operative laparoscopy having a 1.79% complication rate. As with other case reports, they noted that 57% of complications occurred during attempts at intraperitoneal entry, including those using both trocars and insufflation needles.

A large Finnish study evaluated records from 32,205 gynecologic laparoscopies occurring over a period of 2 years. This included all Finnish hospitals where laparoscopic surgery was performed.<sup>3</sup> They found a total of 130 major complications, for an overall complication rate of 0.4%. However, diagnostic and sterilization procedures had very low major complication rates of 0.06% and 0.05%, respectively. Operative cases were noted to have a much higher complication rate of 1.26%.

Several smaller case studies have demonstrated similar results. Mirhashemi and colleagues reported on 843 consecutive nontubal ligation laparoscopies and found an overall complication rate of 1.9%.<sup>4</sup> They found a 4.7% conversion rate to laparotomy consistent with the report being comprised of more difficult operative surgeries. Complications were distributed as follows: 14 bowel, 2 bladder, 1 ureter, 2 vascular, and 5 abdominal wall

**Table 39-1**  
**Laparoscopic Complications, by Organ**

Type of Complication	Incidence (%)
Bowel	0.08–0.33
Bladder	0.2–8.3
Ureter	0.38–2.0
Vascular	0.05–0.07
Inferior epigastric vessels	0.2–2.0

**Table 39-2**  
**Laparoscopic Complications, by Procedure**

Type of Complication	Incidence (%)
Diagnostic laparoscopy	0.06–0.27
Laparoscopic sterilization	0.05–0.45
Operative laparoscopy	1.26–1.9
Conversion to laparotomy	0.32–4.7

injuries. They also noted a surprisingly high rate of laparoscopically assisted vaginal hysterectomy (LAVH) complications, 12.5%, which may be consistent with this study occurring early in the history of the procedure. Leonard reported on 1033 cases from a tertiary care center, of which 80% of cases were operative.<sup>5</sup> They noted a 1.2% conversion to laparotomy and also found that 55% of complications occurred during attempted entry. Surprisingly, they found that only 23.5% of these entry-related complications were with the initial port/needle placement, while 76.5% were with the placement of ancillary trocars.

### Entry Techniques

The previously noted trials suggest that entry complications play a major part in laparoscopic complications in general. Unfortunately there is little agreement regarding the best methodology for obtaining the safest abdominal entry.

Many gynecologists prefer to establish a pneumoperitoneum prior to trocar placement. Jansen's report<sup>2</sup> demonstrates that even a small-bore Veress needle may cause injury. It is recommended that patients be placed supine before initial needle and/or trocar placement and that the bladder be empty. If patients have undergone prior surgery, consideration may be given to placement of the needle or trocar in an area other than the infraumbilical region (Fig. 39-1). Studies have shown that 59% of patients with a prior midline incision were noted to have adhesions.<sup>6</sup> In addition, patients with prior Pfannenstiel incisions might also have adhesions reaching to the level of the umbilicus. The left upper quadrant appears to be a suitable alternative for placement of Veress needle or trocars in patients who have not had surgery in this region or who have underlying splenic abnormalities. However, the surgeon is not limited to this alternative because other areas may also be suitable for placement in different situations.

During placement of a Veress needle, the needle should be directed toward the pelvis in all but the most obese patients. This allows a safe distance from underlying major vasculature. Once the needle has been placed, a syringe with saline aspiration and hanging drop technique should be used to ascertain that a vessel or viscus has not been entered. Abdominal pressures should be low (<10 mm Hg) once insufflation has begun. There are reports of insufflation of major vasculature that can cause a CO<sub>2</sub> embolus. Proceeding with insufflation in the face of elevated pressures may cause a large pneumo-omentum or insufflation of the preperitoneal space. Either of these may make subsequent attempts at establishing an actual pneumoperitoneum very difficult.

Alternatives to needle placement in the abdomen include use of the posterior cul-de-sac to gain entry or transuterine insufflation. Large case series exist for both techniques. Contraindications for posterior cul-de-sac placement include prior vaginal surgery, cul-de-sac obliteration, prior history of pelvic inflammatory disease (PID), and severe cervical or vaginal infection. Contraindications for a transuterine approach are uterine fibroids, patients at risk for uterine adhesion (i.e., prior myomectomy), history of PID, and need for chromoperturbation.

Direct trocar placement is an alternative to use of the Veress needle. Several large series suggest that in appropriately selected patients, a pneumoperitoneum is not necessary before trocar placement. The primary advantages of this technique are that it eliminates the risk associated with Veress needle placement and also thereby improves time efficiency. At least one randomized

1, infraumbilical or intraumbilical; 2, left upper quadrant, midclavicular line; 3, supraumbilical; 4, midline suprapubic; 5, left lower quadrant; 6, transcervical through the uterine fundus or transvaginal through the posterior fornix into the abdominal cavity. (From Nezhat CR, Nezhat FR, Luciano AA, et al: Operative Gynecologic Laparoscopy Principles and Techniques. New York, McGraw Hill, 1995, p 84, fig.8-8.)

comparison showed decreased minor complications such as preperitoneal insufflation with use of the technique.<sup>7</sup>

Open laparoscopy is another widely used technique for entry into the abdominal cavity. Hasson and colleagues reported on his large case series over almost three decades with this technique.<sup>8</sup> This included 5284 patients and only 27 complications. He noted no method failure and reported success in patients with multiple surgeries as well as increased weight ( $>98$  kg). Other authors have not noted the same results with this technique, finding similar or even increased rates of complication.<sup>9,10</sup> The opportunity to evaluate these various techniques in a large randomized prospective trial still remains. Until that time, no one technique will meet all needs; thus the laparoscopic surgeon should be familiar and comfortable with several options for abdominal entry, realizing that this part of the procedure may be associated with the greatest risk.

### Inferior Epigastric Injury

The inferior epigastric artery and vein generally are identified in the lateral third of the rectus muscles. Superiorly they anastomose with the superior epigastric vessels and inferiorly with the external iliac most of the time. Saber and colleagues used computed tomography (CT) to map the epigastric vessels of 100 patients.<sup>11</sup> The results demonstrate the variation in distance from the midline to the epigastric vessels from superior to inferior, as well as the fact that the anatomy on the right is not a mirror image of the left (Table 39-3). Given where ancillary trocars are generally placed, epigastric vessels are at risk of injury that has been estimated at 0.2% to 2%. These vessels can rarely be transilluminated when viewing the abdominal wall from the outside. This is in contradistinction to the superficial epigastric vessels, which can usually be identified. Hurd and colleagues prospectively evaluated the ability to identify these vessels during laparoscopic surgery and found that transillumination was successful in 64% of cases for identifying superficial epigastric vessels and in 82% of cases, laparoscopic visualization identified the inferior epigastric vessels.<sup>12</sup> Increasing weight diminished the effectiveness for identifying both superficial

**Table 39-4**  
**Management of Inferior Epigastric Vessel Bleeding**

- Identification of vessel
- Possible placement of Foley catheter through trocar sleeve to tamponade bleeding
- Consideration of bipolar/electrosurgery vs. suture to control bleeding
- Remember dual blood supply to epigastric vessels

and inferior epigastric vessels, and darker skin color decreased the ability to effectively transilluminate the superficial vessels. Notably, the superficial and inferior epigastric vessels do not run in parallel with one another; thus the surgeon must identify both vessels independently. Often the inferior epigastric vessels are not readily visible and may be identified only as a slight protuberance on the anterior peritoneum. One method for identifying the vessels is through identifying the insertion of the round ligament at the canal of Nuck and creating an imaginary line superior from this point. Often the vessels are in close proximity to this region.

If the inferior epigastric vessels are transected or injured, significant bleeding may ensue (Table 39-4). Placing a small Foley catheter through the trocar, inflating the balloon, and pulling back on the balloon to tamponade the bleeding may quickly control this. Small nicks in the vessel may then seal; however, significant injury will require suture placement. Various needle devices exist to facilitate passage of a suture on either side of the blood vessel. It is relevant to remember that there is a dual blood supply to these vessels and thus if transected two sutures may be required (i.e., superiorly and inferiorly) to completely control bleeding. A sizable hematoma and even hemorrhage may occur if this is not done.

When removing trocars at the conclusion of surgery, it is worthwhile to view the trocar site. Occasionally, the trocar itself will tamponade bleeding during the case only to have bleeding resume after removal of the trocar.

### Bladder Injury

Bladder injury may occur during classic open gynecologic surgery, but the techniques involved in diagnostic and operative laparoscopy may increase the rate of injury to this organ. Because the bladder is positioned in the midline in the same angle as that in which the Veress needle and trocars are being placed, it is at risk. Decompression of the bladder through catheterization may decrease this risk. A review of published studies demonstrated a 0.02% to 8.3% incidence of bladder injury in series reported in the literature.<sup>13</sup> Unfortunately, in this report, 47% of bladder injuries were not made intraoperatively. They also noted that the bladder dome was the most common area of injury. Although it is often easy to discern the margins of the bladder on the anterior surface of the uterus and peritoneum, this is not always true.<sup>12</sup> In addition, prior surgery may make it difficult to delineate the boundaries of the bladder.

Multiple reports have documented injury during laparoscopic surgery ranging from simple diagnostic cases, in which a Veress needle, primary trocar, or secondary trocar injured the bladder, to more complicated cases such a bladder neck suspension or

LAVH. A recent prospective comparison of LAVH techniques demonstrated that whereas laparoscopic colpotomy was associated with decreased blood loss and operating time, vaginal colpotomy had a much lower rate of bladder injury (2.9% vs. 0.4%).<sup>14</sup> It is possible that blunt dissection versus classic sharp dissection of the bladder from the underlying uterus and cervix may predispose to this type of injury.

It is important to recognize a bladder injury during surgery so that repair may be performed at that time (Table 39-5). A common presentation for bladder injury is gross hematuria, but this may not always be present.<sup>15</sup> Oliguria is another finding in patients with bladder injury. Instillation of methylene blue or other agents into the bladder may facilitate recognition and identification of the area of disruption. Very small defects such as that created by a Veress needle may require no treatment or merely drainage for a limited period. Larger defects may require suture repair. It is also important to define where the defect has occurred and that the trigone is not involved. Cystoscopy should be employed as needed. Depending on the nature of the defect and the skill of the surgeon, repair may be performed laparoscopically or via laparotomy. Various closures ranging from single-layer to multilayer have been reported in the literature, although no comparisons using laparoscopic techniques have been published to date. Drainage with a Foley or suprapubic catheter is generally continued for some days after surgery,

although the specific timing of removal varies throughout the literature. Prophylactic antibiotics are often used concomitantly; however, little information exists regarding the utility of this practice and the length of time for treatment.

### Ureter Injury

There are few good reports in the literature regarding ureter injury and methods to decrease its occurrence. Because of the location of the ureters as they descend through the pelvis, they are at particular risk during operative procedures such as oophorectomy, excision of pelvic endometriosis, and LAVH or laparoscopic hysterectomy.

The ureters are likely at greatest risk in the following three locations: as they pass near the infundibulopelvic ligament, under the uterine vessels, and as they pass lateral to the vaginal fornices. The location at the pelvic brim, near the common iliac vessels, may also be a high-risk area. It may be because of this anatomy that LAVH is a particularly difficult laparoscopic procedure, with a higher risk of ureter injury. Nezhat and colleagues evaluated anatomic relationships at the time of laparoscopy and also found that right and left pelvic anatomy are not mirror images.<sup>16</sup> They also noted (as many anatomists have) the proximity of the ureter to the infundibulopelvic and uterosacral ligaments (Table 39-6).

Interestingly, Tamussino and colleagues reviewed 790 operative laparoscopic procedures and found a ureteral injury rate of 0.38%, all occurring during LAVH.<sup>17</sup> Johnson and colleagues, in reviewing published trials on mode of hysterectomy, also found that laparoscopic hysterectomy was associated with a higher risk of urinary tract injury versus abdominal hysterectomy (odds ratio, 2.61).<sup>18</sup>

Ostrzenski and colleagues reviewed the published literature on laparoscopic ureteral complications and reported injury rates ranging from less than 1% to 2%.<sup>19</sup> They noted that in many of the reviewed series, critical information such as initial procedure, type of injury, and location were not reported. They did note that in series that provided information, LAVH was the most common antecedent procedure (Table 39-7). Also, diagnosis was made postoperatively in 70% of cases.

LAVH, laparoscopically assisted vaginal hysterectomy.  
\*When data has been available for review.  
From Ostrzenski A, Radolinski B, Ostrzenska KM: A review of laparoscopic ureteral injury in pelvic surgery. *Obstet Gynecol Surv* 2003;58:794–799.

Ureteral injury may be difficult to diagnose intraoperatively. This may underscore the need for the gynecologic surgeon to be very familiar with the pelvic sidewall and retroperitoneal anatomy. However, even opening the retroperitoneal space and evaluating the path of the ureter does not guarantee freedom from inadvertent injury. Unlike the bladder, which may be readily evaluated for injury via cystoscopy or instillation of methylene blue, the ureter is less amenable to inspection. Parenteral injection of indigo carmine in association with cystoscopy can identify jets of the dye emanating from each ureteral orifice, signifying the ureters are intact.

### Bowel Injury

Bowel injury is a constant threat to the gynecologic laparoscopic surgeon. Given the size of the bowel and its location throughout the abdomen and pelvis as well as the propensity for bowel to form adhesions to the anterior abdominal wall, significant care must be taken during entry into the abdomen and throughout laparoscopic surgery. van der Voort and colleagues evaluated multiple studies comprising 329,935 laparoscopic procedures and noted a bowel injury rate of 0.13%.<sup>20</sup> Unfortunately, as with other complications, the diagnosis may not be straightforward. They noted that the diagnosis of injury was made at the time of surgery or within 24 hours 67% of the time, which may explain

the 3.8% mortality rate with this complication. The small intestine was most frequently injured (55.8%), with the large bowel accounting for 38.6% of the injuries (Table 39-8). Trocars or the Veress needle were identified as the inciting instrument in 42% of bowel injuries (Table 39-9).

Shen and colleagues reviewed a large series of LAVH cases and found a rate of small bowel injury of 0.19%.<sup>21</sup> In evaluating the literature, Brosens and colleagues similarly found a low incidence of injury, with diagnostic and minimal laparoscopic procedures carrying a risk of 0.08% and operative laparoscopy a risk of 0.33%.<sup>22</sup> They noted that delay in diagnosis may occur in up to 15% of cases with a 20% chance of death with this delay. They also state that at times, "... even in experienced hands injury during access can not be avoided."

Vilos evaluated 40 litigated cases of bowel injury that occurred over almost a decade in Canada.<sup>23</sup> Consistent with other reports, injury was related to entry difficulties in 55% of cases—of which three cases of bowel injury occurred with the "open" technique. Injury was only recognized intraoperatively in 55% of cases, although surprisingly the ultimate outcome was not different for large versus small bowel injury or in cases where diagnosis was made intraoperatively versus postoperatively. There may be significant bias in these results, because intraoperative recognition could lead to a better outcome and thus less litigation.

Table 39-8 Location of Laparoscopy-induced Gastrointestinal Bowel Injuries

## Minimally Invasive Surgery

It appears that one of the keys to avoidance of bowel injury during laparoscopy is the recognition that entry poses the greatest risk for bowel injury and that prior surgery may predispose the patient to a higher risk of injury secondary to adhesions to the anterior abdominal wall. Preoperative use of mechanical bowel preparation solutions such as GoLYTELY (polyethylene glycol) may occur in the day prior to surgery. It is best to begin these types of preparations early in the day and to maintain excellent hydration of the patient up until the time she must be NPO. Alternatives such as Fleets Phospho-Soda (sodium phosphate enema) may also be used. The addition of antibiotics to these regimens has fallen out of favor. It is best to have discussions with your general or colorectal surgeon, who might be involved if the need arises, to ascertain their biases regarding preoperative preparation.

The possibility of delayed diagnosis of bowel injury should be considered if patients complain of increasing pelvic or abdominal pain (with or without rebound), fever and elevated white blood cell (WBC) count, abdominal distention, and kidney-ureter-bladder x-rays or CT scans suggestive of ileus or continued free air more than 24 to 48 hours after surgery. Unfortunately, depending on the site of injury, few, some, or all of these findings may be present. Indeed, in the septic patient, WBC counts will no longer be elevated and may at times be depressed.

### Vascular Injury

Injury to a major abdominal vessel is an uncommon complication of gynecologic laparoscopic surgery. When this complication occurs, identification and quickness of response become critical in reducing patient morbidity and mortality. Often this complication is a result of a misadventure during either needle or trocar placement and underlies the importance of use of correct technique during this pivotal portion of the surgery.

A large French study of over 100,000 laparoscopies reported 47 cases of major vascular injury.<sup>24</sup> Unfortunately eight patients died of this complication, yielding a mortality rate of 17%. Chapron and colleagues reported 21 vascular injuries in 29,966 cases, with 85% occurring during initial trocar placement.<sup>1</sup> Baggish similarly analyzed 31 cases of major vessel injury and noted that 90% were related to complications during entry; 78% of the cases involved injury to the iliac vessels, and blood loss in these cases ranged from 1000 to 7000 mL.<sup>25</sup>

Investigations into distances from point of entry to major vessels have been performed in several studies. Hurd and colleagues evaluated magnetic resonance imaging and CT studies of women and noted increasing distance from abdomen to aorta with increasing body mass index (BMI).<sup>26</sup> Narendran and Baggish prospectively evaluated distances from entry point to key vascular structures in patients who were undergoing laparoscopy.<sup>27</sup> They noted that as BMI increased, both abdominal wall thickness as well as distance to aortic bifurcation increased. Distance to the iliac vessels or bladder increased relative to the patient's height but did not change when patients were placed in Trendelenburg position.

An understanding of normal anatomy as well as normal variation, along with an understanding of distance from entry point to these areas, may be helpful in reducing injury. Entry may become especially challenging as BMI increases. Pre-

**Table 39-10**  
**Vascular Injury Management**

- Alert anesthesia
- Exploratory laparotomy – ideally with midline incision
- Obtain baseline and serial labs: CBC
- Type and cross-match for 4–6 units
- Cell saver if available
- Insert additional large-bore IV lines
- Summon surgeon-vascular surgeon STAT
- Compress aorta if necessary

peritoneal insufflation may be particularly problematic in these cases because it exacerbates the difficulty in traversing the distance from entry to peritoneum. There may also be a concomitant decrease in the distance from the peritoneum to the major vascular structures as well as bowel and bladder. In these settings, changing to an open laparoscopic approach, moving to another area such as the left upper quadrant, or converting to laparotomy may be required.

Should vascular injury occur during the course of surgery, the surgeon and the surgical team should be prepared to quickly mobilize to attend to the situation (Table 39-10). Immediately and concurrently a vascular surgeon or surgeon with experience repairing vascular structures should be called, a complete blood count and other baseline laboratory studies should be obtained along with a type and crossmatch for 4 to 6 units of blood. If available a cell saver device should be summoned. The anesthesia department should be made aware of the potential for significant blood loss, and additional large-bore lines should be placed. Laparotomy should be performed through a vertical incision to aid in quickly entering the abdomen as well as maximizing visualization to aid in isolation of the injured vessel(s). Aortic compression may also be required until a vascular or general surgeon is available. In this situation, often other injuries have occurred, including multiple vascular injuries as well as injuries to bowel and bladder, for example. Ultimately all structures should be systematically evaluated to ensure that no injuries are left unrepairs at the completion of the surgery.

In this situation, surgeons may delay some of these necessary steps because they believe they can manage the problem either expectantly or laparoscopically. Large hematomas should not be observed, because it is difficult to ascertain the amount of blood loss and access the stability. In addition, as a hematoma enlarges, further anatomic distortion ensues, making subsequent identification of the injury all the more difficult.

### Conclusion

Laparoscopy is generally a safe and well-tolerated procedure. Like all invasive procedures, there are certain risks associated with the technique. The most significant risk for injury to any structure occurs during the entry phase of the procedure. An understanding of the available options for entry and knowledge of the inherent risks will hopefully help the surgeon minimize the chance of injury or facilitate recognition and treatment when injury occurs. Unfortunately, the significant anatomic variation that exists both within and between patients creates challenges for even the most skilled surgeon.<sup>16</sup>

## HYSTEROSCOPIC COMPLICATIONS

Hysteroscopic complications may be divided between problems associated with entry into the endometrial canal, difficulties with fluid distention, and procedural/postoperative complications. Although many of these complications may be more innocuous than laparoscopic complications, significant morbidity and even mortality may occur. As with most complications, recognition of the problem may decrease subsequent additional morbidity.

### Complications Associated with Entry

In one of the few large studies of hysteroscopic complications, Jansen and colleagues evaluated data from 82 hospitals and 13,600 hysteroscopies and noted that entry-related complications occur infrequently, yet are the most common hysteroscopic complication—representing 50% of all complications.<sup>28</sup> Specific risk factors are noted in Table 39-11. Most hysteroscopists have had experience with postmenopausal patients with a stenotic cervix or cervix that is flush with the vagina. Similar situations may also be seen in some patients after cone biopsy. In such cases, cervical lacerations may also occur as dilation is attempted. Use of very small hysteroscopes (i.e., 3.5 to 5 mm) and placement under direct visualization can decrease these risks but do not eliminate the problem. Campo and colleagues prospectively evaluated the use of a 3.5-mm versus a 5-mm hysteroscope for office diagnostic hysteroscopy and found less pain, better visualization, and higher success rates with the use of the smaller scope.<sup>29</sup> In some cases the surgeon is easily able to identify the external os and the canal up to the internal os but is unable to maneuver past this point. It is quite easy to create a false passage at the level of the obstruction and into the myometrium. This will appear as striations of musculature as the false passage is distended and has a markedly different appearance than the endometrial cavity itself. If the ostia cannot be visualized, it is unlikely that the uterine cavity has been entered. Once a false passage has been developed, it may be quite difficult for entry to be gained into the actual cavity, because the hysteroscope or dilators tend to follow the path of least resistance. Carefully removing the hysteroscope and continuously viewing the passage in a circumferential fashion can occasionally allow the actual passage to be visualized. Transabdominal ultrasound may be used, but in these difficult situations we have found this of limited assistance.

Cervical dilation and softening may be attempted before a procedure. *Laminaria* have been used as well as cervical ripening agents such as misoprostol. Several studies have evaluated the use of both vaginal (200 µg 12 hours prior to surgery) and oral (400 µg 12 hours prior to surgery) misoprostol and found

success.<sup>30,31</sup> Unfortunately if the cervix becomes over dilated, the surgeon may have difficulty with distention.

Uterine perforation may occur through either a false passage or through the endometrial cavity. Once this has occurred, further uterine distention becomes very difficult and distention media will be lost into the peritoneal cavity. This may be problematic if hypo-osmolar media are being used. The surgeon generally is able to identify the perforation because enteric structures are visualized. Significantly anteverted or retroverted uterus may be susceptible to perforation because even placement of a tenaculum and downward traction may not be able to straighten the canal. Care must be taken to note that a bladder or bowel perforation has not occurred. If necessary, cystoscopy or sigmoidoscopy may be performed. Generally bleeding from small fundal perforations is self-limited and may require no further action. If a larger instrument such as a resectoscope has caused the perforation, the patient may need to be observed over a period of time for hemodynamic stability. Consideration should be given to further evaluation with laparoscopy or laparotomy in the following situations: if there is any question regarding enteric injury, if the resectoscope was being activated electrosurgically at the time of perforation, if there is a question of lateral damage that may include the uterine vessels, and if uncontrollable bleeding has resulted from a hysteroscopic procedure.

### Complications Associated with Distention Media

The various types of distention media have been reviewed in Chapter 35. One key facet to the successful performance of hysteroscopy is the appropriate use of the correct distention media, which allows optimal visualization. Unfortunately, significant morbidity may occur secondary to intravasation of media into the vasculature.

In the past, carbon dioxide was a commonly used media for hysteroscopy. More recently, many hysteroscopists have switched to use of fluid media even for simple diagnostic cases. However, CO<sub>2</sub> may still be successfully employed for diagnostic hysteroscopy and has a long track record of safety. If a change to an operative case is required, this is not an optimal media given the inability of gas to be miscible with blood. CO<sub>2</sub> is also relatively unforgiving if the surgeon is not careful during entry and examination of the endometrial cavity. Discrete hysteroscopic delivery systems exist for CO<sub>2</sub>, which are markedly different and not interchangeable with laparoscopic insufflators. These allow low flow but higher pressures, the opposite of most laparoscopic insufflators. Pellicano and colleagues evaluated CO<sub>2</sub> versus normal saline use during diagnostic hysteroscopy in infertility patients in a prospective, randomized trial.<sup>32</sup> They noted decreased abdominal pain and vasovagal reactions, as well as decreased operative time when saline was used as the distention media.

Fluid media have also been associated with various complications. Use of any media, whether hypotonic or not, may lead to fluid overload, pulmonary edema, and congestive heart failure (CHF). Once adequate distension has been achieved, further increases in intracavitary pressure will not lead to better visualization, only to an increased risk of fluid absorption. A patient's inherent ability to withstand this type of fluid challenge will determine if CHF will result. Patients with underlying medical

**Table 39-11**  
**Risk Factors for Uterine Perforation**

- Nulliparity
- Severely anteverted or retroverted uterus
- Menopause
- Prior cervical surgery
- Use of GnRH agonist
- Cervical stenosis

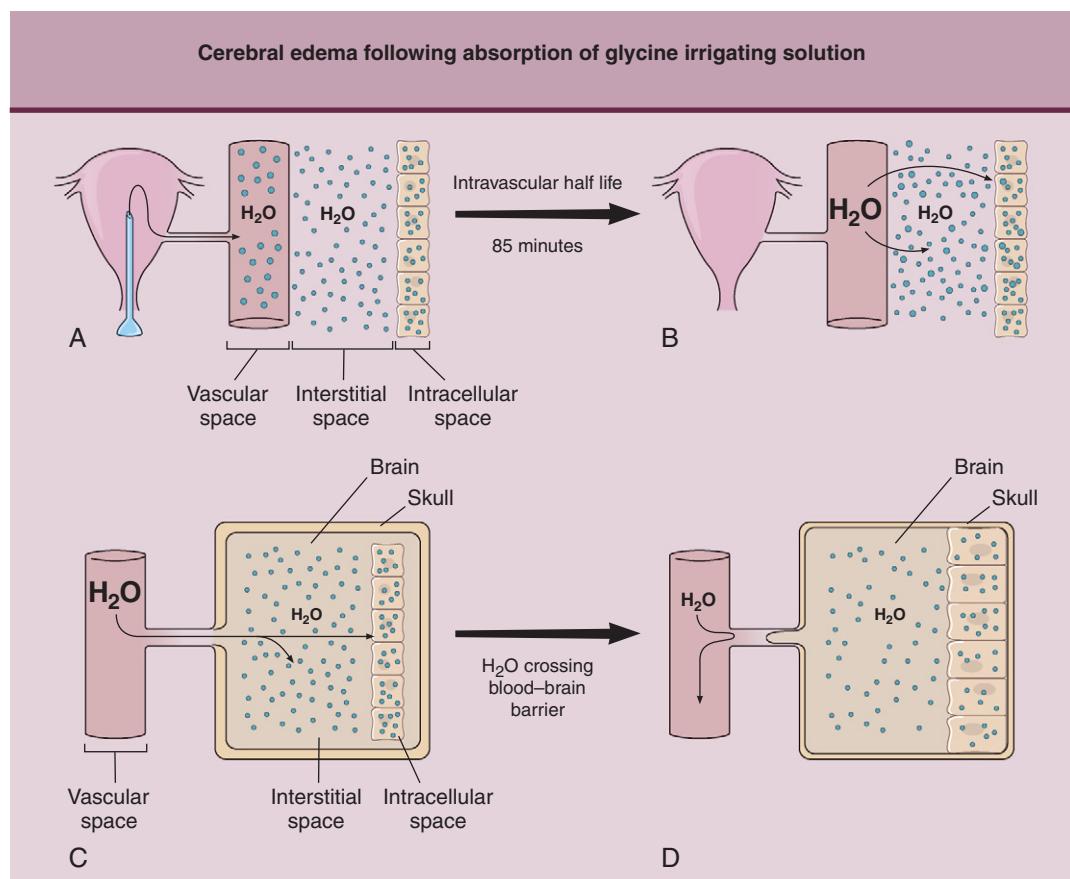

**Table 39-12**  
**Treatment of Fluid Overload with Hyponatremia**

- Terminate procedure
- Alert anesthesia
- Send stat electrolytes
- Administer diuretic
- Central monitoring as needed
- Track input/output carefully
- Follow serial electrolytes until sodium normalized
- Comanagement with anesthesia and/or critical care team

conditions may be at higher risk and unable to withstand fluid absorption versus a young healthy patient who will easily tolerate a transient fluid challenge.

A more risky situation is the compounding of fluid overload with hyponatremia, as seen when using hypotonic solutions such

as 1.5% glycine or 3% sorbitol, which are commonly used in operative hysteroscopic/resectoscopic procedures. In this situation the fluid itself has a tonicity of less than 200 mOsm, which is well below physiologic range. Because these fluids contain no electrolytes, absorption of the media will dilutionally decrease sodium and other electrolytes. Table 39-12 details the steps necessary when this occurs. Key to avoidance of this complication is to continuously track fluid input and output during surgery. It is important to be aware that the patient may quickly go from absorbing very little fluid to a situation in which more than 1 liter of fluid has been absorbed. If input exceeds output above a predetermined limit (usually 1000 mL in a healthy patient), the procedure should be stopped. Blood should be drawn to evaluate electrolytes immediately and diuretics administered as necessary. The process of diuresis will quickly begin to correct the underlying problem, which is excess free water. In some situations, central monitoring is necessary and should be managed jointly with anesthesia and a critical care team. Unlike

**Figure 39-2 Cerebral edema following absorption of glycine irrigating solution.** A, Intravascular osmolarity is initially maintained by glycine molecules (G) contained in the intravascular space. B, When glycine moves from the intravascular space into the cell, intravascular osmolarity falls. The concentration of water (H<sub>2</sub>O) is greater in the intravascular space than in the interstitial space. As a result, water moves from the vascular space into the interstitial and intracellular space (arrows). C, Because of the intravascular hypo-osmolar state, water moves across the blood-brain barrier into the interstitial and intracellular space. D, Cerebral edema develops with compression of the brain against the skull. Water will continue to move into the brain until the hydrostatic pressure of the brain offsets the osmotic force. (From Witz CA, Silverberg KM, Burns WN, et al: Complications associated with the absorption of hysteroscopic fluid media. Fertil Steril 1993;60:745-756, fig. 1. Copyright 1993. Reprinted with permission from the American Society for Reproductive Medicine.)

## Laparoscopic and Hysteroscopic Complications

the situation of chronic hyponatremia, sodium levels may quickly be reversed and care should be taken not to overshoot during sodium replenishment and cause hypernatremia. The significant fluid shifts that occur with profound hyponatremia may cause cerebral edema and the most significant morbidity (Fig. 39-2).<sup>33</sup> Quickly recognizing the problem and instituting treatment should help to minimize this risk (see Table 39-12).

Previously, Dextran 70 or Hyskon was used widely for hysteroscopic surgery. The consistency of the solution allowed excellent visualization even in the presence of blood. Unfortunately, the unique characteristics of Hyskon may have also been the cause of complications during hysteroscopic surgery. Reports of anaphylactic shock have been intermittently published. In addition, "dextran syndrome" has been reported, with anemia, coagulopathy, hypotension, shock, and noncardiogenic pulmonary edema.<sup>34</sup> Because of the large molecular size of dextran 70, intravasation of the media during hysteroscopy may cause an intravascular fluid shift, creating fluid overload. Limiting the amount of media used and, if necessary, aggressively managing patients with overload should decrease these risks.

### Procedural and Postoperative Complications

Intraoperative bleeding may occasionally occur during operative hysteroscopic surgeries. This may be more common with hysteroscopic myomectomy or endometrial resection than with other types of surgery. Agostini and colleagues reviewed 2116 operative hysteroscopies and found a 0.61% incidence of hemorrhage, with lysis of adhesions and myoma resection having the greatest risk (RR=5.2 and 6.5, respectively).<sup>35</sup> If abnormal bleeding occurs during hysteroscopy, care should be taken to note that a false passage has not been created and that a major vessel has not been lacerated. If necessary, a Foley catheter may be placed within the cavity for several hours. The balloon may then be deflated while leaving the catheter in place to access any further bleeding. If none occurs, the catheter may be removed. If bleeding continues, the catheter may be re-inflated and left in place for approximately 24 hours of in-house observation. The surgeon should be cognizant of not missing an expanding broad ligament hematoma in the case of major vessel injury.

Infection is an unusual complication of any hysteroscopic procedure. Several large series report rates of infection of less than 1%.<sup>36</sup> It is reasonable to obtain cervical cultures in patients who may be at risk for *Chlamydia* or other infections. Although little data is available regarding antibiotic prophylaxis, most authors recommend use of antibiotics during longer procedures and in patients with underlying fertility issues.

Care should be taken during the use of any media to purge the line of all air. Recent case reports have focused attention on the significant morbidity and mortality associated with air embolism occurring during hysteroscopic procedures.<sup>37</sup> CO<sub>2</sub> is readily absorbed and buffered in the bloodstream, whereas air is not, thus creating the potential for embolism. Besides removing the air that may exist in tubing, several other techniques have been suggested to reduce the risk of air embolism, including minimizing use of steep Trendelenburg position, covering the vaginal or cervical opening when changing instruments, and limiting the movement of instruments in and out of the cervix. Key to avoiding morbidity in this situation is awareness by the anesthetist. Common signs and symptoms exhibited by patients

with air embolism include tachypnea, hypotension, hypoxia, hypercapnia, arrhythmias, pulmonary hypertension, and decreasing end-tidal CO<sub>2</sub>. It is critical in this situation that the procedure be terminated, appropriate anesthetic measures begun, the patient be turned to the left lateral decubitus position, and a central venous catheter be used to aspirate the gas if necessary (Table 39-13).

Intrauterine and intracervical adhesions may form after any procedure but are less likely following simple diagnostic or operative procedures. Endometrial ablation has been associated with the formation of intrauterine adhesions as well as cervical stenosis. Some authors had even recommended sounding or curette passage in the office after the procedure to attempt to reduce these risks.<sup>38</sup> A variation of intrauterine adhesions is the "postablation tubal sterilization" syndrome that was first reported by Townsend and colleagues.<sup>39</sup> Patients were noted to have hematometra, with no point of egress given their prior tubal ligation, and may present with cyclic pain or abnormal uterine bleeding some months after endometrial ablation. Ultrasound will demonstrate a hematometra generally located near one of the cornua. It is unclear if the different modalities for performing endometrial ablation (e.g., cryoablation, thermal balloon ablation) impact on the risk of subsequent adhesions or hematometra. It has been suggested that limiting ablation to the active endometrium and not ablating near the internal os and cervix may decrease the risk of subsequent stenosis. Intrauterine adhesions may also form after submucous myomectomy. A special case may occur when multiple myomata are juxtaposed within the cavity. In this circumstance, it may be preferable to resect only one myoma at a time so as to not have two denuded areas in contact with one another.

Pregnancy complications have also resulted after hysteroscopy or endometrial ablation. During lysis of intrauterine adhesions, submucous myomectomy, or hysteroscopic metroplasty, the myometrium may be entered with or without eventual perforation. Although rare, uterine rupture during labor has been reported in patients who have undergone operative hysteroscopic procedures.<sup>40</sup> Generally, it has been felt that most patients undergoing these procedures will not require an elective cesarean section; however, individualization should occur depending on the nature of the prior procedure.

Pregnancies have also resulted after endometrial ablation. The exact incidence is unclear but may be as high as 1% to 2%.<sup>41</sup> For this reason, patients should understand that endometrial ablation is not a sterilization procedure. In addition, various

## Minimally Invasive Surgery

complications have been reported in pregnancies after endometrial ablation, including intrauterine growth restriction, preterm labor, placental abruption, and placentation abnormalities, such as placenta accreta, placenta increta, and placenta percreta (Table 39-14).<sup>42</sup>

Overall hysteroscopy appears to have a low complication rate. The Jansen report demonstrated only 38 complications in 13,600 procedures, for a complication rate of only 0.28%. This rate was lowered further for diagnostic procedures (0.13%) and slightly increased for operative procedures (0.95%). Intrauterine adhesiolysis was associated with the greatest rate of complications in this trial (4.48%), whereas endometrial resection, myomectomy, and polypectomy all had complication rates less than 1% (Table 39-15). Propst and colleagues evaluated 925 hysteroscopies and noted a slightly higher overall complication rate of 2.7%.<sup>43</sup> They found that hysteroscopic myomectomy and resection of uterine septum had increased odd ratios for complications (OR=7.4 and 4.0, respectively), although the latter did not reach statistical significance (Table 39-16). Surprisingly, they noted that use of gonadotropin-releasing hormone agonists as well as cases being performed by a reproductive endocrinologist were associated with increased risk of complication, possibly because in both situations, more difficult and complex procedures were being performed (Table 39-17).

Hysteroscopy appears to be a well-tolerated procedure with a relatively low rate of complications. An understanding and awareness of the various problems that the surgeon may encounter while performing surgery will alert the clinician when an unusual situation or complication does arise. Management of distention media with vigilant observation of fluid input and output are critical to decreasing patient morbidity. In addition, the previously noted trials suggest a need for care during the entry phase of the procedure.

**Table 39-14**  
**Table of Pregnancy-associated Complications Following Endometrial Ablation**

- Spontaneous abortion
- Intrauterine growth restriction
- Abnormal fetal presentation
- Placental accreta, increta, percreta
- Placenta previa
- Premature rupture of membranes
- Placental abruption
- Preterm labor
- Ectopic pregnancy
- Preterm delivery
- Hysterectomy

**Table 39-15**  
**Surgical Complications During Operative Hysteroscopic Procedures**

Procedure	n	Complication	Rate (per 100)
Adhesiolysis	134	6	4.5
Endometrial ablation*	494	4	0.8
Myomectomy	798	6	0.8
Polypectomy	784	3	0.4
Rest†	305	0	0
<i>Total</i>	2515	19	0.8

Comparison of rates showed statistical significance for adhesiolysis ( $P < 0.001$ ) versus other procedures. No statistical significance was found for resection versus myomectomy versus polypectomy ( $P = 0.39$ ).

\*Ablation included procedures of endometrium resection ( $n = 155$ ), rollerball ( $n = 116$ ), and combination ( $n = 223$ ).

† Removal corpus alienum ( $n = 180$ ), sterilization ( $n = 81$ ), septum resection ( $n = 40$ ), rest ( $n = 4$ ).

## Section 7 Gynecologic Oncology

### Chapter 40

# Breast Carcinoma

Padma C. Nadella, MD, Karen Godette, MD, Monica Rizzo, MD,  
Toncred M. Styblo, MD, and Ruth M. O'Regan, MD

#### KEY POINTS

- Breast cancer is the second most common cause of cancer-related mortality in women in the United States.
- Screening with mammography is recommended for all women over age 40 years.
- Mortality from breast cancer has been decreasing over the last decade.
- Newer surgical and radiation techniques have decreased treatment-related morbidity.
- Chemotherapy and hormonal therapies reduce recurrence rates and improve survival from early stage-breast cancer.
- Systemic therapies improve quality of life in metastatic breast cancer.

Breast cancer is the most common cancer and the second most common cause of cancer-related mortality in women in the United States. It is estimated that 1 in 8 women in the United States will develop breast cancer during their lifetime. However, mortality from breast cancer has been decreasing over the last decade because of earlier diagnosis and better treatments. Screening with mammography is recommended for all women over the age of 40, and newer screening methods, including MRI,<sup>1</sup> are being actively researched. Although several risk factors for breast cancer have been identified, in most cases there is no identifiable cause. However, the discovery of two breast cancer genes<sup>2</sup> has allowed identification of women at very high risk of breast cancer and ovarian cancer.

New surgical techniques, in particular, the widespread use of sentinel lymph node biopsies, have decreased surgery-related morbidity. Additionally, new radiation techniques, for example, brachytherapy, are under investigation and offer the possibility of improved tolerability and convenience. Over the past decade, the use of adjuvant therapies, including both chemotherapy and hormonal therapies, have reduced recurrence rates and improved survival from early-stage breast cancer.<sup>3,4</sup> Although tamoxifen has been the mainstay of treating all stages of hormone-responsive breast cancer, selective aromatase inhibitors offer the possibility of increased efficacy,<sup>5-7</sup> with an improved side effect profile.

Metastatic breast cancer remains incurable; however, the use of chemotherapy and hormonal therapies has been shown to improve quality of life. Additionally, the identification of the

HER2/neu receptor and the subsequent development of trastuzumab, a monoclonal antibody that targets the extracellular domain of this receptor, have resulted in survival advantages in patients with poor prognostic metastatic breast cancer.<sup>8</sup> Lastly, bisphosphonates have been demonstrated to reduce complications relating to bone metastases in patients with breast cancer.<sup>9,10</sup>

#### EPIDEMIOLOGY

Breast cancer is the most common neoplasm affecting women in the United States.<sup>11</sup> It is the second leading cause of cancer-related mortality in women. An estimated 215,990 women will be given a diagnosis of breast cancer in 2004 in the United States, resulting in approximately 40,110 deaths. The incidence rate of breast cancer increased by approximately 4% during the 1980s but leveled off to 100.6 cases per 100,000 women in the 1990s. The death rates from breast cancer also declined significantly between 1992 and 1996, with the largest decreases among younger women. It is estimated that the lifetime risk of breast cancer is 12%.

#### RISK FACTORS

Several factors that increase an individual's risk of breast cancer have been identified. The most important risk factors for breast cancer are increasing age and family history. The risk of breast cancer increases with the number of relatives who have the disease. The likelihood of carrying one of the two breast cancer genes, *BRCA1* and *BRCA2*, increases based on the factors shown in Table 40-1. Carriers of *BRCA1* have a significantly high risk of developing breast cancer, both primary and secondary, and of ovarian cancer, while carriers of *BRCA2* have a similar risk of breast cancer but a lower—but still increased—risk of ovarian cancer.<sup>2,12-14</sup> Individuals of Ashkenazi Jewish descent have an increased likelihood of carrying both *BRCA* genes. Preventive maneuvers for individuals who carry *BRCA* genes range from observation to prophylactic surgeries, both mastectomies and oophorectomies.<sup>15,16</sup> Recently, a specific gene expression has been noted in breast cancers in patients who carry *BRCA1*.<sup>17</sup>

The association between hormonal factors and breast cancer was identified over a century ago.<sup>18</sup> Early menarche and late menopause have been demonstrated to increase the risk of breast cancer.<sup>19,20</sup> The earlier a woman has her first child, the

**Table 40-1****Factors Associated with Increased Likelihood of Having a *BRCA* Mutation**

- Relative with breast cancer at a young age
- Multiple relatives with breast cancer
- Relative or personal history of bilateral breast cancer
- Relative or personal history of ovarian cancer
- Relative with male breast cancer
- Ashkenazi Jewish descent

lower her risk of breast cancer, and a woman who has her first child after the age of 35 has the same risk of developing breast cancer as a nulliparous woman.<sup>20</sup> Recent evidence suggests that the longer a woman breastfeeds, the lower her risk of breast cancer.<sup>21</sup> Exogenous estrogens have been clearly associated with an increased risk of breast cancer.<sup>22,23</sup> The use of combined estrogen and progestin hormone replacement therapy increases the risk of breast cancer, with longer durations resulting in greater risks of breast cancer.<sup>22,23</sup> Interestingly, birth control pills only marginally increase breast cancer risk and appear protective against ovarian cancer.<sup>24,25</sup>

Although dietary fat intake has not been conclusively shown to increase the risk of breast cancer, obesity in postmenopausal women is associated with increased breast cancer risk, likely due to increased conversion of androgens to estrogens in adipose tissue.<sup>26</sup> Alcohol use in excess of 2 units per day is associated with an increased risk of breast cancer, and there is evidence to suggest that folic acid may abrogate this risk.<sup>27</sup>

Certain breast diseases clearly are associated with an increased risk of breast cancer. Lobular carcinoma in situ is a nonmalignant condition that increases the risk of breast cancer, both ductal and lobular, in both breasts.<sup>28</sup> Likewise, atypical hyperplasia is associated with an increased risk of breast cancer. In both these conditions, the selective estrogen receptor modulator (SERM) tamoxifen reduces the risk of breast cancer.<sup>29</sup>

## **PREVENTION**

Using the risk factors for breast cancer mentioned above, it is possible to determine whether a woman is at increased risk of breast cancer. The Gail model<sup>30</sup> (Table 40-2) utilizes age, family history, hormonal factors including age of menarche and age at birth of first child, number of prior breast biopsies, and presence of hyperplasia to estimate a woman's 5-year and lifetime risk of breast cancer. Any woman with an estimated 5-year risk of developing breast cancer of greater than 1.66% is considered

at high enough risk to receive chemoprevention. However, the Gail model probably underestimates the influence of family history, as it accounts for only first-degree relatives and puts too much emphasis on hormonal factors.

The National Surgical Adjuvant Breast and Bowel Project (NSABP) Prevention (P-1) trial<sup>29</sup> randomized women with a 5-year risk of breast cancer of greater than 1.66% to tamoxifen or placebo for 5 years. Following the accrual of 13,000 women, a significantly reduced number of breast cancers were noted in women receiving tamoxifen. The rates of ductal carcinoma in situ and of invasive breast cancers were reduced by 50% and 49%, respectively. As would be expected, tamoxifen only significantly reduced the rate of estrogen receptor (ER)-positive breast cancers and had no impact on ER-negative breast cancers. Based on the results of this large trial, and despite two other negative trials<sup>31,32</sup> in Europe, tamoxifen was approved for the prevention of breast cancer in women at high risk in 1998. A follow-up trial from the NSABP is comparing tamoxifen with another SERM, raloxifene, in women at high risk. It is hoped that raloxifene will be as effective as tamoxifen in reducing the incidence of breast cancer, without the associated increase in uterine cancer seen with tamoxifen.

How effective tamoxifen is in reducing the incidence of breast cancer in women with hereditary breast cancer is unclear. The majority of breast cancers in women who carry *BRCA1* are ER-negative<sup>33</sup>; therefore, the rate of breast cancer would be unlikely to be affected by the use of tamoxifen. This is corroborated by the finding of a specific gene expression pattern in breast cancers occurring in *BRCA1* carriers.<sup>34</sup> This gene expression pattern is designated as basilar type, is ER-negative, and carries a poor prognosis.<sup>34</sup> However, bilateral oophorectomies have been demonstrated to not only reduce the risk of ovarian cancer but also to reduce the risk of breast cancer by 50% in women who carry *BRCA1*.<sup>15</sup> Additionally, bilateral prophylactic mastectomies are effective in preventing breast cancer in *BRCA1* carriers.<sup>16</sup> In contrast to *BRCA1*, the majority of breast cancers in *BRCA2* carriers are ER-positive,<sup>33</sup> so tamoxifen may be effective in reducing breast cancer incidence in these patients.<sup>35</sup>

## **STAGING**

Staging of breast cancer is based on tumor size, extent of breast involvement, axillary lymph node involvement, and distant metastases (the TNM system). The most important changes in the 2003 American Joint Committee on Cancer (AJCC) classification compared with the 1998 classification include a reclassification of nodal status by the number of involved axillary lymph nodes, size-based discrimination between micrometastases and isolated tumor cells, and classification of metastasis to internal mammary nodes and supraclavicular nodes as N3 rather than M1 disease.<sup>36</sup> These changes in the staging system dramatically affect stage-specific survival.<sup>37</sup> AJCC staging system is summarized in Table 40-3.

## **PROGNOSTIC FACTORS**

Stage IV breast cancer remains incurable, and treatment of this disease remains palliative. Several prognostic factors have been identified in early-stage breast cancer. The most important is

**Table 40-2****Gail Model for Increased Risk of Breast Cancer**

- Race
- Age
- Age of menarche
- Age at birth of first child
- Number of first-degree relatives with breast cancer
- Number of previous breast biopsies
- Atypical hyperplasia (Yes/No)

status of the axillary lymph nodes, and the greater the number of lymph nodes involved, the worse the prognosis. Another important prognostic factor is tumor size, with larger tumors having a worse prognosis. Less important prognostic factors include tumor grade, hormone receptor status,<sup>4</sup> HER2/neu status,<sup>38</sup> and S phase. Using known prognostic factors, it is possible to estimate likelihood of recurrence and to make decisions regarding the appropriateness of adjuvant therapies. An on-line model, ADJUVANT!, is available to estimate the prognosis of a patient's disease and its likelihood of recurrence with and without adjuvant therapies.<sup>39</sup> Newer molecular techniques are becoming available that may add to existing prognostic factors utilized in breast cancer.

Despite advances in determining prognoses, the majority of patients in the United States receive adjuvant therapy. Therefore, the identification of factors that *predict* outcome from adjuvant therapies is becoming more important than *prognostic* factors. The most important predictive factors in current use include hormone receptors, which predict the likelihood of recurrence following hormonal therapies.<sup>4</sup> Other predictive

factors include HER2/neu, which not only predicts response to trastuzumab,<sup>8</sup> a monoclonal antibody that targets this receptor, but also may predict lack of response to tamoxifen.<sup>40</sup> Newer molecular tools are being researched that may be able to determine more accurately the likelihood of responding to both chemotherapy and hormonal agents.

## TREATMENT OF EARLY-STAGE BREAST CANCER

### Local Therapy

#### *Surgical Management of Breast Cancer*

Surgery has been the primary treatment for breast cancer for thousands of years. In 1889, William Halsted originated an operation named "the radical mastectomy" for the treatment of breast cancer, based on his theory of tumor biology and tumor metastases.<sup>41</sup> For the next 100 years, it was the gold standard and a life-saving operation for women, many of whom had advanced breast cancer by today's standards. With increasing knowledge of tumor biology, newer and less extensive surgical approaches for breast cancer were evaluated in a scientific manner. These trials demonstrated that limited surgical procedures could result in good local control and the same overall survival as more extensive surgical procedures. Modified radical mastectomy refers to several different operative procedures, all of which include complete removal of the breast tissue, the underlying fascia of the pectoralis major muscle, and some but not all of the axillary lymph nodes. Breast conservation is surgical removal of the tumor followed by radiation therapy. In addition, the importance of micrometastatic disease and the role of adjuvant therapies in increasing survival were noted.<sup>3</sup> In 1990, the National Institutes of Health Consensus Development Conference on Treatment of Early-Stage Breast Cancer brought together surgical, radiation, and medical oncologists, biostatisticians, psychologists, nurses, and other health care professionals as well as the public to address the role of mastectomy versus breast conservation, the role of adjuvant therapy, and the use of prognostic indicators in the treatment and management of early-stage breast cancer. Following 2 days of presentations by experts and discussion by the audience, a consensus panel weighed the evidence and prepared their consensus statement. Among their findings, the panel recommended that breast conservation treatment is an appropriate method of primary therapy for the majority of women with Stages I and II breast cancer and is preferable because it provides survival equivalent to total mastectomy and axillary dissection while preserving the breast.<sup>42</sup>

There are some patients for whom primary surgical therapy is not appropriate. These patients include those with locally advanced breast cancer (T4 lesions including skin edema peau d'orange, skin ulceration, satellite nodules, and/or infiltration, or N2 fixed or matted axillary lymph nodes). If these patients are treated with mastectomy alone, local recurrence rates are greater than 50% and few survive more than 5 years.<sup>43</sup> An alternative approach for these patients is primary or preoperative chemotherapy. It is clear from multiple studies<sup>44</sup> that the use of primary chemotherapy results in a down-staging of the primary tumor with a subsequent increase in surgical tumor resection rates. Many patients can then proceed to surgical resection of the tumor, which would not have been possible prior to the

## Gynecologic Oncology

administration of primary chemotherapy. (The use of pre-operative chemotherapy in resectable breast cancer is discussed in the section on neoadjuvant chemotherapy.)

Axillary lymph node dissection (ALND) has remained an integral part of breast cancer management for more than a century. Among patients with T1/T2 tumors, up to 70% have a negative axillary dissection, and more than 50% of these node-negative patients develop morbidity related to ALND.<sup>45</sup> Shoulder stiffness and numbness and paresthesias in the upper arm are common complaints following ALND, impacting on quality of life. The likelihood of arm edema is higher in women who undergo more extensive axillary lymphadenectomy and combined axillary surgery and RT. More recently, sentinel lymph node biopsy has replaced axillary dissection for staging. The sentinel lymph node is identified using lymphazurin, a blue dye, radiolabeled colloid, or both. The sentinel lymph nodes are excised and pathologically evaluated. If there are no tumor metastases in the nodes, then no additional nodes are removed. This reduces the morbidity of complete axillary dissection (arm edema and neuropathy).<sup>46</sup>

### Radiation Therapy

Radiation therapy is an integral part of the management of patients with breast cancer. It can be utilized definitively, in breast conservation therapy, or following mastectomy. It can also be used to for palliation in advanced stage of disease. With new technologies impacting the treatment planning and the delivery of radiation, there have been advances in the historical way that breast cancer patients were traditionally treated with irradiation. The integration of radiation therapy with surgery and systemic therapies has also changed.

#### Breast Conservation for Invasive Cancer

Several randomized trials in the United States and Europe have confirmed that breast conservation consisting of lumpectomy followed by adjuvant radiation therapy yields survival rates that are equal to mastectomy in women who have tumors up to 5 cm in diameter.<sup>47</sup> NSABP-06 trial randomized patients to total mastectomy, lumpectomy, and lumpectomy followed by irradiation. There was no significant difference in disease-free survival, distant disease-free survival, and overall survival in these three groups. Irradiation reduced the risk of recurrence in the ipsilateral breast from 39.2% to 14.3% in patients who had a lumpectomy.<sup>48</sup>

Absolute contraindications to irradiation are first or second trimester of pregnancy, prior irradiation, diffuse-appearing microcalcifications, presence of persistent positive margins especially with extensive intraductal component, and two or more lesions in separate quadrants. Relative contraindications to breast irradiation are a history of collagen vascular disease, multiple tumors in the same quadrant, a large tumor in a small breast, and very large or pendulous breasts.

Efforts have been made to identify a subgroup of patients with invasive breast cancer who do not require breast irradiation. In a recent article the authors concluded that lumpectomy plus adjuvant therapy with tamoxifen alone is a reasonable choice for the treatment of women 70 years of age or older who have early estrogen receptor-positive breast cancer. There was a 3% difference in local or regional recurrence but no difference in

distant metastases or overall survival at 5 years.<sup>49</sup> In contrast, another study reconfirmed that women under age 70 still do require irradiation and tamoxifen to reduce the risk of recurrence in the breast or axilla in women with T1 node-negative, hormone receptor-positive tumors.<sup>50</sup>

#### Technique and Regional Irradiation

A treatment-planning CT scan of the chest enables the physician to define the underlying structures and to limit the volume of these structures encompassed in the radiation portal. The breast is treated in its entirety through medial and lateral tangents, usually with 6 MV photons. This field is treated to 4500–5000 cGy in daily fractions of 180–200 cGy per day for 25 to 28 treatments for over a course of 5 to 6 weeks. A boost of 10–16 cGy is then delivered over 5 to 8 days just to the tumor bed. Lymph nodes in the axilla and supraclavicular fossa are treated if there is a suboptimal axillary dissection, gross disease in the axilla, or gross extracapsular extension.

#### Breast Conservation for Noninvasive Cancer

The management of ductal carcinoma in situ (DCIS) is controversial. NSABP-17 trial demonstrated that irradiation after lumpectomy is more beneficial than lumpectomy alone in women with DCIS. This was due to a reduction in risk of developing invasive (13.4% to 3.9%) and noninvasive cancers (13.4% to 8.2%) at 8-year follow-up.<sup>51</sup> Further subgrouping of the various histologies would help define a subgroup of these patients who might be treated effectively with excision alone.

#### Postmastectomy Irradiation

Multivariate analysis showed that four or more positive nodes and tumor size up to 5 cm were associated with an increased risk of locoregional recurrence.<sup>52</sup> Two well-publicized trials examined the role of adjuvant irradiation in premenopausal, node-positive women. Both studies found a survival advantage from post-mastectomy radiation therapy (PMRT). In both trials all regional nodes were treated.<sup>53,54</sup> The radiotherapy techniques, types of surgery, and systemic treatments varied, and because of this there is disagreement about the optimal radiation therapy field. American Society of Clinical Oncology guidelines recommend PMRT for patients with four or more positive axillary lymph nodes and suggest it for patients with T3 tumors with positive axillary lymph nodes and operable Stage III tumors. With PMRT the chest wall should always be treated and the supraclavicular field added in patients with four or more nodes positive after adequate dissection. Irradiation of the internal mammary nodes should be individualized, with the morbidity of treatment weighed against the possible benefit.<sup>55</sup>

#### Side Effects of Irradiation

The risk of moderate arm edema is 5% to 25%.<sup>47,56</sup> The quoted incidence varies depending on the definition of the term and the extent of surgery. Brachial plexopathy, symptomatic pneumonitis, and pericarditis are seen in less than 1% of patients.<sup>55,56</sup> Rib fracture has been noted in 2% to 7% of patients who received chemotherapy along with irradiation.<sup>55</sup> Although the data conflict, a recent meta-analysis of 40 randomized trials demonstrated a decrease in breast cancer mortality but an increase in cardiac-related deaths after irradiation in early-stage breast

cancer.<sup>57</sup> Another meta-analysis published that same year showed a decrease in overall mortality.<sup>58</sup> However, the different techniques used to deliver the radiation treatment (many now outdated), the type of surgical procedures performed, and the type and duration of chemotherapeutic agents must be taken into account.

#### Newer Techniques

The traditional gold standard for breast conservation is external beam irradiation to the entire breast for 5 to 6 weeks following lumpectomy and axillary dissection. Three-dimensional conformal treatment planning is now routinely used. Intensity-modulated radiation therapy (IMRT), in which the intensity of irradiation varies within the beam, improves dose homogeneity<sup>59</sup> and may decrease toxicity to underlying structures in selected cases. Active breathing control devices can reduce the amount of heart treated within the radiation portal.<sup>60</sup> For many patients, treatment time, geographic inaccessibility, and cost of therapy and side effects of treatment may act as deterrents to breast conservation therapy. Studies examining recurrence after breast conservation therapy show that the majority of failures occur within or close to the tumor cavity.<sup>61</sup> An exciting and viable option is accelerated partial breast irradiation with external irradiation or brachytherapy. Brachytherapy catheters may be placed at the time of surgery and then after-loaded with iridium sources. The local failure rates at 5 years are comparable to results from external beam irradiation.<sup>62</sup> The MammoSite is a brachytherapy applicator consisting of a balloon catheter, which is inserted in the tumor cavity. Early studies are promising.<sup>63</sup>

### Systemic Therapy

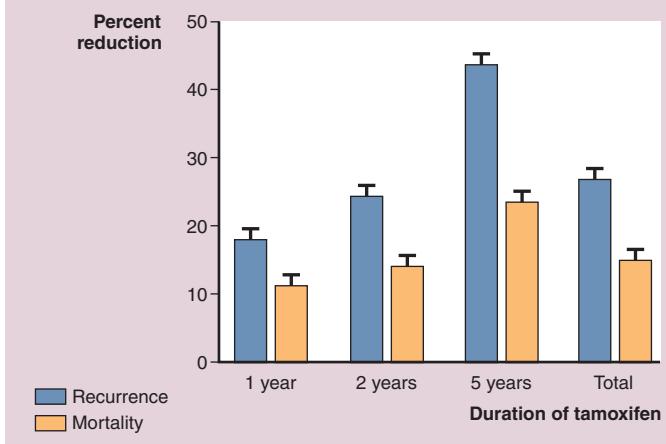

#### Neoadjuvant Therapy

The use of neoadjuvant or preoperative chemotherapy for treating breast cancer is increasing in the United States. The NSABP B-18 trial<sup>64</sup> demonstrated that both disease-free and overall survival are similar in patients with resectable breast cancer treated with preoperative chemotherapy, as compared with postoperative chemotherapy. This trial also demonstrated that preoperative chemotherapy can be used to down-stage breast tumors, allowing less extensive surgery.<sup>64</sup> Additionally, patients who had a complete pathologic response had significantly better disease-free and overall survival, compared with patients with any invasive cancer in the breast after chemotherapy.<sup>65</sup> Subsequent trials have demonstrated that complete pathologic response rates can be increased by the sequencing of non-resistant chemotherapy regimens.<sup>66</sup> The investigational use of preoperative chemotherapy may allow the identification of specific tumor profiles that may be used to predict response to specific agents. The uses of preoperative hormonal agents and of trastuzumab are currently being researched.

#### Hormonal Therapy

Five years of adjuvant tamoxifen therapy reduces the recurrence rate and decreases mortality from ER-positive early-stage breast cancer<sup>4</sup> (Fig. 40-1). Five years of tamoxifen appear superior to shorter durations in reducing breast cancer recurrence.<sup>4</sup> Additionally, tamoxifen reduces the rate of breast cancer events, both preinvasive and invasive, in patients with ductal carcinoma *in situ*.<sup>67</sup> Unfortunately, tamoxifen is associated with potentially

**Proportional reduction of recurrence and mortality from tamoxifen in estrogen receptor-positive early stage breast cancer**

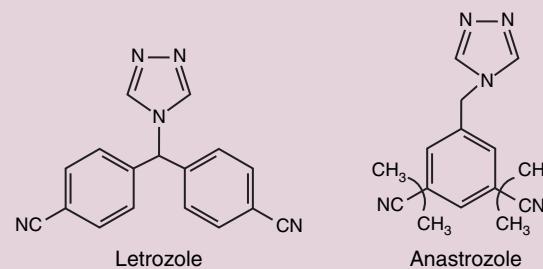

**Figure 40-1 Proportional reduction of recurrence and mortality from tamoxifen in estrogen receptor (ER)-positive early-stage breast cancer.**

serious side effects, including a 4-fold increase in uterine cancer in postmenopausal patients<sup>29</sup> and a significant increase in thromboembolic events and cerebrovascular events.<sup>7,29</sup> Additionally, many patients treated with tamoxifen experience disease recurrence because of the development of resistance.

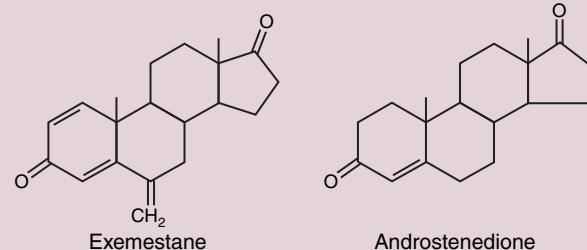

The aromatase inhibitors (Fig. 40-2) are a newer type of hormonal agent that are now being used as adjuvant therapies in

#### Aromatase inhibitors

##### Nonsteroidal inhibitors

##### Steroidal inactivator

##### Androgen substrate

**Figure 40-2 Aromatase inhibitors.**

## Gynecologic Oncology

early-stage breast cancer. These agents inhibit the conversion of androgens to estrogens in postmenopausal women and are ineffective in women with intact ovarian function. Anastrozole, a selective, nonsteroidal, competitive aromatase inhibitor, has been demonstrated to significantly improve disease-free survival, compared with tamoxifen, in postmenopausal patients with early-stage breast cancer<sup>5,6</sup> and has been approved as an alternative to tamoxifen for this indication. A recent trial<sup>7</sup> compared 5 years of adjuvant tamoxifen with 2 to 3 years of tamoxifen followed by the selective aromatase inactivator exemestane for the remainder of the 5 years in postmenopausal patients with early-stage breast cancer. Changing to the aromatase inhibitor resulted in superior disease-free survival at 30 months, compared with continuing tamoxifen for a total of 5 years.<sup>7</sup>

An extension to the NSABP B-14 trial<sup>68</sup> demonstrated no advantage to continuing tamoxifen through 10 years, compared with stopping the drug at 5 years, in patients with early-stage node-negative breast cancer. Based on the results of this trial, the National Cancer Institute recommended administering tamoxifen for no longer than 5 years. Two trials were initiated to examine the use of aromatase inhibitors following 5 years of adjuvant tamoxifen. The MA-17 trial randomized patients to the selective, competitive aromatase inhibitor letrozole, or to placebo, following 5 years of adjuvant tamoxifen. This trial was discontinued prematurely after a significantly improved disease-free survival was noted at a follow-up of 24 months in the patients randomized to receive the aromatase inhibitor.<sup>69,70</sup> Final analysis of this trial, at a follow-up of 30 months, demonstrates an improved disease-free and overall survival in patients with involved axillary lymph nodes treated with letrozole.<sup>70</sup>

Five years of tamoxifen remains the adjuvant therapy of choice for premenopausal patients with early-stage breast cancer. However, several trials are evaluating the use of aromatase inhibitors, along with ovarian ablation, by oophorectomy or luteinizing hormone-releasing hormone agonists, compared with tamoxifen, in premenopausal patients.

#### **Adjuvant Chemotherapy**

Polychemotherapy produced significant proportional reductions in recurrence in women under 50 years of age by 35% and in women aged 50 to 69 years by 20%.<sup>3</sup> Few women aged 70 or over had been studied. For mortality, the reductions were also significant both among women aged under 50 (27%) and among those aged 50 to 69 (11%). Applying the proportional mortality reduction in women less than 50 years old would translate into an absolute 10-year survival benefit of 7% for those with node-negative disease and of 11% for those with node-positive disease. The smaller proportional mortality reduction observed in women aged 50 to 69 at randomization would translate into smaller absolute benefits—2% for those with node-negative disease and 3% for those with node-positive disease. The greater impact of chemotherapy in younger women might be partly attributable to premature menopause. This hypothesis is supported by some studies that demonstrated better outcome for women with drug-induced amenorrhea than for women whose menses persist following adjuvant chemotherapy.<sup>71–74</sup>

The reduction in the relative risk of recurrence and death with adjuvant systemic therapy is similar in node-negative and node-positive disease. However, patients with the lowest risk of

recurrence are least likely to benefit from systemic therapy when the lower absolute benefit and associated toxicities are considered. Women with node-negative tumors that are over 1 cm should be considered for chemotherapy if the tumors are associated with poor histologic features. There are no prospective clinical trials in women with tumors smaller than 1 cm. However, a retrospective analysis of tumors less than 1 cm suggested a benefit from adjuvant chemotherapy in tumors with poor-risk features.<sup>75</sup> The degree of risk reduction and risks of chemotherapy should be discussed with patients so they can make informed choices.

Several chemotherapy regimens are used for breast cancer (Table 40-4). The benefit of anthracycline over nonanthracycline regimens is controversial. Doxorubicin and cyclophosphamide (AC) for four cycles is equivalent in efficacy to the oral cyclophosphamide, methotrexate, and fluorouracil (CMF) regimen for six cycles.<sup>76</sup> However, in the overview analysis, compared with CMF, anthracycline-based regimens were associated with a modest but significant reduction in disease recurrence and death.<sup>3</sup> Seven hundred and ten premenopausal women with node-positive disease were randomized to six courses of oral CMF or cyclophosphamide, epirubicin, and fluorouracil (CEF).<sup>77</sup> With 59-month median follow-up, women receiving

Oral CMF	Cyclophosphamide 100 mg/m <sup>2</sup> PO on days 1–14 Methotrexate 40 mg/m <sup>2</sup> IV on days 1 and 8 Fluorouracil 600 mg/m <sup>2</sup> IV on days 1 and 8 Repeat every 28 days
AC	Doxorubicin 60 mg/m <sup>2</sup> IV on day 1 Cyclophosphamide 600 mg/m <sup>2</sup> IV on day 1 Repeat every 21 days
CAF	Cyclophosphamide 500 mg/m <sup>2</sup> IV on day 1 Doxorubicin 50 mg/m <sup>2</sup> IV on day 1 Fluorouracil 600 mg/m <sup>2</sup> IV on day 1 Repeat every 21–28 days
Oral CEF	Fluorouracil 50 mg/m <sup>2</sup> IV on days 1 and 8 Epirubicin 60 mg/m <sup>2</sup> IV on days 1 and 8 Cyclophosphamide 75 mg/m <sup>2</sup> PO on days 1–14 Repeat every 28 days
AC → T	Paclitaxel 175 mg/m <sup>2</sup> IV on day 1 after 4 cycles of AC Repeat every 21 days
TAC	Docetaxel 75 mg/m <sup>2</sup> IV on day 1 Doxorubicin 50 mg/m <sup>2</sup> IV on day 1 Cyclophosphamide 500 mg/m <sup>2</sup> IV on day 1
<b>Common toxicities</b>	<b>Uncommon toxicities</b>
Nausea and vomiting Alopecia Fatigue Mucositis Weight gain Premature menopause Neuropathy from taxanes Myalgias from taxanes	Febrile neutropenia (common with TAC) Thrombosis Hemorrhagic complications Cardiomyopathy from anthracyclines Secondary leukemia
IV, intravenously; PO, orally.	

CEF had significantly better relapse-free survival (RFS) and overall survival (OS); however, CEF was associated with a higher likelihood of chemotherapy-induced amenorrhea and more cases of acute leukemia. When oral cyclophosphamide, doxorubicin, and fluorouracil (CAF) and oral CMF were compared in high-risk women, CAF was marginally superior to CMF for both RFS and OS; however, CAF was also associated with more toxicity.<sup>78</sup>

Since taxanes have shown benefit in the metastatic setting, several studies have been designed to look at their benefit in the adjuvant setting. The addition of paclitaxel for four cycles following the AC regimen was associated with a statistically significant 17% reduction in the risk of disease recurrence at 5 years and an 18% reduction in risk of death compared with AC alone.<sup>79</sup> In another study, the addition of paclitaxel to AC resulted in a significant improvement in disease-free survival but not in overall survival.<sup>80</sup> The addition of docetaxel was studied in BCIRG study. Patients treated with a combination of docetaxel, doxorubicin, and cytoxan (TAC) had a statistically significant 30% reduction in the risk of both recurrence and death.<sup>81</sup> Febrile neutropenia was more common with TAC.

Dose-dense therapy is a method of administering chemotherapy with shorter intertreatment intervals to minimize the potential of tumor regrowth. CALGB trial 9741 compared sequential therapy with doxorubicin, paclitaxel, and cyclophosphamide versus concurrent AC followed by paclitaxel administered at either 14-day (with filgrastim on days 3 to 10) or 21-day intervals in 2005 women with node-positive disease.<sup>82</sup> The dose-dense arm was associated with significant improvements in 4-year disease-free survival and 3-year overall survival compared with the standard arm.

## TREATMENT OF METASTATIC BREAST CANCER

Despite earlier diagnosis and better adjuvant therapies, many patients develop metastatic disease. Metastatic or Stage IV breast cancer remains, in almost all cases, an incurable disease. However, it is a heterogeneous disease, and some patients can live for 10 years with a good quality of life. The goals of therapy, therefore, are to improve quality of life and attempt to improve survival. Common sites of distant metastases include bone, lung, liver, and brain. Patients with bone-only disease do better than if visceral metastases are present. Therapy options include local therapy with surgery and irradiation and systemic therapy with endocrine therapy, chemotherapy, and novel approaches. These options can be used in combined or sequential fashion. Hormonal therapy and antibody treatment offer the advantage of excellent toxicity profiles and should be used when possible.

Broadly, metastatic breast cancer can be classified according to expression of hormone receptors and HER2/neu. HER2/neu is a member of the epidermal growth factor receptor (EGFR) family, which contains four transmembrane receptors. All the receptors have extracellular domains, which can be targeted with antibodies, such as trastuzumab, which targets HER2/neu. Additionally, each of the EGF receptors except HER3 has an intracellular tyrosine kinase domain, which can be targeted with small molecules, such as gefitinib.

### Treatment of Hormone Receptor-Positive Metastatic Breast Cancer

Metastatic breast cancer expressing ER and/or PR should be treated with hormonal agents. The only indication for chemotherapy as first-line treatment in this setting is a life-threatening visceral disease such as diffuse liver metastasis. Tamoxifen continues to be widely used in the treatment of hormone-responsive metastatic breast cancer, and the likelihood of responding can be predicted by the hormone receptor status of a patient's tumor. Patients are most likely to respond if their tumor expresses both ER and PR, but patients with tumor expressing one or other of the receptors benefit from hormonal therapy in 30% to 40% of cases.<sup>83</sup> A patient who benefits from one hormonal therapy can benefit from second-, third-, and even fourth-line hormonal therapy.

Recent trials have demonstrated that aromatase inhibitors are at least as effective as tamoxifen as first-line therapies for hormone-responsive metastatic breast cancer.<sup>84-88</sup> Newer agents, such as fulvestrant, which down-regulates ER and PR, are effective in patients whose cancer has progressed on tamoxifen.<sup>89</sup> Progestins, such as megestrol acetate, estrogens, and androgens can be used as third- and fourth-line agents in patients who continue to benefit from hormonal therapy.

### Treatment of HER2/neu-positive Metastatic Breast Cancer

HER2/neu is overexpressed in approximately 30% of breast cancers and may be associated with an aggressive course.<sup>38</sup> Trastuzumab is a monoclonal antibody that targets HER2/neu and has demonstrated survival advantages in metastatic breast cancer. When it is used as a single agent as first-line therapy,<sup>90</sup> approximately 50% of patients with HER2/neu-positive metastatic breast cancer benefit. Trastuzumab has marked synergy in preclinical studies with several chemotherapy agents on HER2/neu-positive breast cancer cell lines.<sup>91,92</sup> A pivotal trial randomized patients with HER2/neu-positive metastatic breast cancer to chemotherapy alone or chemotherapy plus trastuzumab.<sup>8</sup> Patients who received trastuzumab had longer disease-free and overall survival compared with those treated with chemotherapy alone. An unexpected side effect of trastuzumab was an increased incidence of cardiomyopathy, particularly in patients who received the drug concomitantly with anthracyclines. Therefore, trastuzumab is currently approved as a single agent, and with paclitaxel, for patients with HER2/neu-positive metastatic breast cancer. Several other agents, including docetaxel and vinorelbine, appear synergistic with trastuzumab. Adjuvant trials examining trastuzumab in early-stage breast cancer are ongoing.

### Treatment of Metastatic Breast Cancer with Chemotherapy

Several different antineoplastic agents have shown benefit in breast cancer (Table 40-5). Even though with first-line chemotherapy response rates are 50% to 60%, only 10% will have complete remission. Average duration of response is 6 to 12 months. Significant palliation can be achieved with chemotherapy. Subsequent chemotherapy agents used in sequential fashion produce fewer responses, which are short-lived. Even though several trials have shown significant response benefit of combination

Table 40-5

## Chemotherapy Agents Commonly Used in Metastatic Breast Cancer

Doxorubicin	Response rates of 35% to 50% in previously untreated metastatic disease
Epirubicin	Less cardiotoxicity compared with doxorubicin
Liposomal doxorubicin	Reduced cardiotoxicity and comparable efficacy to doxorubicin in first-line treatment <sup>96</sup> Not FDA-approved for breast cancer
Paclitaxel	Weekly administration has better efficacy with less myelosuppression but more neurotoxicity than higher doses given every 3 weeks <sup>97,98</sup>
Docetaxel	Compared with paclitaxel, has significantly better response rate, median time to progression, and median overall survival Greater toxicity than paclitaxel <sup>98</sup>
Capecitabine	Response rates are 20% to 27% in taxane-pretreated patients Better efficacy than CMF <sup>99</sup>
Vinorelbine	Response rates of 25% to 50% even in heavily pretreated patients
Gemcitabine	Response rates of 14% to 37%
Cyclophosphamide	Response rate of 25%
Trastuzumab in HER2-over expressing tumors	50% response rate in combination with chemotherapy <sup>8</sup>

chemotherapy over single-agent chemotherapy,<sup>93,94</sup> no clinical trial has shown a benefit of combination chemotherapy over sequential use of different chemotherapy agents. However, combination therapy is appropriate when immediate response is needed, for example, in women with rapidly progressive tumor growth. Bisphosphonates have utility in advanced breast cancer patients with bone metastasis. Intravenous pamidronate delays the appearance of clinical skeletal complications and reduces the proportion of women with skeletal complications.<sup>95</sup>

## KEY POINTS

- Mammary (or breast) gland development is noted in both male and female fetuses at the fifth or sixth week of development.
- The sentinel lymph node is the first node draining from the tumor site. Pathology within this node determines the necessity for further axillary evaluation.
- Witch's milk may occur in both newborn females and males as a result of transplacental transfer of maternal hormones (primarily estrogen).
- Breast cancer is the most common cancer in women and is second only to lung cancer in cancer deaths for women.
- A history of multiple affected first-degree relatives, bilateral disease, early or premenopausal age of onset, a family history of both ovarian and breast cancer, or male breast cancer increases the probability of having an inherited predisposition to breast cancer.
- Breast self-examination has not been shown in randomized, controlled trials to decrease mortality associated with breast cancer.
- Ultrasound, magnetic resonance imaging, digital mammography, and computer-assisted diagnosis have insufficient data to justify support in breast cancer screening.
- The sensitivity of ductal lavage in detecting breast cancer is low; however, it may be helpful in detection of preneoplastic cells in women at high risk for the development of breast cancer.

Issues surrounding breast diseases are one of the most pervasive concerns of women today. From abnormal development to mastitis, discussions about breast maladies are widespread. Moreover, breast health and treatment are among the most controversial subject matters of the day. From estrogen therapy and breast cancer risk to mammographic screening, women are bombarded with decisions related to breast health, which may have important outcomes and significant impact on their future quality of life. Thus, disorders of the breast are of particular importance to those who function as primary caregivers for women from reproductive age through the perimenopause, the specialty of obstetrics and gynecology.

Because gynecologists continue to assume a position of extensive importance with respect to diagnosing and treating breast diseases in women, the diagnosis of breast cancer in its most curable forms lies within this specialty for large numbers of

women. To effectively respond to the challenge of this profound medical responsibility, physicians must have an understanding of the natural history as well as the contemporary diagnostic and screening modalities for both benign and malignant disorders of the breast.

This chapter reviews the anatomy and physiology of the breast and examines recent advances in breast cancer knowledge, with emphasis on mammographic screening recommendations, alternative imaging modalities, assessment of risk factors, breast cancer susceptibility testing, and chemoprevention in high-risk women. Women who develop breast cancer require a multidisciplinary team approach, which includes the gynecologist, general surgeons, radiation oncologists, and medical oncologists. Thus, the gynecologist must be a knowledgeable participant in treatment planning.

## EMBRYOLOGY

Embryologic differentiation of the paired mammary glands begins at the fifth or sixth week of fetal development in both genders. Thickened ectoderm (known as *mammary ridges* or *milk lines*) develops from the area of the future axilla to the future inguinal region. During normal development, regression of the ridges results in persistence of only one gland bilaterally at the level of the thorax. Failure of regression may give rise to accessory mammary glands (*polymastia*) or accessory nipples (*polythelia*) along the original mammary ridge. This minor congenital anomaly may occur in both sexes, with an estimated frequency of about 1%.<sup>1,2</sup>

Extension of the remaining ectoderm into the underlying mesenchyme initiates development of the primary bud. From 15 to 20 secondary buds develop as outgrowths of each primary bud and extend into the surrounding connective tissue of the chest wall. Canalization of these epithelial cords (under the influence of placental sex steroids) during the third trimester heralds the development of the lactiferous ductal system. Proliferation of basal mesenchymal cells initiates transformation into the fully formed nipple. Continued elevation is supported by both expansion of underlying connective tissue and smooth muscle development in the areolar gland. Failure of elevation of the nipple above the skin level occurs in 2% to 4% of the population, resulting in inverted nipples.

## Anatomy

The breast, or mammary gland, is a highly modified sudoriferous (sweat) gland situated between two layers of superficial fascia on the pectoralis major, serratus anterior, and external oblique muscles. The second rib and the sixth intercostal space in the

## Gynecologic Oncology

vertical plane, and the sternum and the midaxillary line in the horizontal plane, border it. It is composed of 15 to 20 lobes, with the greatest volume of glandular tissue located in the upper outer quadrant. The breast lobes branch into lobules and then into terminal duct lobular units, which are thought to be the originating site for breast cancer. Each lobe terminates in a lactiferous duct, which opens onto the nipple.

Cooper's (or suspensory) ligaments are fibrous septa that interdigitate between the tissue to connect the two fascial layers. Cancerous invasion of Cooper's ligament may result in skin retraction or dimpling.

The nipple contains smooth muscle fibers, which is the only muscle "within" the breast tissue. Stimulation of these muscle fibers in response to various sensory stimuli accounts for erection of the nipple. The vast array of sensory nerve cell endings provide the neurohumoral pathway necessary for milk letdown during suckling. The areola consists of many sweat, sebaceous, and accessory glands. During pregnancy, accessory glands called *Montgomery tubercles* become very prominent.

The breast tissue is well supplied by an extensive system of arteries and veins. The medial and central aspect of the breast is supplied by the anterior perforating branches of the internal thoracic (internal mammary) artery. A branch of the axillary artery, the lateral thoracic artery, supplies the upper outer quadrant. The two vessels combined also provide the major blood supply to the nipple. Other vessels of the extensive arterial and venous system include the anterior and lateral branches of the intercostals, the pectoral branch of the thoracoacromial artery and other branches of the axillary artery, and the subscapular and thoracodorsal arteries.

Venous and lymphatic drainage follows the course of the arteries. The principal venous drainage of the breast is the internal thoracic vein medially, the axillary vein superolaterally, and the intercostal veins, which drain to the vertebral and azygous veins posteriorly. This drainage pathway explains the frequent sites of metastasis, because breast cancer will enter the venous system and metastasize to the lungs through the axillary or intercostal veins or to thoracic, abdominal, and pelvic organs by way of the vertebral vein. Similarly, the primary lymph node drainage is initially into the axillary region, but additional drainage can proceed to the infraclavicular and supraclavicular and mediastinal (parasternal) areas, thus suggesting the need to extend the routine breast examination to the bony margins (rather than simply the breast tissue) to assure adequate coverage of these potential cancer-bearing areas. The lymphatic plexus is divided into levels based on the relation to the pectoralis minor muscle. Level one nodes are located lateral to the muscle and level three nodes are located medially. Level two nodes are located deep or posterior to the pectoralis minor muscle. The sentinel lymph node, which has gained important significance in breast cancer treatment over the past decade, is the first node draining from the tumor site. Pathology within this node determines the necessity of further axillary evaluation.

## PHYSIOLOGY

The anterior lobe of the pituitary gland and the ovaries orchestrate the development and physiologic functioning of the breast. This development is a lifelong process that begins in utero. A

transient enlargement of the breast bud and/or associated milk-like nipple secretion (witch's milk) may occur in both newborn females and males as a result of transplacental transfer of maternal hormones (primarily estrogen). The fluid secretion may appear for a week postpartum, but subsequent involution of the tissue results by the third or fourth week postpartum.

Before the transformation that occurs at puberty, the function and histology of the human breast is identical in males and females. During puberty in the female, the rudimentary gland buds proliferate and increase in size while the nipple and areola become pigmented. The ductal system develops as a consequence of estrogen stimulation, and the lobular-alveolar system develops due to progesterone secretion.

Menstruation, pregnancy, and menopause are sentinel events in breast development. Before the onset of menstruation, breast development begins with ductal branching and proliferation of interductal stroma. With each menstrual cycle ductal proliferation occurs under the influence of estrogen. Under the influence of progesterone, proliferation of the terminal duct structure and increased mitotic activity in the basal epithelial cells occur in the secretory phase. Stromal proliferation and edema, in response to the hormonal milieu, account for the sense of fullness or tenderness experienced premenstrually. The fall in hormones that occurs with menstruation is associated with the disappearance of stromal edema, desquamation of epithelial cells, atrophy of intralobular connective tissue, and overall shrinkage in the size of the ducts.

Further maturation of the breast occurs with pregnancy. Significant growth of glandular tissues and decrease in the surrounding stroma portends reversal of the previous stromal predominance within the stromal/glandular relation seen before this stage. After pregnancy these changes regress but do not return completely to their prepregnancy state. Menopause heralds a further reduction and shrinkage of the ducts, gland buds, and surrounding stroma.

### Lactation

Hormonal and structural changes that occur during pregnancy prime the breast for future milk production. Increased estrogen and progesterone secretion in early pregnancy results in ductal development and maturation as well as enlargement of lobular size. During the latter half of pregnancy, glandular epithelium is transformed into secretory epithelium as a result of hormonal stimulation, including insulin, thyroxine, growth hormone, and corticosteroids. Human placental lactogen and prolactin also play critical roles in breast development during pregnancy. Paradoxically, despite considerable increases in prolactin, this hormone's functioning is inhibited at the alveolar level by progesterone. Thus lactation does not occur until the rapid decline of estrogen and progesterone at the time of delivery.

At delivery, stimulation of the afferent neural arc suppresses prolactin-inhibiting hormone, allowing release of prolactin-releasing hormone and further elevation of the prolactin concentration. Not only breast suckling, but also auditory and visual stimuli, stimulate the neural arc. Prolactin-inhibiting hormone is thought to be dopamine and prolactin-releasing hormone is thought to be thyrotropin or thyrotropin-releasing hormone. Additionally, stimulation of the neural arc triggers release of oxytocin by involving the paraventricular and supraoptic nuclei

of the hypothalamus. Oxytocin release from the posterior pituitary induces contraction of the myoepithelial cells surrounding the nipple ducts, resulting in milk letdown. Continued suckling induces additional prolactin secretion as well as replenishment of the milk supply. Discontinuation of suckling results in increased levels of prolactin-inhibiting hormone, which inhibits prolactin production. Ultimately, lactation will cease, with resultant decrease in size of the alveoli.

## BREAST CANCER

Although the etiology of most breast symptoms is a benign disorder, the fear of cancer is often the motivating factor for women seeking evaluation of breast symptomatology. Breast cancer remains the most common cancer in women, with the American Cancer Society (ACS) estimating nearly 215,990 new cases of invasive breast cancer in the United States during 2004. Startlingly, approximately 1450 men will be afflicted with breast cancer as well.<sup>3</sup> Moreover, an estimated 40,580 deaths from breast cancer (40,110 women, 470 men) are anticipated during the same period. Cancer of the breast is second only to lung cancer in the number of cancer deaths in women, making it an especially dreadful adversary. Although breast cancer incidence rates have continued to increase since 1980 (albeit the rate of increase slowed in the 1990s), mortality rates have declined by 2.3% per year since 1990.<sup>3</sup> This decline is surmised to be directly attributable to increased utilization of screening mammography, resulting in earlier detection, improved treatment, and a heightened awareness of breast cancer symptoms among women.<sup>4</sup> Further advances in hormonal treatment, deciphering of genetic etiologies, and risk reduction therapies has thrust breast health issues into the forefront of the media and medical technology. The zeal to achieve the ideal cure or prevention strategy persists unabated in the medical profession and remains an ongoing challenge. A thorough understanding of the evaluation of breast disease is essential for the practicing gynecologist.

### Risk Factors

Breast cancer prevention is now an achievable medical objective; thus, an understanding of the epidemiology of breast cancer is critical in assessing the individual's risk for development of the disease. Breast cancer risk factors are covered in detail in Chapter 40, but a brief review is appropriate at this juncture.

The etiology of breast cancer is multifactorial; although numerous risk factors have been identified, fewer than 15% of patients with breast cancer have an identifiable risk factor, which means nearly 85% of women with breast cancer have no identifiable risk factors other than gender and age. Thus, all women should be considered at risk for breast cancer.<sup>5</sup>

Age is the most significant risk factor, because the risk of breast cancer increases with advancing age. Additional risk factors include nulliparity, delayed childbearing (childbirth before age 18 portends one third the risk of breast cancer of a woman delivering at age 35), a personal or family history of breast cancer, benign proliferative breast disease (ductal or lobular hyperplasia, particularly with atypia), obesity in postmenopausal women, alcohol intake, early menarche (before age 12), late menopause (after age 53), and higher socioeconomic status. Breast cancer susceptibility genes account for approximately 5%

to 10% of breast cancer cases. Genetic etiologies associated with breast cancer are discussed later in this chapter.

Breast cancer rates vary among racial and ethnic groups. For all ages combined, white women have a higher incidence of breast cancer (are more likely to develop breast cancer), yet African American women have a higher mortality (are more likely to die) from breast cancer. Native Americans have the lowest incidence of breast cancer, nearly one third the rate of white women. In addition, Native American and Asian women have approximately one third the breast cancer mortality of African American women.<sup>6</sup>

Family history is the most widely recognized epidemiologic risk factor.<sup>7</sup> First-degree female relatives of women with breast carcinoma have 2 to 3 times the general population risk of developing the disease. The risk increases even more if the affected relative was premenopausal with bilateral breast disease on diagnosis (eightfold increased risk) compared to a postmenopausal affected relative with only unilateral disease (up to twofold increased risk). First-degree relatives include the patient's mother, sister, or daughter. Second-degree relatives include grandmothers, nieces, and aunts. Due to information we now have regarding breast cancer susceptibility genes and their possible inheritance from the paternal side of the family, a careful paternal family history must be obtained, including relatives with prostate and brain cancers as well.

### Screening

#### **History**

A thorough clinical history is a vital aspect of the initial evaluation, because it identifies the patient's personal and family health history, which is useful in assessing risk. The practitioner should obtain detailed information regarding the patient's complaint, if any (duration, onset), and pertinent positive and negative symptoms related to the complaint. The clinical history also provides an important opportunity to explain the benefits and limitations of the breast examination. The valuable information useful in assessing breast health includes age; menstrual, gynecologic, sexual, reproductive, and lactation history; and any family history of breast disorders. In addition, a total body review of systems (e.g., headache, blurred vision for macroadenomas) focused to the patient's complaint should be included. The patient's menopausal status; timing and specific nature of her symptoms and their relation to the menstrual cycle; onset, duration, and growth pattern of any masses; presence of pain; relief measures that have been attempted or have succeeded; alleviating or aggravating factors; use of hormone replacement therapy or oral contraceptives; and presence or absence of risk factors for breast cancer are vitally important. All previous breast imaging, diagnostic procedures, and surgical procedures should be documented. One should not forget to review the patient's past medical and surgical history, as well as her current medications and social history (including smoking, alcohol use, and educational level). Because most breast complaints in reproductive-age women are associated with a benign etiology, reassurance may be an important aspect in reducing anxiety. However, the practitioner should be careful to notify the patient of any concerns regarding the history and examination to ensure that the patient understands the significance of follow-up and does not misconstrue the practitioner's reassurance to mean the diagnostic workup is completed.

## ROLE OF RISK ASSESSMENT IN BREAST CANCER SCREENING

Truly individualized breast cancer risk assessment would require the identification of a histopathologic or serologic marker indicating that this particular woman's breast tissue has initiated the preneoplastic process, thus providing clinicians an opportunity to intervene in the natural history of malignant development. Hence, studies have documented the most consistent pathologic feature, the presence of atypical hyperplasia. Cellular atypia has been found to be predictive of an increased risk of developing breast cancer, especially in women with a family history of breast cancer.<sup>8–10</sup> Recent studies indicate that breast cancer incidence may be substantially reduced in high-risk cohorts by treatment with tamoxifen, prophylactic oophorectomy, and prophylactic mastectomy.<sup>11–13</sup> (This is discussed in more detail in Chapter 40.) In the NSABP-P1 (National Surgical Adjuvant Breast and Bowel Project) study, patients with atypical ductal hyperplasia had the greatest benefit from tamoxifen chemoprophylaxis, with an 86% lower incidence of breast cancer among this group of patients. This highlights the need for accurate risk stratification as women contemplate the utilization of these invasive procedures. Further studies are needed to elucidate the optimal management of these patients. In the absence of consensus about which risk level is best suited to

which option, decisions about risk reduction depend as much on an individual's priorities and risk aversion as on numerical risk estimates. In the field of research, high priority is being placed on the development of accurate short-term risk models so that women most likely to benefit from preventive strategies can be readily identified. Risk assessment is likely to offer the greatest potential benefit for women younger than age 40, based on greatest gain in life expectancy offered by existing risk reduction options.

Several algorithms have been developed to estimate a woman's risk of developing breast cancer, with the best known of these being the Gail and Claus models.<sup>14,15</sup> The Gail Model Risk Assessment Tool (Fig. 41-1) incorporates the patient's race, current age, age at menarche, age at first live birth, number of first-degree relatives with breast cancer, number of previous breast biopsies, and pathology results in generating an estimate of breast cancer risk. Conversely, the Claus model utilizes fewer categories, including only the number of relatives with breast cancer, their relationship to the patient, and the relative's age at cancer diagnosis. Although helpful in diagnosis, models are often inapplicable to the proband. In particular, the Gail model cannot be used for women younger than age 35 (because these age groups were not included in the initial validation studies) and is less accurate in those with second-degree affected relatives, those with *BRCA* mutations, those with a personal history of

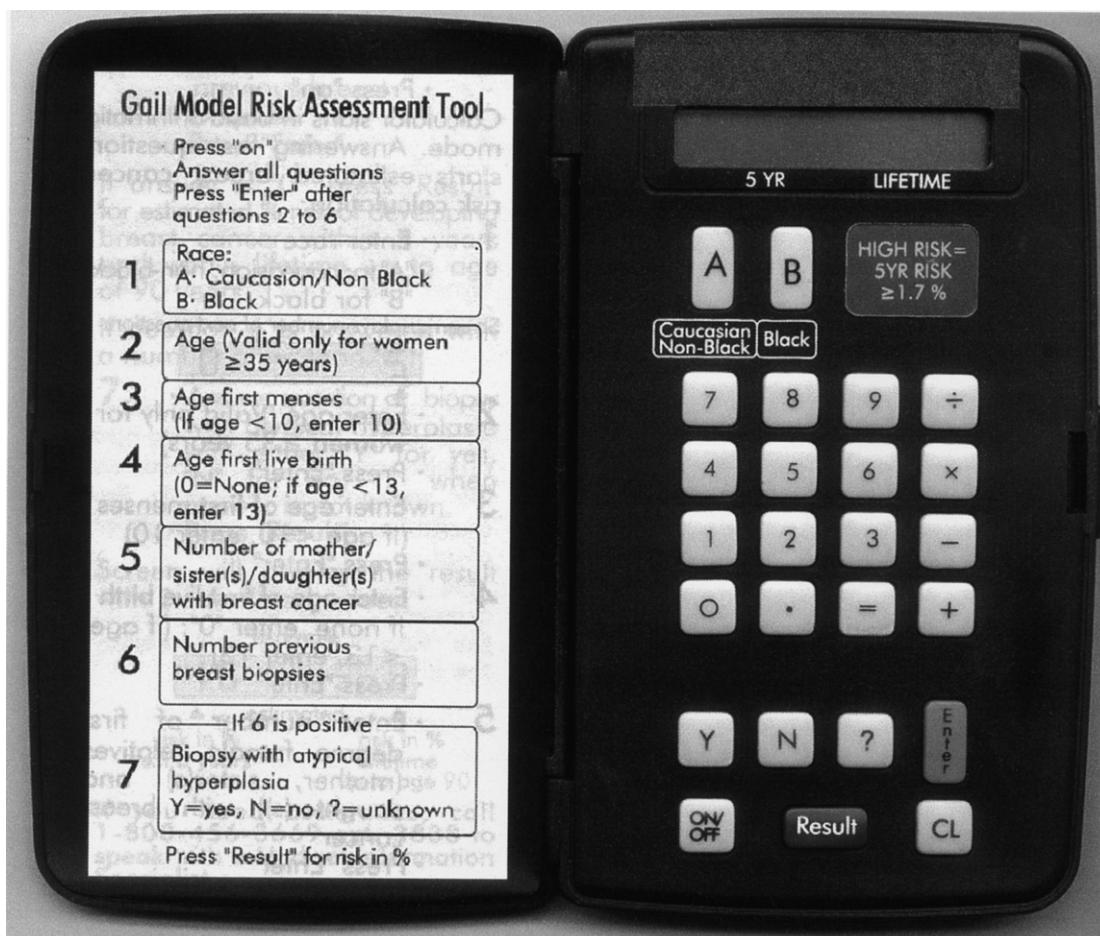

Figure 41-1 The Gail Model Risk Assessment Tool.

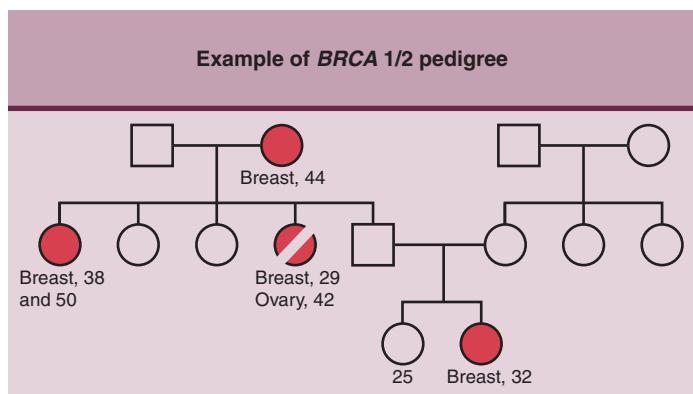

breast cancer, and those who do not obtain annual mammograms. Several studies have shown a lack of correlation in minority patients. BRCAPro is another helpful model, which estimates an individual's likelihood of harboring a *BRCA* mutation. This model incorporates additional factors, including bilaterality of breast disease and history of ovarian cancer. Although initial policy statements suggested testing for those with a probability greater than 10%, current recommendations are less stringent.<sup>16</sup> Unlike the Gail model, neither the BRCAPro nor the Claus model have been validated in clinical studies. Counseling must stress that these figures are estimates and not absolute risks and thus balance the magnitude of risk for the individual patient.

Moreover, those patients carrying germ line mutations have a dramatically higher risk for ipsilateral recurrence or contralateral primary cancer after a diagnosis of breast or ovarian cancer (Table 41-1). Thus, genetic testing is integral in tailoring surveillance, chemoprevention, and surgical management plans for patients (and their families) at risk of hereditary cancer syndromes. Obstetrician/gynecologists will play a pivotal role in eliciting detailed personal and family histories from patients, determining which of those histories is suggestive of an individual at significantly high risk, facilitating referrals for genetic counseling and testing or risk assessment procedures (such as ductal lavage or periareolar fine-needle aspiration), and incorporating the results of testing into the patient's short- and long-term management plans.

### Testing for *BRCA1* and *BRCA2*

The past decade has witnessed an explosion of knowledge in the arena of cancer genetics and inherited susceptibility to cancer syndromes. Approximately 5% to 10% of breast cancers are thought to be inherited in an autosomal dominant pattern (Fig. 41-2). Two breast and ovarian cancer susceptibility genes have been identified and mapped to chromosomes 17q and 13q, namely *BRCA1* and *BRCA2*.<sup>17,18</sup> They are thought to be tumor suppressor genes, which become ineffective in suppression of cancerous proliferation if mutation in both copies evolves.

*BRCA1* is a very large protein, encoding for 1863 amino acid pairs. Several hundred different mutations have been found in both the *BRCA1* and *BRCA2* genes.<sup>19</sup> A *BRCA1* mutation is believed to account for nearly half of all inherited breast cancer cases and nearly 90% of hereditary ovarian cancer cases. Similarly, *BRCA2* mutations are responsible for approximately 40% of familial breast cancer and 5% to 10% of familial ovarian cancer. Li-Fraumeni syndrome,<sup>20</sup> *TP53* mutations, *HRAS* mutations, ataxia-telangiectasia,<sup>21</sup> and other genetic changes as yet

**Figure 41-2** Affected individuals are often seen in each generation with a *BRCA1*/*BRCA2* mutation.

undetected appear to account for the other cases of inherited breast cancer.

Initial studies suggested the lifetime risk of developing breast cancer in families with *BRCA1* and *BRCA2* mutations was approximately 80% to 90%, and the risk of ovarian cancer was approximately 10% to 60%. The overall lifetime risk of developing breast or ovarian cancer was nearly 100%.<sup>22</sup> However, population-based studies (versus studies based on specific families) now suggest that the actual overall lifetime cancer risk for mutation carriers is closer to 56% for breast cancer and 16% for ovarian cancer, based on knowledge regarding penetrance and modification of penetrance and risk factors by other genes. Further longitudinal studies may resolve this question.

Interestingly, *BRCA* mutation carriers not only have an increased overall risk of developing cancer, but also commonly have a younger age of onset and a greater probability of second tumors. Accordingly, although the inherited *BRCA* mutations account for only 5% to 10% of all breast cancers, they account for nearly 25% of breast cancer cases diagnosed before age 30. Thus, knowledge of *BRCA* status may impact the type of surgery suggested for mutation carriers (lumpectomy versus mastectomy, including associated contralateral prophylactic mastectomy).

Eligibility criteria for testing for *BRCA* status vary among institutions. Most agree the likelihood of harboring a *BRCA* gene is elevated (and thus these women are eligible for testing) in women with histories suggestive of an autosomal dominant pattern of inheritance and/or with a known *BRCA*-positive individual in the immediate family. They often differ as to the number of relatives with breast cancer that prompt concern or the age of onset (some suggest testing in families with ovarian cancer at any age). The ACS would offer testing to those with two or more relatives with breast or ovarian cancer in addition to the previously cited criteria.<sup>23</sup>

Not only are the *BRCA* genes associated with increased risk of female malignancies, but they have also been shown to be a marker for hereditary cancer syndromes in males. Interestingly, male breast cancer is much more common in *BRCA2* mutation carriers compared to the general population.<sup>24</sup> In addition, mutation carriers may be at increased risk for other malignancies, such as laryngeal, prostate, gallbladder, stomach, and pancreatic cancer; malignant melanoma; and primary peritoneal

**Table 41-1**  
Characteristics Suggestive of a Germ Line Mutation

## Gynecologic Oncology

carcinoma.<sup>17,25–29</sup> Hence, the *BRCA* mutation may be transferred through a male or female relative. It is therefore important to elicit a history of all related malignancies from both sides of the family, including age of onset, bilaterality, and history of multiple primary cancers in an individual family member, not just a family history of breast and ovarian cancer. Patients are often unaware that the risk of transmission of a *BRCA* mutation is equally high from the paternal side and do not volunteer information about cancers from that side.

The frequency of a *BRCA1* mutation in the general population is estimated to be 1/500 to 1/1000 (with *BRCA2* mutations occurring somewhat less frequently), although it appears to be higher in certain ethnic groups, such as Ashkenazi Jews, in whom it is estimated to be 1%.<sup>30</sup> In the Ashkenazi Jewish population (of Eastern or Central European origin), three different founder mutations have been identified: 185delAG and 5382insC in *BRCA1*, and 6174delT in *BRCA2*. Estimates indicate that 1 in 40 Ashkenazi individuals carry one of these founder mutations, and they are responsible for 25% of cases of early-onset breast cancer in this population.<sup>31,32</sup> Current investigations indicate the estimated gene frequency in the general population may be artificially high due to ascertainment bias in the initial studies of high-risk families.

The benefit of genetic testing remains hypothetical because there is no proof that testing and increased surveillance or other risk reduction initiatives would translate into a decrease in breast and ovarian cancer mortality. The accuracy of screening tests (the sensitivity and specificity of the test) is affected by the prior probability of having the condition.<sup>33,34</sup> Given the current cost of testing (\$2900; \$350 for specific mutations) and the fact that its benefits remain unproven, physicians should discourage individuals from undergoing testing in the absence of a strong family history or early disease. Moreover, the ability to reassure those with negative tests is limited by the possible existence of other as-yet undiscovered genes.

It is preferable to test an affected family member to document the particular familial *BRCA1* or *BRCA2* mutation. A negative result is most meaningful in a situation in which the family member has previously tested positive. In this scenario—the absence of the detectable mutation in the proband—the patient may be reassured that she does not share the high risk for cancer seen in her family. She should be counseled, however, that she still has the baseline risk of cancer seen in the general population (1 in 8 for women who live to age 85) and that she should continue usual care, such as mammography, and consider breast self-examination (BSE). Present techniques do not identify all disease-causing mutations, and patients need to be informed of the limitations of present technology.

## CLINICAL SCREENING FOR BREAST CANCER

Breast cancer remains one of the most dreaded diseases of the millennium. As statistics state that 1 in 8 women will be affected, mass attention has been focused on determining the cause and prevention. Because 80% of patients with breast cancer have no risk factors other than gender and age, early identification of those at highest risk for developing the disease is difficult. Thus, one of the most important aspects in combating this disease is diagnosis at an early stage when the prognosis for

**Table 41-2**

Average risk (asymptomatic)
Age 20–40
BSE monthly (optional)
CBE every 1–3 years
Age over 40
BSE monthly (optional)
CBE annually or biannually
Mammography annually

BSE, breast self-exam; CBE, clinical breast exam.

Modified from Smith RA, Saslow D, Sawyer KA, et al: American Cancer Society guidelines for breast cancer screening: Update 2003. CA Cancer J Clin 2003;53:141–169.

cure is greatest. The three-pronged approach of breast imaging, clinical breast examination (CBE), and BSE has become the hallmark of early breast cancer detection. But breast cancer screening is not without risks. The potential benefit must be carefully weighed against the potential harm, including radiation exposure, false-positive testing, and overdiagnosis resulting in anxiety and unnecessary breast biopsies (Tables 41-2 through 41-4).

Not only is increasing breast cancer surveillance suggested for *BRCA* mutation carriers, ovarian surveillance is also recommended. Patients may receive annual CA 125 and vaginal probe ultrasounds beginning between age 25 and 35 (based on the age of the affected relative). Patients and practitioners should, however, realize that current recommendations have not been shown to decrease mortality from breast or ovarian cancer; thus, clinical evidence for support is minimal.<sup>35</sup> Guidelines suggest that women with positive *BRCA* status and those at increased risk for the development of breast cancer may benefit from these alternative screening strategies, such as earlier initiation of screening, shorter screening intervals, or the use of adjunctive screening modalities in conjunction with mammography and

physical examination, such as ultrasound or magnetic resonance imaging (MRI). However, there are no randomized, controlled trials supporting their benefit.<sup>23</sup>

All women in their twenties should have an opportunity to become informed about the benefits, limitations, and potential harms associated with regular breast cancer screening. Clinicians must emphasize the importance of prompt reporting of any breast symptomatology. Those who choose to do BSE should receive instruction and have their technique reviewed regularly. It is acceptable for women to choose not to do BSE or to do it irregularly. Whether to continue screening in older women should be individualized based on the potential benefits and risks of mammography considering their current health status and estimated life expectancy. However, the ACS suggests continuation of annual mammographic screening after 40 years of age as long as a woman is in reasonably good health and would be a candidate for cancer treatment.

Mammography is the only widely accepted imaging modality used to screen for early, otherwise occult breast cancer. Although mammography is especially valuable as an early detection tool, significant controversy surrounds the efficacy of mammographic screening in decreasing breast cancer mortality. Early detection of malignant disease has usually resulted in a more favorable outcome. However, a systematic review of the literature regarding screening with mammography did not show a survival benefit of mass screening for breast cancer; the evidence was inconclusive for breast cancer mortality. This may be secondary to earlier detection of ductal carcinoma *in situ* lesions, detection of early breast cancers that may not have been aggressive and thus may not have caused death, or detection of lesions in older patients who may die from causes unrelated to the breast cancer. It has therefore been questioned whether screening with mammography does more good than harm.

The appropriate age for commencing annual mammography has generated substantial debate. The American Medical Association,<sup>36</sup> ACS,<sup>23</sup> the American College of Radiology,<sup>37</sup> the American College of Surgeons, and the American Society of Clinical Oncology advocate annual mammographic screening in women beginning at age 40. In contrast, the Canadian Task Force on Preventive Health Care<sup>38,39</sup> and the American College of Preventive Medicine espouse annual surveillance beginning at age 50 (although the Canadian Task Force does not suggest the inclusion or exclusion of mammography in the periodic health examination of women age 40 to 49 at average risk for breast

cancer). The American Academy of Family Physicians<sup>40</sup> and the American College of Obstetricians and Gynecologists (ACOG)<sup>41</sup> promote 1- to 2-year screening intervals beginning at age 40 corroborated by evidence-based analysis of published screening trials. A 1997 Consensus Development Panel convened by the National Institutes of Health concluded that the evidence was insufficient to determine the benefits of mammography among women aged 40 to 49. This panel recommended that women in this age group should be counseled about potential benefits and harms before making a decision about mammography screening.<sup>42</sup> General screening guidelines are not intended to apply to women at increased risk of breast cancer, symptomatic women undergoing diagnostic mammography, or women with a history of breast cancer receiving follow-up mammograms.

### Breast Self-Examination

Women have been trained in the technique of BSE for years, with the goal of earlier detection of breast abnormalities. An additional goal of BSE is to increase awareness of normal breast composition (i.e., topography, structure, design), which may heighten awareness of changes that may be detected during BSE. The value of heightened awareness, however it may be achieved, is commonly acknowledged based on the value of earlier treatment of both nonpalpable and palpable breast cancers. Studies show that breast cancers detected while practicing BSE are diagnosed at an earlier stage and tend to be smaller than those diagnosed in the absence of any screening. In addition, women are more likely to find their tumor themselves when practicing BSE regularly.<sup>23</sup> However, data documenting the efficacy of BSE in reducing breast cancer mortality is lacking. Moreover, many clinicians criticize this technique because of concerns that it creates excessive fear of cancer in some women and may result in unnecessary surgery for benign conditions.<sup>43–45</sup> It may represent the only viable alternative for women who do not meet screening eligibility requirements, however, or for whom mammography services are simply unavailable. Furthermore, Shen and Zelen analyzed data from selected mammography screening trials and found the sensitivity of BSE to be appreciable (39%–59%).<sup>46</sup>

To review the evidence, one recent study randomized over 250,000 women in Shanghai to intensive BSE instruction compared with no intervention. This was followed by reinforcement sessions at 1 and 3 years and medically supervised BSE practice at least 12 times in a 5-year period. The study found no reduction in mortality.<sup>45</sup> In the routine health care group (no intervention), nearly 65% of the women received one or more annual examinations. No mammographic screening was available to women in the study population, and the level of clinical breast examination activity was low. The results, however, suggested that teaching BSE did enhance a woman's level of awareness and ability to find lumps in her own breasts. In addition, a slightly higher percentage of breast cancers in the instruction group than in the control group were diagnosed at either the Tis (carcinoma *in situ*) stage or the T1 ( $\leq 2$  cm in diameter) stage. Diagnosis of tumors at these early stages was weakly associated with level of attendance at study activity sessions. Furthermore, a high proportion of women in the instruction group reported that they had found their breast cancer as a result of practicing BSE, and they sought medical

## Gynecologic Oncology

attention after detecting their tumor in somewhat less time than did women in the control group. However, in spite of these apparent successes of the BSE teaching program, as many cancers in the instruction group as in the control group were diagnosed with axillary lymph nodal metastases.

In a randomized trial in Russia, more cancers were found in the instruction group than in the control group (RR, 1.24; 95% CI, 1.09 to 1.41); this was not the case in Shanghai (RR, 0.97; 95% CI, 0.88 to 1.06).<sup>47</sup> Yet, these trials review BSE instruction, not the practice of BSE, because this information could not be reliably obtained from self-report. The implication of these results for women who have periodic mammograms is unclear. Further randomized trials reviewing SBE in conjunction with mammography are warranted. Accordingly, promotion of BSE as a single screening method is often not recommended. Conversely, to negate SBE as an important component of overall personal health care seems inappropriate if there is any possibility to affect the survival rate in women. In breast disease, where early detection is so clearly related to improved survival, the value of this relatively simple, economical, and minimally inconvenient technique should not be underemphasized. With this in mind, ACOG and the ACS continue to recommend performance of BSE monthly beginning at age 20.

Therefore, literature on the effectiveness of BSE as a detection modality has shown mixed results, but recent evidence reviews have focused on the absence of direct evidence of benefit in two randomized controlled trials and on data indicating that the rate of benign biopsy is higher in women who regularly perform BSE compared with women who do not do so. The U.S. Preventive Services Task Force concluded that the evidence is insufficient to recommend for or against teaching or performing routine BSE. The Canadian Task Force on Preventive Health Care went further and recommended against routine instruction in BSE in periodic health examinations on the basis of evidence showing lack of benefit and evidence of harm, primarily increased false-positive results. The Canadian Task Force agreed with the ACS in recommending that women should be taught to report any breast changes or concerns and should be provided with careful instruction and information about risks, benefits, and limitations of BSE. Conversely, in an accompanying editorial, Nekhlyudov and Fletcher argued that the existing data did not provide a sound basis for dismissing the value of BSE based on both the limitations in the randomized, controlled trial data and on the basis of the principle that when evidence is lacking, it is best to err on the side of prudence.<sup>43,45,48–50</sup>

Effective instruction of patients in the technique of BSE incorporates description of the procedure while the patient views the providers' performance of the examination or demonstrates the technique using models. Additionally, having the patient reiterate her understanding of what has been taught and then demonstrating her mastery of the technique using manufactured breast models further solidifies compliance. Ensure that the patient understands the significance of breast inspection in various positions as well as the utility of breast palpation in the standing and supine positions. The circular method of breast palpation is routinely the easiest to master, although for patients with pendulous breasts, positional changes to ensure positioning of the breast tissue on the chest wall must be emphasized. The

best time to perform the examination is usually the week after the menses, although menopausal women should pick a convenient time of the month, such as their birth date or the first of each month. After hysterectomy, patients with continued estrogenic support of the ovaries should observe for breast fullness or tenderness. Breast examination should then be performed 7 to 10 days after maximal breast symptoms.

### Clinical Breast Examination

As with BSE, clinical breast examination (CBE) seeks to detect breast abnormalities at an earlier stage of disease, when treatment options are more numerous, include less invasive alternatives, and are generally more effective than treatment options for cancers detected at later stages. However, of the commonly employed methods of breast cancer screening, CBE has received the least attention in the medical literature. In actual fact, CBE is a common component of current comprehensive preventive health maintenance with widespread performance across the United States. Moreover, tools to assist practitioners in improving performance of the examination may be of particular importance in the arena of breast cancers because failure to diagnose breast cancer is a primary cause of action for malpractice claims. It is also the second-leading reason for payments to claimants.<sup>51</sup> Obstetrician/gynecologists should not abdicate their responsibilities by relying on previous examinations performed by other specialists. The practitioner must be concerned with protecting him/herself from future lawsuits due to errors of omission.

A recent committee of national and international experts well versed in CBE, comprised of representatives from the ACS advisory group, the Breast Cancer Early Detection Guideline Review Physical Examination Working Group, the Centers for Disease Control and Prevention, and the National Cancer Institute, published recommendations to enhance CBE performance and reporting.

Each portion of the breast examination may be performed in both the sitting and supine positions because positional changes will often expose a lesion that was otherwise masked by the patient's normal anatomic variations. CBE should begin with visual inspection of the breasts. The practitioner should assess the breast for erythema, skin retraction, rashes, nipple retraction/deviation, and breast asymmetry. Use of the acronym BREAST may assist providers in remembering critical physical signs associated with advanced breast cancer, including Breast mass, Retraction, Edema, Axillary mass, Scaly nipple, and Tender breast.<sup>52</sup> While seated, the patient should press hands firmly on her hips to tighten the pectoral muscles and enhance identification of asymmetries. Not only does this allow visualization of the lateral aspects of the breast (which are often obscured by excess arm girth), but it also provides a superior view of the skin on the undersurface of the breast (inframammary ridge). In patients with rheumatoid arthritis or other conditions that prevent pressure on the hip joint, more comfortable options are available. The patient may grasp her fingertips at a level near the waistline while pulling laterally or may press her palms together while extending her arms above her head. Because the breast lies on the pectoral muscle and Cooper's ligaments are attached to the muscle and the skin, tension on the muscle will accentuate carcinoma invading these structures. Additional positions, such

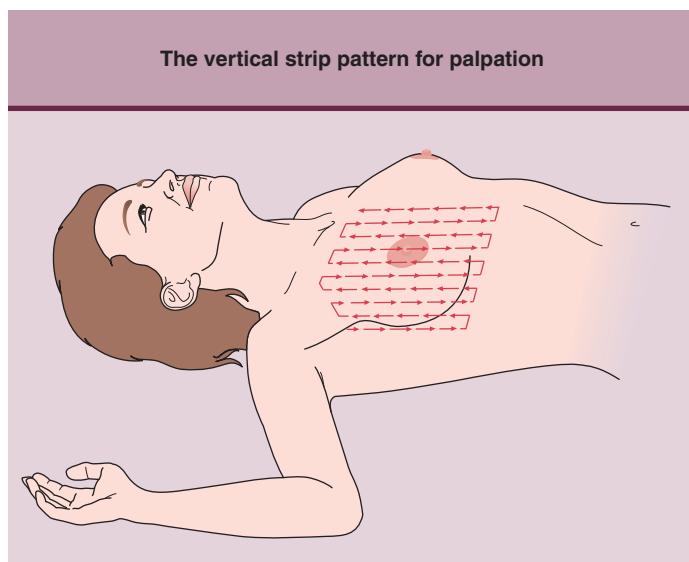

as hands overhead and at her side, may further assist identification of symmetries, but the committee did not feel they added substantively to the single position described previously. Nipple inversion is generally significant only when developed secondarily and unilaterally. If gentle manual eversion may be accomplished, the inversion is likely a normal variation.

An alternative position for breast inspection that is especially helpful in women with pendulous breasts is to have the woman lean forward while placing her hands on the practitioner's shoulders. Palpation of the breast in this position (while the breast tissue is away from the chest wall) is helpful to differentiate chest wall pain from true breast pain.

Several postures are helpful for evaluation of the axilla in both the seated and supine positions. The physician may hold the patient's elbow or wrist in his/her hand, with the patient's arm at a 90-degree angle and slightly abducted from her side (or gently across the front of the patient's torso). The opposite hand is then used to evaluate the axilla. Another position rests the patient's hand on the shoulder of the practitioner while asking the patient to relax her elbow. This allows the examiner to utilize both hands in evaluation of the axillary area. Adequate evaluation of the axilla in the supine position requires the patient's arm to be at a right angle rather than posterior to the head. For all positions, one must ensure that the patient's shoulder girdle is relaxed to allow proper assessment of the axilla. Following evaluation of the axilla, one should palpate the infraclavicular and supraclavicular lymph nodes, which are important sites for breast cancer metastasis.

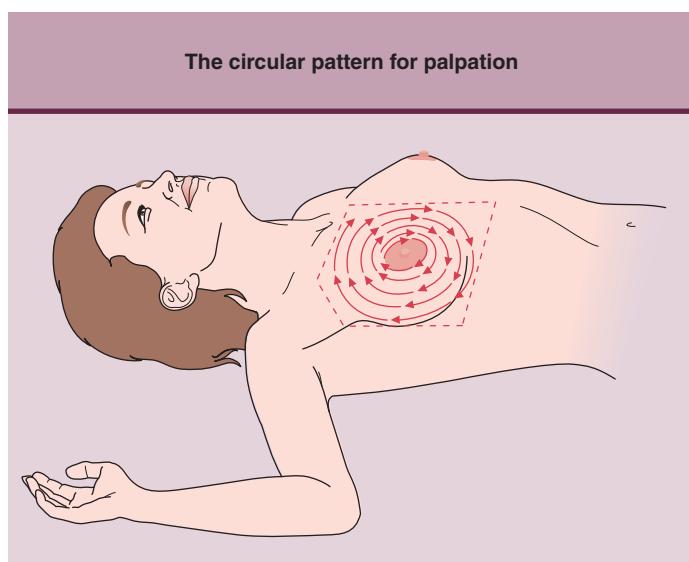

Next, the patient should be placed in a comfortable supine position with her arm on the same side as the breast being examined and raised above her head to evenly distribute the breast over the chest wall, thereby making its deeper regions more easily assessed. Care must be taken to ensure that the patient is properly gowned with only the area being examined exposed. The patient must be positioned (by tilting her hips and torso) to allow the portion of the breast tissue being examined to lie directly on the chest wall. For patients with pendulous breasts, this may require three to four positional changes for each breast. The pads of the fingers (and not the fingertips) are the most sensitive and should be used in examination. Three overlapping dime-sized circular motions are made with the pads of the middle three fingers using three levels of pressure (superficial, medium, and firm) on each  $1 \text{ cm}^2$  area of the breast. Not only will this improve mass detection, but it also prevents masking a lesion through excessive pressure. The perimeter of the examination should incorporate the midaxillary line, one to two ribs below the inframammary ridge, the sternum, across the clavicle, and through the axillary area to ensure nodal involvement in these areas is discernible.

Although the circular pattern is the most frequently used in practice to evaluate the asymptomatic patient, the vertical strip pattern has been shown to have greater thoroughness of coverage when studied during BSE.<sup>53</sup> During the vertical strip search pattern the provider will begin the overlapping circular motions in the axilla, extending inferiorly (1 cm at a time) to one to two ribs below the breast tissue. The fingers are then moved inward 1 cm and the pattern of search is extended superiorly, in a straight line, to the clavicle. This pattern is continued until the sternum is reached (Fig. 41-3). The patient's position may have

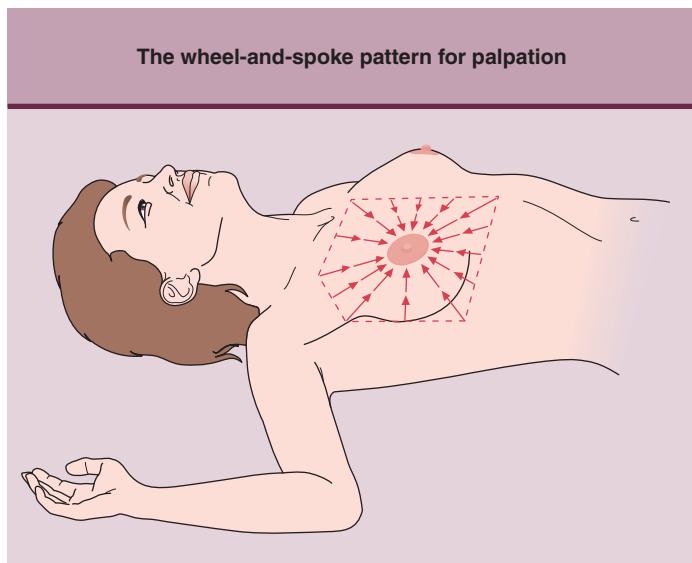

**Figure 41-3 The vertical strip pattern for palpation.**

to be changed several times during this portion of the examination to ensure that the tissue being examined lies directly on the chest wall. With the circular method of palpation, the breast tissue is examined with the pads of the fingers. The examination proceeds clockwise around the full circumference of the breast at its perimeter and gradually moves inward toward the nipple (Fig. 41-4). The wheel-and-spoke method requires radially palpating from the clavicle, sternum, and other bony margins and palpating toward the nipple (Fig. 41-5). Each method should be mastered, because they may be helpful in certain clinical and diagnostic situations, such as in patients with large breasts. Most practitioners use two hands to perform the breast examination, although a thorough and systematic use of a single hand is satisfactory (especially for an asymptomatic screening examination) and is recommended by The Mammicare method

**Figure 41-4 The circular pattern for palpation.**

**Figure 41-5 The wheel-and-spoke pattern for palpation.**

of breast examination and the consensus committee.<sup>54</sup> When using two hands, the second hand follows behind in the same pattern as the first hand, thus providing dual evaluations of each area.

If the patient presents with breast complaints, it is advisable to palpate the unaffected breast first, because it provides the physician a “tactile baseline” with which to compare the involved breast and prevents omitting lesions in the unaffected breast. Regardless of the pattern of breast examination used, the importance of using a consistent and methodical pattern of evaluation and allowing sufficient time for a thorough assessment should not be underemphasized as factors that will increase detection capabilities.

Routine evaluation of the nipple for discharge is controversial. Some authors do not recommend this as a routine portion of the breast examination in women without nipple discharge or complaints. It is well known that excessive breast manipulation may lead to a nipple discharge. If one excludes this as a routine part of the examination, one must ensure that a detailed history is obtained to rule out any nipple complaints. Patients will often have such complaints but forget to relate this information to the practitioner, particularly if she has experienced the symptoms for an extended period. In general, only spontaneous nipple discharge will render abnormal pathology.<sup>55</sup> Squeezing the nipple may actually obstruct the ductal orifice and impede any discharge from coming to the surface. Utilizing a milking technique will improve your ability to elicit a nipple discharge; slide the fingers from the outer quadrant in a clockwise fashion toward the nipple and document the location of any fluid accumulation.

Not surprisingly, the committee’s final recommendation is a call for research into particular questions that will provide a firmer foundation for decisions about the practice of CBE as a component of women’s health care.

Generally, CBE has been shown to increase the sensitivity of mammography, has fewer false-positives than mammography, and is more effective in detecting cancers in younger women than mammography. However, the impact of these advantages

on breast cancer survival and mortality is not known. Moreover, the sensitivity of CBE was estimated in a recent meta-analysis to be only 54%.<sup>56</sup> As stated, the evidence supporting the value of CBE as a method of reducing breast cancer mortality is limited and mostly inferential, because there is no definitive prospective randomized, controlled trial evidence from which to draw conclusions. Thus, current recommendations rely on existing evidence<sup>57</sup> and expert opinion.

Screening CBE targets asymptomatic women, as opposed to a diagnostic CBE, which is performed on a woman with breast complaints. In the primary care setting, screening CBE is more commonly performed than diagnostic CBE. Authors have argued, therefore, that screening CBE demands greater care and attention than diagnostic CBE because the patient’s symptoms do not guide the examination.<sup>58</sup> Strategies to improve a practitioner’s ability to detect a mass include increasing the time devoted to the examination, using a technique with variable degrees of pressure, and developing a systematic, consistent search mode. The size of the lesion, of course, also correlated with the practitioner’s ability to detect the mass.<sup>59</sup> The appropriate duration for a thorough examination is based on a variety of factors including proficiency, breast size, tenderness, lumpiness, body weight, and risk factors.

The ACS and the ACOG recommend CBE and mammography for women age 40 and older, because randomized, controlled trials and demonstration projects have established that CBE is able to detect some cancers that were not detected on mammography and, when used in combination with mammography, results in decreased mortality from breast cancer.<sup>60–63</sup> Conversely, the U.S. Preventive Services Task Force declined to recommend either for or against breast cancer screening with CBE alone and also recommend mammography with or without CBE, concluding that there is insufficient evidence to quantify the incremental benefits of adding CBE to mammography. This decision is based on the fact that the randomized, controlled trial data incorporating CBE into the screening program derives from a period predating modern breast imaging. With advancements in technology, the proportion of breast cancers not visible with modern mammography may be considerably lower than in the past.

In this increasingly litigious society, breast assessment demands careful documentation of the history, examination, and disposition of the case. A clear and legible note should record all findings from the breast examination, noting texture, size, consistency, and a detailed description (including diagrams) of abnormal and suspicious findings as well as the plan for follow-up. Although abnormal findings are very important, it is equally important to list negative findings in the medical record as well. Appropriate clinical follow-up is of utmost importance as based on patient’s age, clinical suspicion, proficiency of the provider, and other patient characteristics, including risk factors. One third of all breast malpractice cases involve inadequate chart documentation. Because 75% of successful malpractice lawsuits involve the specialties of family medicine, internal medicine and obstetrics and gynecology, the importance of documentation becomes evident.<sup>5</sup>

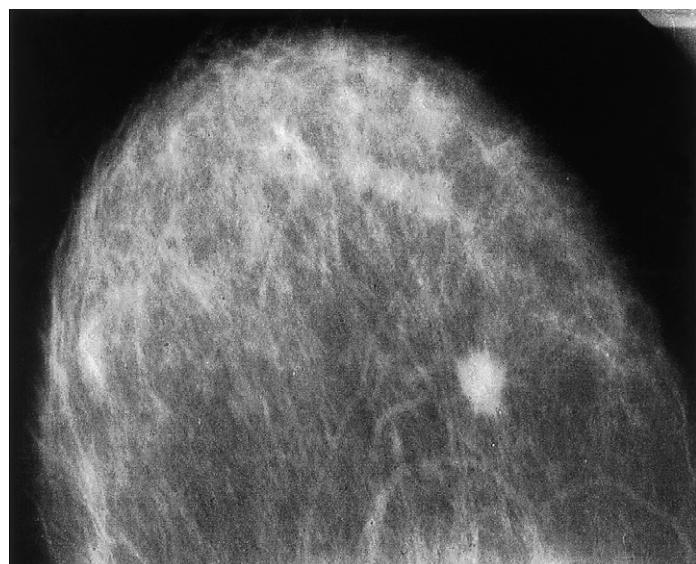

### Mammography

A German surgeon, Albert Solomon, used conventional radiography equipment to image mastectomy specimens in

1913, thus beginning the history of modern breast imaging. Dedicated film mammography was introduced by Robert Egan, a radiologist from Texas, nearly a half century later. As mammography became associated with excellent breast cancer detection rates in the 1970s, use of dedicated equipment for screen-film mammography became widely adopted by most breast imaging facilities in the United States in the 1980s.

Despite recent controversy surrounding the efficacy of mammographic screening, it remains the only imaging study that has been extensively evaluated in randomized controlled trials and has been shown, in many cases, to reduce breast cancer mortality (Fig. 41-6).<sup>64,65</sup> Eight randomized prospective trials have examined the impact of screening mammography on breast cancer mortality: the Health Insurance Plan (HIP) of New York trial, the Swedish Two-County trial, the Gothenburg trial, the Stockholm trial, the Malmö trial, the Edinburgh trial,<sup>66</sup> and the Canadian National Breast Screening Study (CNBSS) I and II trials. These trials were conducted in North America and Europe beginning in the 1960s and involving a combined total of nearly 500,000 women, with mortality as the endpoint for each study. The studies vary greatly in terms of design. Lower age limit for enrollment varied from 40 to 50 years. Some screenings consisted of the standard two-view mammograms; others, of a single view. The screening interval varied from 12 to 33 months, and the number of rounds of screening ranged from two to six. Moreover, four of the eight trials (HIP, Edinburgh, and CNBSS I and II) also included CBE as a screening modality. Meta-analysis of the results from these studies has shown a statistically significant reduction in mortality from breast cancer on the order of 25% to 30% among screened populations compared with controls after 5 to 7 years.<sup>67</sup> Based on the results of these trials, routine mammography has become established as a valuable screening tool for breast cancer detection.

The HIP of New York trial, initiated in 1963, sparked the controversy that continues today. Over 60,000 enrollees were randomized to either screening with mammography and CBE

**Figure 41-6** Typical mammographic features of malignancy are seen in this lesion, with stellate “fingers” extending into the surrounding stroma and irregular borders.

or routine health examinations; however, none received mammography alone. After 10 years of follow-up a 29% reduction in breast cancer mortality was noted in the screened group.<sup>68</sup>

An overview of randomized studies in Sweden demonstrated at least a 25% reduction in mortality in a screened population (an even greater reduction—35%—was seen in the cohort aged 45 to 46 at entry into the study).<sup>69–71</sup> Three other trials (Malmö, Stockholm, and Gothenburg) found nonsignificant reductions in breast cancer deaths of 19%, 20%, and 14%, respectively.<sup>72</sup>

Subsequently, findings of the Breast Cancer Detection Demonstration Project (BCDDP), a nonrandomized trial, demonstrated that mammography conducted in optimal surroundings had a true-positive rate greater than 90% and was significantly more accurate than clinical examination in detecting small cancers.<sup>73</sup> In both the HIP and BCDDP studies, 80% of those patients who had carcinomas detectable only by mammogram had no axillary nodal disease. In contrast, patients who had clinically detected breast cancer were more likely to have axillary node involvement (50%). When breast cancer is detected before the axillary nodes are involved, the 5-year survival rate is 97%. If there are regional nodal metastases at the time of breast cancer detection, the survival rates drops to 78.7% and more drastically to 23.3% with even more distant metastases.<sup>3</sup> In recently updated information of the Swedish two-county screening trial, Tabar and colleagues reported that 50% of screen-detected cancers were in the good prognostic category (generally stage 0 or 1, depending on histologic type), as opposed to 19% in the clinically detected group.<sup>74</sup> Earlier stage disease requires less aggressive therapy options, thus highlighting the importance of early detection.

The controversy intensified when the results of the Canadian National Breast Screening Study (NBSS), a randomized clinical trial that enrolled nearly 90,000 women ages 40 to 59, were published in late 1992.<sup>75</sup> The data did not demonstrate a reduction in mortality from breast cancer among women undergoing yearly mammography without an established baseline as compared with women who had a baseline breast examination. Updated results were reported in 2000 and 2002 for NBSS-1 and NBSS-2. Miller and colleagues reported 13-year follow-up results that compared annual two-view mammography and CBE with annual CBE only in women age 50 to 59 at randomization. The authors reported no difference in the breast cancer mortality rate between the groups and concluded that mammography provided no additional advantage compared with carefully conducted CBE. NBSS updated additional results comparing annual mammography and CBE with usual care in women age 40 to 49; after 11 to 16 years of follow-up there was no difference in breast cancer mortality in the group invited to mammography screening compared with usual care. Even before the initial paper on NBSS-1 was published, serious questions were raised by mammographers about the validity of the study results. Criticisms were leveled regarding poor imaging technique, technically unacceptable films, bias in the randomization process, short follow-up times, and inadequate interpretation of the final results. The Kaiser Permanente Study Group has also reported no mortality differences in a screened population.<sup>76</sup>

A meta-analysis of the most recent results of the eight studies showed a 16% to 24% mortality reduction associated with “an invitation to screening.”<sup>77,78</sup>

**Table 41-5**  
**Reasons for False-Negative Mammograms**

- Failure to image the region of interest
- Poor image quality
- Errors of perception
- Breast cancer indistinguishable from normal breast tissue
- Poor image quality due to overlying breast tissue

The controversy regarding screening in younger women is multifold. Reduction of mortality rates in this younger cohort as a result of screening is a subject of debate; the cost-effectiveness when compared with older women is unknown; finally, the frequency of screening intervals has become a point of disagreement among the committees that issue imaging guidelines. Authors have argued that mammograms performed in women younger than age 50 are not useful because younger women have more radiographically dense breast tissue that obscures abnormalities. By contrast, some investigators have strongly advocated yearly mammograms for all women age 40 to 49 because breast cancer is often more aggressive and faster growing in younger women.<sup>79</sup> Though the initial overview of Swedish randomized trials failed to show an advantage of screening women younger than age 50,<sup>70</sup> a follow-up study showed a 23% reduction in breast cancer mortality in women age 40 to 49.<sup>80</sup> The most recent meta-analysis, published by Hendrick and colleagues, found a statistically significant mortality reduction of 18% for women invited to screening in their forties. With increasing length of follow-up, successive meta-analyses have shown progressively greater, statistically significant mortality reductions for women age 40 to 49, regardless of whether the NBSS results are included or excluded.<sup>81</sup>

Based on an observed 45% reduction in breast cancer mortality among women age 39 to 49 offered screening every 18 months in the Gothenburg trial, Feig suggested that mortality from breast cancer could be reduced by as much as 65% if all women age 40 and older were screened annually with mammography and physical examination. The authors based their assumptions on the observed 80% compliance rate and estimated even higher mortality reductions of 75% if a 100% compliance rate could be attained.<sup>82</sup> Moreover, Michaelson and colleagues suggested a 51% reduction in breast cancer deaths with annual mammography in this age group using a computer simulation of biologic data from

cancer growth rates and metastatic spread.<sup>83</sup> It is suspected that improved screening with detection of smaller tumors will expand the population of women for whom breast-preserving surgery is an option and reduce the need for systemic therapy.

The meta-analysis of Gotzsche and Olsen, published in 2001, rekindled the acrimonious debate over the efficacy of mammography. This meta-analysis reviewed the methodologic rigor of the then seven existing randomized, controlled trials of screening mammography, deeming five trials seriously flawed and only two trials as having adequate methods. Thus, the meta-analysis based their negative findings (no reduction of breast cancer mortality with screening mammography) on only these two “adequate” trials.<sup>84,85</sup> In their assessment, the authors cited differences in the ages of women in the screened and control groups (range, 1 to 5 months) as indicative of serious flaws in randomization. However, the age distributions of the women in the two studies judged to be “adequately randomized” (Canadian and Malmö) were not known. Practitioners must realize that no study has ever been performed entirely without flaws or questions regarding methodologic validity. However, to discount and nullify the results of studies based solely on small differences in age between study groups seems unjustified. Despite the scathing articles by Olsen and Gotzsche, the National Cancer Institute in early 2002 reiterated their recommendation that women of average risk for breast cancer begin mammographic screening at age 40, and the U.S. Preventive Services Task Force lowered their recommendation for commencing screening from age 50 to age 40.<sup>86,87</sup>

Accuracy of mammography depends on a number of factors including expertise of the technician, size and density of the breast, and the location of the lesion. False-negative results occur even in the best installations (Table 41-5). Routinely, a false-negative rate of 10% to 15% is quoted; therefore, a normal mammographic examination does not rule out the presence of breast cancer. A palpable mass requires further evaluation despite a “negative” mammographic examination.

The American College of Radiology established the Breast Imaging Reporting and Data System (BI-RADS) to assist in standardization of mammography reporting (Table 41-6).<sup>88</sup> The likelihood of finding a malignancy at the time of core biopsy with findings suspicious or highly suggestive of malignancy is listed. BI-RADS category zero should not be construed as a normal report because additional testing, such as ultrasound, spot compression, or magnification views, is necessary before

**Table 41-6**  
**Breast Imaging Reporting and Data System**

Category	Assessment Category	Follow-up	Likelihood of Malignancy or Atypia
0	Incomplete	Additional imaging needed	
1	Negative	Routine (annual)	
2	Benign		
3	Probably benign	Short interval follow-up at 6 months for ipsilateral breast, followed by both breasts at 1, 2, and 3 years after initial mammogram	<3%
4	Suspicious for malignancy	Consider biopsy	9%
5	Highly suggestive of malignancy		54%

final disposition. BI-RADS has revolutionized reporting of mammography films in providing common diagnostic terminology to better compare different treatment outcomes and to assist in follow-up and treatment planning. Unfortunately, this standardization does not improve variability of mammographic interpretation or its accuracy.<sup>89</sup>

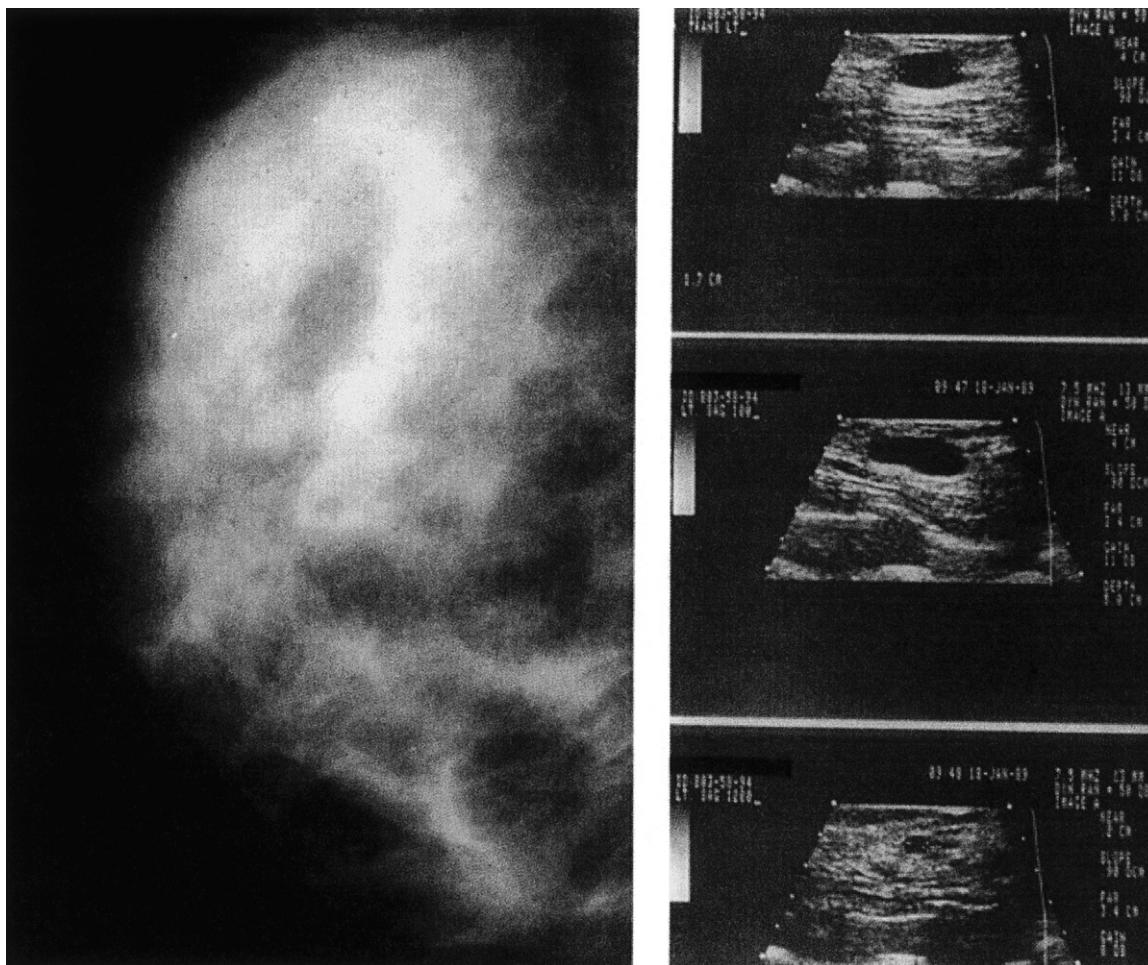

Although mammography remains the gold standard for breast cancer screening and diagnosis, it often cannot differentiate benign from malignant disease and is less accurate in patients with dense glandular breasts, with diffuse involvement of the breast with tumor, and in those taking hormone replacement therapy. From 10% to 20% of breast cancers detectable by physical examination are not visible radiographically. Furthermore, of the women who are referred for biopsy based on mammographic findings, only 20% to 40% of lesions actually prove to be malignant.<sup>90</sup> Clearly, there is room for improvement in both breast cancer detection and lesion characterization.

### Ultrasound

Ultrasonography is used routinely as an adjunct to mammography and has an established role in the evaluation of the breast; namely, to help differentiate benign from malignant lesions and cystic from solid lesions and to provide guidance for interventions. Ultrasound is also helpful where mammographic

sensitivity is decreased, such as in radiographically dense breast tissue and noncalcified masses, and for locations in the breast that may not be included in mammography because of the limitations of mammographic positioning. Ultrasound has evolved into a highly specialized imaging technique that is useful as a primary imaging modality for younger women and for pregnant or lactating patients (Fig. 41-7). More recent uses include assisting in staging of breast cancer and intraoperative evaluation of surgical margins. Although touted as an appropriate screening modality in asymptomatic women, it is currently not widely accepted for this use.

Breast ultrasound is usually performed using a linear array high-frequency transducer of 7.5 MHz or higher. In North America, breast ultrasound is most often a targeted examination (limited to the area of concern based on palpation or mammography); conversely, whole breast (or survey) real-time scanning has been more prevalent in Europe. Improper technique can affect interpretation of breast lesions. Although the Mammography Quality Standards Act of 1992 set standards for screening mammography that decreased faulty radiographic technique,<sup>91</sup> there are no such laws for breast ultrasound. However, the American College of Radiology has guidelines for imaging with sonography.<sup>92</sup> Noncompliance with the standards has been shown to result in misinterpretation of findings.<sup>93</sup>

**Figure 41-7** Ultrasound was useful in detecting a simple cyst in this patient with dense breasts and a negative mammogram in the face of a palpable mass.

Several recent studies have evaluated the relatively new sonographic techniques of spatial compound imaging,<sup>94</sup> tissue harmonics imaging,<sup>95</sup> and three-dimensional imaging<sup>96–98</sup> in breast disorders. Compound imaging of the breast has been shown to increase the conspicuousness of the lesion by enhancing soft tissue contrast, improving the definition of tumor margins, and improving evaluation of the internal architecture and surrounding distortion. Use of tissue harmonics imaging also improves lesion conspicuity and overall image quality. Lastly, three-dimensional imaging has been shown to have a higher specificity for diagnosing malignancy over two-dimensional imaging (86.9% vs. 64.1%). However, three-dimensional imaging is cumbersome and time consuming. Moreover, if a lesion has suspicious features on two-dimensional imaging, regardless of the three-dimensional results, intervention is warranted. To date these newer sonographic techniques do not appear to offer improved accuracy or diagnostic value over current modalities.<sup>99</sup>

Advocates of ultrasonography have touted its use as a screening tool for the general population. Unfortunately, ultrasound is limited as an imaging modality by its inability to detect microcalcifications, its fairly labor-intensive methodology, and its dependence on operator skill. Nonetheless, promising data is emerging indicating aptitude in certain subpopulations. Ultrasound screening in the asymptomatic population has been evaluated primarily in younger women who have mammographically dense breast tissue or are considered to be at elevated risk of breast cancer.<sup>100–104</sup> Kolb and colleagues reported a 97% sensitivity rate for the combination of whole-breast ultrasound and mammography in screening 4897 BI-RADS category II and IV cases compared with 74% for the combination of mammography and physical examination.<sup>105</sup> Kaplan reported a 0.3% cancer detection rate when sonography was used in women previously found to have a normal mammogram and CBE.<sup>106</sup> The results suggest that ultrasound may be more sensitive but less specific than mammography in this specific subset of women. Thus, ultrasound used as an adjunct to mammography detects additional cancers, but also increases the false-positive rate. The theoretical benefit of detecting and treating these mammographically occult cancers may be decreased mortality or decreased rate of recurrence. The controversies lie in weighing the benefits against the cost and assessing whether detection of these otherwise occult cancers will result in increased patient survival.

In addition to the incidentally found cancers, in three studies ultrasound detected an additional 2088 benign lesions, resulting in more biopsies. But the radiologist was not blinded to the results of the mammogram, which may impact the sensitivity and specificity of the method. The added cost, both financial and psychological (of performing the test, potentially increasing patient anxiety and discomfort, and potentially increasing morbidity from increased number of benign biopsies), must be weighed against the benefits of finding these solely sonographically detected cancers in addition to evaluating this modality's ability to reduce breast cancer mortality.

### Magnetic Resonance Imaging

Breast MRI is an emerging technology that has certain advantages over conventional screen-film mammography, including omission of ionizing radiation, improved image quality, and lack

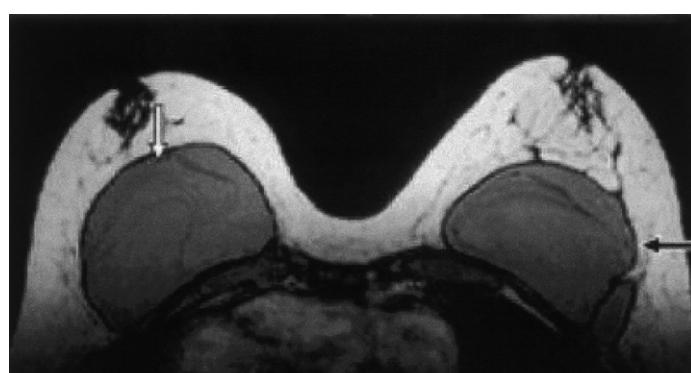

of known radiobiological hazards. However, its low capacity to detect microcalcifications, which may provide evidence of early carcinoma, severely limits its usefulness as a screening method. Although the images produced have similar criteria for the diagnosis of benign and malignant disease as does mammography, they lack sufficient resolution to identify small lesions. Moreover, there is considerable overlap between benign and malignant tissue, which significantly reduces the potential of MRI to detect early breast cancer. The cost of MRI and the time required to perform it will likely be prohibitive to its use for screening evaluation of the breast.

Breast MRI technology relies almost exclusively on the fact that tumors generate neovascularity to support their growth. Thus in theory, administration of an intravenous contrast agent such as gadolinium-diethylenetriamine penta-acetic acid (Gd-DTPA) results in rapid uptake in malignant tissue compared to benign entities. Detection of invasive breast carcinoma is extremely reliable on MRI, with sensitivity approaching 100%. False-negative results have been reported with well-differentiated, invasive ductal and lobular lesions.<sup>107</sup> Despite its sensitivity in detection of invasive cancers (especially in dense breast tissue), sensitivity in noninvasive lesions such as ductal carcinoma in situ has been reported to be as low as 40%, possibly secondary to more variable angiogenesis in these lesions.<sup>108</sup> False-positive results (seen with fibroadenoma, lobular carcinoma in situ, ductal atypia, fibrocystic changes, proliferative changes, papilloma, sclerosing adenosis, and duct hyperplasia) account for the lack of reliability of MRI, with specificities ranging from 37% to 97%.<sup>109</sup>

Currently, MRI of the breast has proven most useful in patients with proven breast cancer to assess for multifocal/multicentric disease, chest wall involvement, and chemotherapy response or tumor recurrence or to identify the primary site in patients with occult breast cancer. It has also been helpful in evaluation of silicone breast prostheses for rupture. Enhanced detection is also noted in women with dense breasts.<sup>110</sup>

### MRI Screening in High-Risk Populations

Despite its limitations, the robustness of this technique has generated considerable enthusiasm for screening women at high risk for breast cancer (usually on the basis of genetic mutations or a strong family history of breast cancer; Fig. 41-8). Although

**Figure 41-8** Magnetic resonance imaging may be helpful in evaluation of patients with dense breasts and in those with implants (arrows), as seen here.

not proven, early diagnosis as a result of intensive surveillance may decrease the rate of death from breast cancer in this select group. In a recent study of over 200 women with *BRCA1* and *BRCA2* mutations who underwent one to three annual screening examinations, consisting of MRI, mammography, and ultrasound in addition to biannual CBE, authors detected 77% (17 of 22) of cancers using MRI. This compares to 36%, 33%, and 9.1% detection using mammography, ultrasound, and CBE, respectively. All four screening modalities combined had a sensitivity of 95% versus 45% for mammography and CBE combined.<sup>111</sup> Although two of the cancers were detected by ultrasound alone, including ultrasound in the protocol resulted in more additional biopsies than MRI after the first year of screening. Whether the benefit of including ultrasound is justified in light of the high false-positive rate remains to be observed. The authors did not observe any benefit from the addition of CBE over and above the combination of the three imaging modalities.

In another similar study, the sensitivity of MRI for detecting invasive breast cancer was 79.5%, compared to 33.3% and 17.9% using mammography and CBE, respectively. The specificity was 98.1%, 95.0%, and 89.8%, respectively.<sup>112</sup> The results suggest that MRI is more sensitive than mammography in selected populations but may also have a lower specificity. Thus, these studies demonstrate that the addition of annual MRI and possibly ultrasound to mammography and CBE may significantly improve the sensitivity of screening for early detection of breast cancer.<sup>103,113</sup> Clinicians must realize, however, that there were less than 40 cancers in all studies combined.

No randomized, controlled trials are available that demonstrate a mortality benefit from employing MRI in current screening regimens for high-risk individuals. However, the preceding authors<sup>103,112,113</sup> state the finding of increased sensitivity for cancer detection in this high-risk subgroup suggests that women with *BRCA* mutations should be offered such screening. Nonetheless, clinicians must be cognizant that both sensitivity and specificity of screening MRI may be substantially less than described based on the technical capabilities at each institution using MRI technologies. For instance, if different imaging protocols are followed or if experienced radiologists and suitable technology, including the capability to perform magnetic resonance-guided biopsies, are not available, similar sensitivities may not be seen.

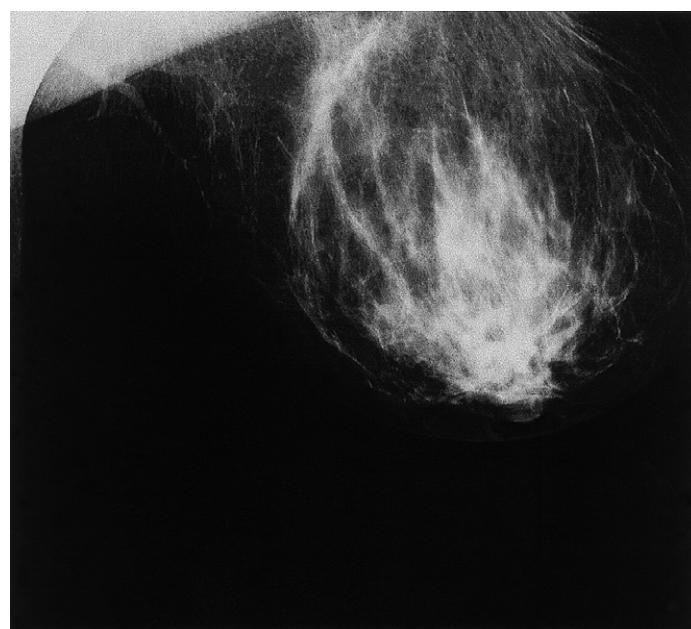

Although these results are encouraging, application of this technology to the high-risk population at large or to the general low-risk population is not advocated at this time until larger studies are performed to validate these data. Ultimately, the false-negative and false-positive rates as well as cost effectiveness need to be addressed before generalized use of MRI for screening in the average population is instituted. Currently several trials are being conducted in the United Kingdom, Europe, and the United States to assess the role of MRI in breast screening.<sup>114</sup>

#### Digital Mammography

Digital mammography is a rapidly evolving technology that has the potential to improve on and/or function as a complement to conventional screen-film mammography for the early detection of breast cancer.<sup>115-118</sup> Digital mammography is an advanced form of screening that offers detection of breast disease secondary to

improved efficiency of absorption of x-ray photons, greater contrast resolution over a larger dynamic range, especially in dense breast tissue (Fig. 41-9), and electronic archiving of breast studies. In screen-film mammography, x-ray photons cause light emission from a phosphor screen, which then imprints an image on the film emulsion. The image is then processed photographically and produces a permanent film image that is the final mammogram. In digital mammography, x-ray photons strike the digital detector and are absorbed by a phosphor material, which is then converted in an electronic (rather than a light) charge. The charge signal is then digitized and results in a computer-generated image.<sup>119</sup> Rather than an unalterable, permanent image as provided with screen-film mammography, digital mammography allows for postacquisition image processing and manipulation. Radiologists have the ability to manipulate the image by changing the brightness and contrast and to enlarge specific areas, either the entire breast or focal areas within the breast. These unique aspects of digital mammography create a significant advantage over screen-film mammography because it provides diagnostic information without exposing the patient to additional radiation (recalls) or the discomfort of further compression and has the potential to eliminate the huge film storage issue, thereby lowering ultimate screening costs associated with breast cancer screening.

In addition, these electronic images may be transmitted to radiologists for remote interpretation, thus facilitating second-opinion consultations by telemammography under near real-time circumstances. In addition, they also offer the potential value of computer-aided interpretations. *Telemammography* refers to the rapid transmission of high-quality mammographic images in digital format from one site to another. Telemammography can be used to enhance the performance of mobile mammography units by eliminating the need to transport films and may allow the off-site radiologist to monitor image quality and direct the technologist in obtaining additional views.

**Figure 41-9** Digital mammography. This allows manipulation of the image to increase mass detection. Here the image is normal.

## Gynecologic Oncology

One study screened 4489 average-risk women age 40 and older and found digital mammography to have a lower overall sensitivity (64.3%) than conventional mammography (78.6%) in detection of invasive cancer. However, despite the lower sensitivity, digital mammography does identify additional cancers not identified on conventional mammography and thus results in an incremental gain in sensitivity of 21.4%. Digital mammography was also reported to have a recall rate of 11.8%, which was significantly lower ( $P < 0.001$ ) than the recall rate of conventional mammography (14.9%).<sup>120</sup> However, incremental improvement in sensitivity will not necessarily translate into an absolute benefit, because the new technology may be selectively detecting cancers that are biologically inconsequential. In addition, characterization of morphologic details is inferior with the digital system, presumably due to reduced spatial resolution; also some lesions were not detected by digital detectors but were visualized on conventional film-screen mammography. Moreover, no statistically significant difference was found in the differentiation of benign from malignant lesions with this technique.<sup>121,122</sup>

The major limitation preventing widespread conversion to digital mammography programs is the considerable expense of purchasing the advanced equipment. Systems may cost \$500,000, compared to \$50,000 to \$70,000 for screen-film mammography units. Ancillary costs include training staff in its use and maintenance, costs of laser printers and display monitors, retraining radiologists, and redesign of imaging facilities; these must be considered in any benefit analysis.

Digital mammography imaging allows multiple images to be shifted electronically, combined into three-dimensional views (tomosynthesis), and subtracted from one another. Areas of active research include tomosynthesis, stereomammography, dual-energy subtraction mammography, and contrast-medium mammography.<sup>123</sup> Ultimately such systems may substantially improve diagnostic accuracy by reducing obscuration by overlying structures, eliminating false-positive findings, and offering assistance with interventional procedures. Dual-energy mammography may improve accuracy by rendering calcifications more obvious in dense breast tissue.

Finally, expanding on the advantages of breast MRI, which compares the differential blood flow of malignancies and normal tissue, digital mammography should be able to depict subtle differences in contrast uptake by tumors, compared with background tissue. Therefore, it may be possible to detect cancers at a smaller size than those currently detected with conventional film-screen mammography as well as improve the accuracy of detection of the extent of cancer invasion.

Major technical challenges remain, and further clinical studies are necessary to determine the actual clinical value of this modality as a probable adjunct to conventional mammography primarily in the dense breast tissue. The diagnostic mammography trial, funded by the Office of Women's Health, will be of considerable assistance in determining the true efficacy of this evolving technology. Early analysis of data revealed approximately equal sensitivity of screen-film and digital mammography. However, digital mammography was shown to significantly lower the recall rate and offer a higher true-positive biopsy rate over conventional mammography in the population studied. As with all research studies caution should be applied because preliminary results are based on only a limited amount of data.

### Computer-Aided Diagnosis

The digital computer revolution at the end of the 20th century played a significant role in advances in medical technology and automation. The field of radiology was a major beneficiary of this knowledge. The sophisticated cross-sectional imaging modalities on which radiology, and much of medicine, now relies would not be possible without high-speed computing capabilities.

The early manifestations of breast cancer can be very subtle and difficult to detect. Moreover, they are portrayed on a complex and variable pattern of normal anatomy. In addition, the limitations of conventional screening mammography are well-documented with an average false-negative rate of 10% to 15%. With the enhanced tools provided by computer assistance, radiologists now need sophisticated assistance in image review.

Sophisticated computer techniques have been applied to the interpretation of radiologic images with ever-increasing success (Fig. 41-10). Computer-aided detection is the detection of a potential abnormality by means of computer analysis of the mammogram. Computer-aided detection is aimed at reducing the false-negative rate of screening mammography by marking the perceived abnormal areas and directing the interpreting radiologist to re-review these areas, as well as reducing the false-positive rate thereby reducing the number of biopsies performed on benign lesions. Computer-aided detection is essentially a tool to prompt the radiologist to look again at potential abnormalities and is complementary to mammography. In the context of the mass screening program, it is potentially equal to another read; that is, a second reading by a computer to increase the yield of screening mammography for the detection of early breast cancer. Several investigators have demonstrated improved radiologist performance in lesion detection and characterization when a computer-aided detection system is used with digitized screen-film mammograms. The computer-aided detection enhancement of digital mammography appears highly promising; however, further clinical studies are needed to evaluate the relative efficacy of different computer-aided detection methods. Moreover, the medicolegal status of computer-aided detection is uncertain at present and needs to be clarified.

Computer-aided detection has been assessed in several studies with over 650 cancers. However, only one of these studies was prospectively conducted.<sup>124</sup> All of the studies examined the incremental value of computer-aided detection and showed improved sensitivity, but the evidence on specificity is conflicting. It is not clear to what extent the improvement compares to other maneuvers, such as having an actual second film reader.

Many image analysis algorithms have been shown to outperform general radiologists in characterizing lesions as malignant or benign, with sensitivities for malignancy as high as 100% described.<sup>125</sup> Computer diagnoses have also been observed to be more specific than radiologists when operating at the high levels of sensitivity required in clinical practice,<sup>126</sup> with one report of an 83% positive predictive value for biopsy at 100% sensitivity, better than both experienced mammographers and general radiologists taking part in the study.<sup>127</sup> Such greater specificity has the potential to aid radiologists in decreasing the number of biopsies done for benign lesions.

Overall, with these imaging techniques (ultrasound, MRI, digital mammography, and computer-aided detection) being used as screening modalities, the evidence is promising but currently

**Figure 41-10** Computers may function as a second reader to prompt radiologists.

insufficient to support their use in population screening, but would support further evaluation.<sup>128</sup>

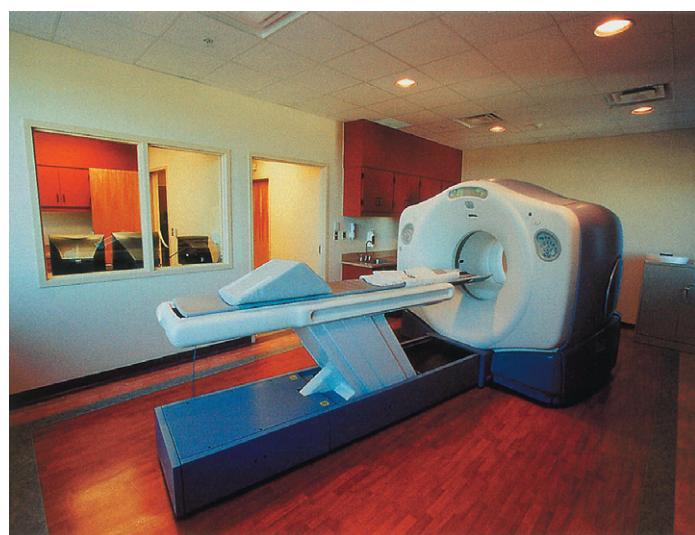

### Positron Emission Tomography

Positron emission tomography (PET) scanning is a noninvasive nuclear medicine imaging modality in existence for more than 30 years (Fig. 41-11). It is rapidly gaining acceptance in oncologic imaging especially in identifying recurrent or metastatic breast, lung, colorectal, and esophageal cancers. The technique involves injection of a short-lived positron-emitting radiopharmaceutical, fluorodeoxyglucose (FDG), which is the most commonly used agent for PET imaging, as well as the only such agent approved by the Food and Drug Administration (FDA). Decay of this

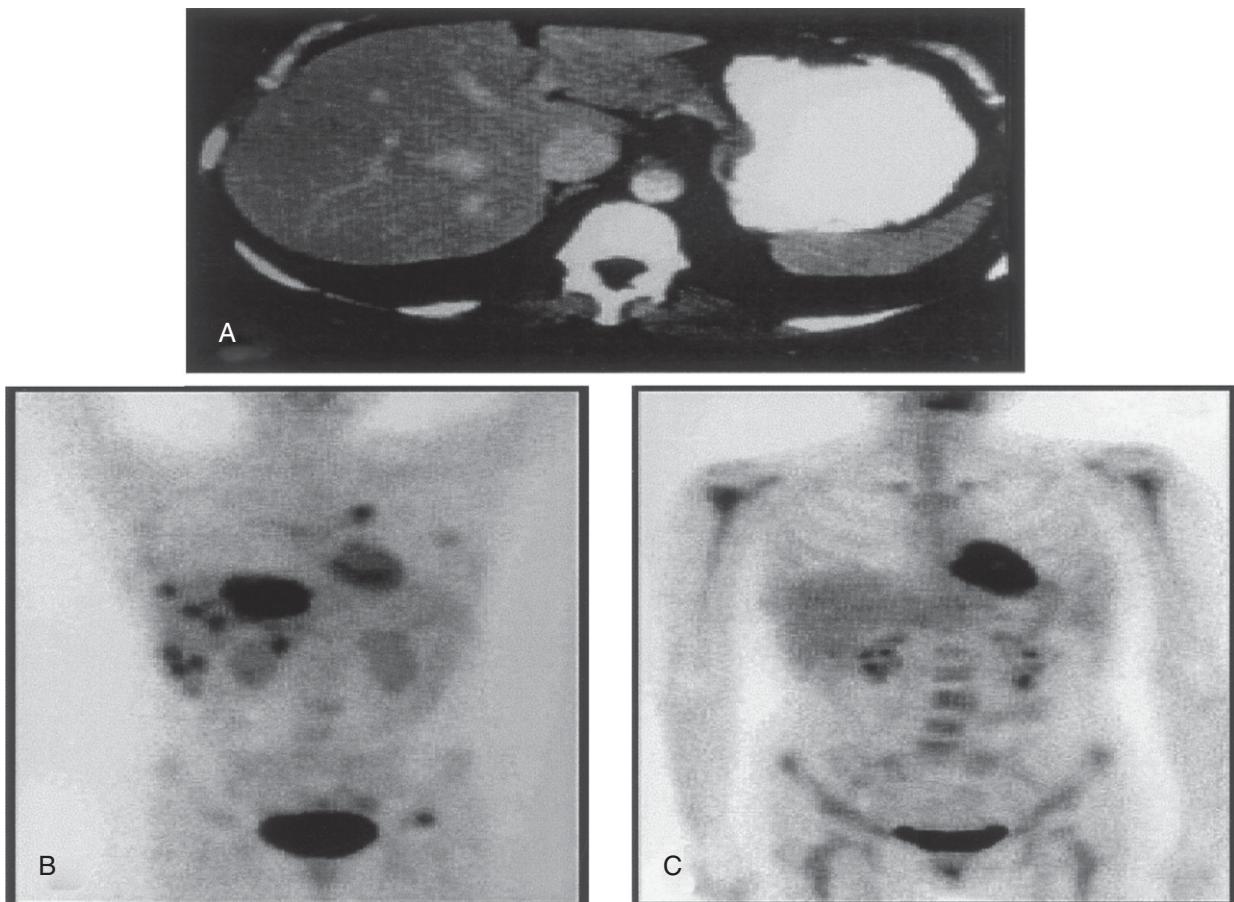

glucose analog releases positively charged energy (positron). PET imaging captures the energy emitted from the body when a positron encounters an electron. Rapidly dividing neoplastic cells display higher metabolism of glucose than the surrounding nonneoplastic cells and, hence, preferential uptake of FDG. Malignant lesions appear visually as areas of increased activity, termed *hot spots* on a PET scan.<sup>129,130</sup> Inflammation or infection may also result in increased FDG uptake, resulting in a false-positive interpretation.<sup>131,132</sup>

Other radiologic studies, such as mammography, sonography, computed tomography, and MRI, provide detailed anatomic information about the size and location of masses, but not the unique metabolic information available with PET imaging. This distinctive characteristic affords PET imaging several advantages over anatomic modalities, including possible earlier detection of malignancy, differentiation of scar or benign disease from active malignancy; detection of metastatic disease in normal size lymph nodes, detection of locoregional recurrence or distant metastases, and assessment of early tumor treatment response (Fig. 41-12). Theoretically, earlier recognition of ineffective therapy could allow a change to an alternative, hopefully more effective chemotherapeutic regimen. Thus, the information obtained from PET imaging can be used to minimize drug toxicity, the costs of ineffective treatment, and delay in initiation of more effective treatment. Studies have shown PET to be better than mammography or ultrasound in initial tumor detection and more sensitive early in the course of effective therapy, but less sensitive for detection of residual tumor measuring less than 1 cm.<sup>133</sup>

Meta-analysis of nonrandomized studies found a sensitivity of 89% and specificity of 80% for PET scans in diagnosing breast cancer. Reported sensitivities range from 80% to 96% and specificities from 83% to 100%.<sup>134–136</sup> Because of limitations of spatial resolution, the sensitivity of PET depends largely on lesion size; thus PET is not accurate in detecting lesions less than 1 cm in diameter. It is also limited in identifying ductal carcinoma *in situ*. Hence, the authors noted flaws in most of these studies,

**Figure 41-11** This multimodality CT/PET scanner may be helpful in assessing both anatomic and metabolic information about the size and location of masses.

**Figure 41-12** Here the PET scan shows evidence of subdiaphragmatic metastasis in a patient with a normal MRI scan.

the most significant of which were small study sizes, large mean tumor sizes (2 to 4 cm), and the high prior probability of malignancy in subjects studied with PET.

Positron emission tomography imaging shows promise in identifying regional nodal and distant metastases in a patient with known primary breast cancer and in monitoring treatment response. However, it is currently recommended as an adjunct to mammography rather than as an alternative technique due to high false-negative results.<sup>137</sup> PET imaging is not suitable for breast cancer screening because both the scanners and radiopharmaceuticals are expensive. Current PET scanners can cost from \$1 million to \$1.75 million. However, PET imaging may be cost effective in offering an alternative to surgery/biopsy.

Because the technology has not undergone sufficient clinical testing, its use in screening for breast cancer would not be justified. However, of particular interest is the observation that early PET findings appear to predict long-term outcome. Smith and colleagues, in a study of 30 patients with cancers larger than 3 cm in diameter, found that PET imaging after a single pulse of chemotherapy was predictive of complete pathologic response, with sensitivity of 90% and specificity of 74%.<sup>138</sup> Schelling and colleagues found similar results in a study of 22 patients. After the first course of chemotherapy, patients responding to treatment were identified with sensitivity of 100% and specificity of 85%.<sup>139</sup>

### Sestamibi Scintimammography

This technique, like PET scanning, requires cellular activity and reflects metabolic activity. Technetium-99m-sestamibi is currently the only FDA-approved scintigraphic agent for breast imaging. It is a cationic lipophilic compound that is transferred across the cell membrane into the cytoplasm and mitochondria and retained because of electrical potentials across membranes. Selective uptake by cancer cells depends on cellular perfusion, mitochondrial uptake, and transmembrane electronegativity. Similar to PET scanning, false-negative and false-positive results can occur secondary to radiobiologic potentials. Slow-growing tumors and those of low cellularity often do not demonstrate significant tracer uptake; conversely, infection, inflammation, and benign tumors such as papillomas, hyperproliferative fibrocystic disease, and fibroadenomas may show increased uptake.<sup>140</sup> In clinical study, sensitivities range from 85% to 89%, specificities from 52% to 89%, positive predictive values from 61% to 89%, and negative predictive values from 67% to 92%. Detection of lesions less than 1 cm was limited in nearly all studies.<sup>141–145</sup>

Sestamibi scintimammography is also not used as a screening tool due to its high cost and limited ability to detect lesions smaller than 1 cm. It has been studied as an adjunct to standard imaging modalities in obviating “unnecessary” biopsies, detecting axillary nodal metastases, and monitoring treatment. Several studies have shown that sestamibi scintimammography is more

specific than mammography, ultrasound, or MRI of palpable masses<sup>146–149</sup>; however, the negative predictive value remains insufficiently high to replace biopsy.

The cost effectiveness of these newer modalities remains to be evaluated, but all have the potential to significantly advance the diagnosis, and management of women with breast cancer. Research continues on other technologies. A National Institutes of Health–sponsored project is reviewing a laser-imaging system, which may provide more accurate views of breast tissue. Initial reports showed the system was able to detect some growths that were not seen on traditional film-screen mammography. In addition, this system was successful in predicting whether tumors were benign or malignant, which could lead to a reduction in the huge number of unnecessary biopsies performed.

### Ductal Lavage

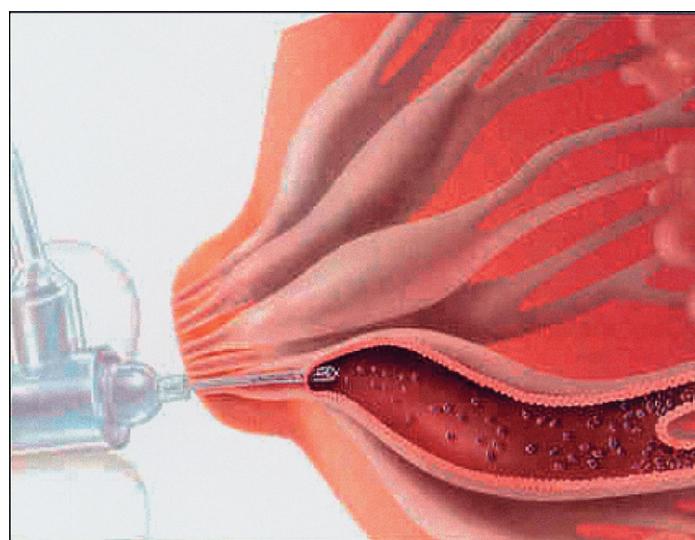

The initial fervor over ductal lavage, which obtains tissue to check for initiation of the preneoplastic process, appears to be declining swiftly among the clinical community. Dooley and colleagues were successful in performing ductal lavage in 92% of women yielding nipple aspirate fluid<sup>150</sup> (Fig. 41-13). This and other risk assessment procedures have been mistaken as screening for cancer rather than screening for preneoplastic processes as labeled. Sensitivity in detecting breast cancer is low<sup>151</sup>; however, 20% of women in one study were shown to have pre-cancerous or cancerous changes.<sup>150</sup>

Breast carcinoma is thought to have its earliest expression in the epithelial cells lining the terminal ductal lobular units that comprise the ductal system of the breast,<sup>152,153</sup> yet until recently, we have not had direct access to this area for pathologic correlation other than by blindly removing tissue by core biopsy or fine-needle aspiration. Ductal lavage is a safe, minimally invasive office procedure performed on women considered to be at high risk for breast carcinoma. Ductal lavage is used to collect breast ductal epithelial cells in the terminal ductal lobular units for cytologic analysis to provide further risk stratification. In a clinical trial of 507 high-risk women, cells collected through

ductal lavage allowed clinicians to detect the presence of pre-cancerous and cancerous changes in 20% of the women. Each participant in the study had a normal mammogram or physical examination within 1 year of enrollment.<sup>150,154</sup> Moreover, this procedure yielded fewer acellular samples compared with nipple aspirates (22% vs. 73%). The presence of these changes correlated with a fivefold to 18-fold increased risk of developing breast cancer, depending on family history and the patient's risk of breast cancer development as determined by the Gail model.<sup>8,155–157</sup> The procedure involves the insertion of a microcatheter approximately 1.5 cm into the nipple orifice after topical anesthesia, lavaging the cannulated ductal system with normal saline, and analyzing the collected lavage effluent for the presence of normal, atypical, or malignant breast ductal cells.

Ductal lavage may not only be a helpful adjunct to determine which high-risk women require closer, more active management, but also may be used to track cell status in particular ducts over time. Because breast cancer may have insidious progression over time and can be present nearly 6 years before earliest detection on mammography, availability of this technique is surmised to provide practitioners with a tool to detect precancerous and cancerous breast cells before they become imageable, palpable cancers, thus allowing closer surveillance, surgical intervention, or chemoprevention. Studies in patients undergoing mastectomy has shown ductal lavage to have low sensitivity for carcinoma *in situ* in breasts containing invasive carcinoma.<sup>158</sup> Thus patients should have continued close follow-up. This procedure may be considered for women with a prior history of breast cancer and women at high risk for development of breast cancer, as defined by Gail Index score, family history, *BRCA* mutation, or previous benign breast biopsies.<sup>16</sup> Many institutions utilize other combinations of epidemiologic risk factors to determine eligibility.

Although reports of benefit in reducing the incidence of breast cancer from pharmaceuticals and surgery are encouraging, chemopreventive therapy and prophylactic surgery are expensive and have inherent side effects. Moreover, the only validated risk assessment model (the Gail model)<sup>159,160</sup> was used clinically primarily in white women who underwent annual mammography screening. Although the Gail model is used to determine eligibility for these risk management options, it has been shown to be woefully inadequate in detecting a particular woman's risk for the development of disease, although it is helpful in population risk assessment.<sup>161–168</sup> Conversely, ductal lavage and similar procedures may be a reasonable option for further evaluation of patients who already have clinical evidence of increased breast cancer risk, but for whom additional evidence is sought to facilitate decisions regarding these therapies. The finding of cytologic atypia on ductal lavage may provide a woman with additional information regarding her individualized risk of developing breast cancer. This information may assist the woman and her physician in weighing the risks and benefits of hormone replacement therapy, antiestrogen therapy (tamoxifen and possibly other selective estrogen receptor modulators or estrogen receptor down-regulators in the near future) and, in very-high-risk women, prophylactic surgery. In a study from the Memorial Sloan-Kettering Cancer Center, Port and colleagues found that fewer than 5% of high-risk women counseled about tamoxifen therapy accepted the chemoprevention option, whereas 61%

**Figure 41-13 Schematic diagram of the ductal lavage procedure to access intraductal cells.** (Courtesy of Cytec Corporation and affiliates.)

remained undecided and 35% declined definitely.<sup>169</sup> Detection of atypia seems to be a more convincing element in motivating high-risk women to pursue chemoprevention, as documented by Vogel and colleagues.<sup>170</sup> Recent assessment of women screened for participation in the Study of Tamoxifen and Raloxifene (STAR) trial revealed that overall, 21% of risk-eligible women agreed to randomization. For the subset of risk-eligible women who also had atypia, however, 36% agreed to randomization.<sup>170</sup>

Ductal lavage has also been studied in conjunction with intensive screening utilizing biannual CBE, annual mammography, and breast MRI in a high-risk cohort. Breast MRI identified high-grade ductal carcinoma *in situ* and high-risk lesions that were missed by mammography. Ductal lavage detected cytologic atypia in an individual with a normal MRI and mammogram. Additional research is necessary not only to determine the sensitivity and specificity of this method but also to determine whether the identification of malignant and high-risk lesions at an early stage will affect breast carcinoma incidence and mortality.<sup>171</sup>

### **Random Periareolar Fine-Needle Aspiration**

Fine-needle aspiration is a simple, fast, sensitive, and cost-effective method for evaluating breast lesions whereby tumor markers such as DNA ploidy, G-actin, p53, *HER2/Neu*, and *c-myc* can be analyzed and quantitated.<sup>172</sup> Multiple biomarker analysis may be helpful in individual risk assessment of breast cancer development.<sup>173</sup> Random periareolar fine-needle aspiration is a modification of fine-needle aspiration and has been touted as a technique to obtain breast tissue repeatedly over time for risk assessment in a high-risk cohort or for measurement of response to preventive interventions. Fabian and colleagues found this procedure to be inexpensive, and noted that it could be performed repeatedly with minimum morbidity.<sup>174,175</sup> In addition the majority of samples are cellular in these high-risk premenopausal and postmenopausal women in contrast where even in experienced hands approximately 40% of nipple aspirates are acellular.<sup>8,176</sup>

During this procedure, women at increased epidemiologic risk on the basis of family history of breast cancer, a prior breast cancer, or precancerous biopsy undergo a variation of the routine fine-needle aspiration procedure. Under local anesthesia, a 21-gauge needle attached to a 10- to 12-mL syringe is used to aspirate in eight different positions per breast at the 3:00 and 9:00 locations. Tissue is probed deeply to sample the terminal lobular-ductal units. Authors were able to predict those women who later developed cancer based on evidence of hyperplasia with atypia in the initial periareolar fine-needle aspiration and a 10-year Gail projected probability of developing breast cancer.

Ductal lavage has obvious advantages over periareolar fine-needle aspiration in that it is less invasive and enables localization of atypical or malignant cells to an individual ductal structure, whereas random periareolar fine-needle aspiration evaluates a pooled sample of multiple aspirates. An NIH-sponsored trial is under way to compare nipple aspirate versus ductal lavage versus periareolar fine-needle aspiration and determine the sensitivity, specificity and positive predictive value of each method. There are currently insufficient data to recommend either procedure as an independent screening modality or in combination with screening mammography.

## **THE FUTURE**

Future advances in technology that are presently being studied could revolutionize screening for breast carcinoma. An experimental breast cancer vaccine may eventually help treat or prevent nearly 80% of breast cancers.<sup>177</sup> The vaccine is based on a novel breast cancer-associated antigen, mammaglobin-A, which is expressed in 80% of breast tumors and amazingly absent (or found at only low levels) in normal breast cells. Administration of the vaccine to mice bred to have breast cancer resulted in more than a 30% reduction in tumor volume. The vaccine is thought to work by stimulating the immune system to attack breast cancer tumor cells.<sup>178</sup> Clearly, further research is needed to avoid potentially dangerous side effects in normal breast tissue.

Proteomic and genomic technology is rapidly advancing with definition and refinement of biomarkers that vary with level of risk and response to preventive interventions. Gene profiles and microarray technology have detected several genes and proteins that define specific cancer biology. These markers, which include mammographic breast density, serum insulin-like growth factor-1 and its binding protein, insulin-like growth factor-binding protein-3, serum levels of estradiol and testosterone in postmenopausal women, and breast tissue markers<sup>174,175</sup> have been biologically and statistically significantly associated with cancer development. Thus techniques have been developed to quantify and standardize endpoint markers to be used to refine risk estimates based on epidemiologic models and to measure response to prevention interventions.

## KEY POINTS

- Carcinoma in situ is usually asymptomatic.
- Careful inspection and biopsy of suspicious lesions is central to managing carcinoma in situ.
- Treatment of carcinoma in situ should be guided with an aim to preserve anatomy and function.
- Lesion size and depth of invasion predict for nodal involvement in invasive vulvar cancer.
- Nodal spread is predictive of survival.
- An adequate surgical margin is essential to prevent local recurrence.
- Draining inguinal-femoral nodes must be treated unless there is less than 1 mm of invasion.

Vulvar cancer is a relatively rare neoplasm that accounts for less than 5% of all gynecologic cancers. Because of the relatively small number of cases, it has taken considerable time to accrue significant series of patients and analyze the outcomes of prior therapies to see what effect they may have had on survival and complications. Therefore, changes in therapy have been slow to be instituted relative to other gynecologic cancers.

From 90% to 95% of vulvar cancers are squamous cell carcinoma arising from the native epithelial covering of the vulva (Table 42-1). Other malignant lesions that can arise along the vulva include melanoma, Paget's disease of the vulva, and adenocarcinomas arising from the glandular components of the epithelium and sarcomas arising from the mesenchymal component of the vulva. These cumulatively account for less than 10% of invasive vulvar neoplasms. This chapter therefore focuses on the natural history, diagnosis, and treatment of squamous cell carcinoma of the vulva.

## PREINVASIVE DISEASE

### Epidemiology, Risk Factors, and Pathogenesis

Previously, it was felt that lichen sclerosus et atrophicus was the precursor lesion to invasive vulvar cancer. Retrospective analyses of patients treated for vulvar cancer in the mid-1900s found that lichen sclerosus was adjacent to most of the vulvar cancers resected, leading to acceptance of the conclusion that lichen sclerosus was indeed a precursor lesion to invasive squamous cell cancers. Several clinicians advocated total vulvectomy for lichen sclerosis to prevent the development of invasive cancer.<sup>1</sup> However, it has been found that this conclusion was far from true, in that only a small percentage of patients who had lichen sclerosus actually went on to develop invasive vulvar cancer. Today, treat-

ment of lichen sclerosus aims to control symptoms while carefully observing for the development of new lesions, which might indicate invasive cancer in a small minority of patients.

Although not very commonly seen in the United States, several infectious lesions can cause epithelial abnormalities to arise within the overlying dermis and eventually develop into squamous cell cancers of the vulva. Most notably, this has been seen with lymphogranuloma venereum and granuloma inguinale. These disease processes need to be considered, especially when evaluating and treating patients from tropical environments.

Squamous cell carcinoma in situ is by far the most common precursor lesion for squamous cell carcinoma of the vulva in the United States and other developed countries at this time. The incidence of carcinoma in situ did appear to increase significantly during the latter half of the twentieth century, but this increase was not accompanied by any significant change in the incidence of invasive squamous cancers of the vulva. One possible explanation may be that not all cases of carcinoma in situ are capable of progressing into invasive squamous cell cancer. This phenomenon may also be partly due to the increased recognition of the disease as clinicians became aware of it and actively evaluated patients for its presence. Because patients with squamous cell carcinoma in situ are largely asymptomatic, the lesions may go unnoticed in the absence of a careful systematic search of the vulva.

Although the vulvar epithelium is directly contiguous with the vaginal epithelium and squamous epithelium of the cervix, these tissues are not necessarily identical in their response to external stimuli. It has been seen that, as with cervical lesions, an increase in cigarette smoking has accounted for an increase in the incidence of squamous cell lesions involving the vulva.<sup>2</sup> However, although almost all cervical cancers appear to be related to infection with human papillomavirus (HPV), studies in squamous lesions involving the vulva have shown various degrees of association with HPV. One possible explanation may be that two distinct forms of this disease occur. In younger patients, multifocal lesions are more common, even multiple confluent lesions that may cover the vulva; these are more commonly associated with HPV (Table 42-2). However, in older

Carcinoma in Situ—Two Different Diseases

Age	No. of Patients	Type of Lesion			
		Multifocal	Unifocal	Diffuse	Unknown
<30	12	66%	33%		
30–50	33	26%	70%	2%	2%
>50	36	25%	44%	11%	20%

From Benedet JL, Murphy KJ: Squamous carcinoma in situ of the vulva. Gynecol Oncol 1982;14:213.

patients, carcinoma in situ tends to be more unifocal, the lesions are less condylomatous in appearance, and lesions are far less likely to be associated with HPV infection.<sup>2,3</sup>

### Clinical Features

As previously discussed, most patients with carcinoma in situ of the vulva will be asymptomatic. These patients are largely discovered as part of a routine examination or for follow-up of prior squamous disease that involved the upper portion of the genital canal. The most common symptom seen in association with squamous carcinoma in situ is pruritus (Table 42-3). The lesions are usually quite pruritic; patients occasionally develop ulcerations and bleeding secondary to scratching at the lesions. Bleeding, however, is relatively unusual with squamous carcinoma in situ unless scratching has led to disruptions of the epithelium. If patients do present with bleeding as their main complaint in the absence of pruritus, the practitioner should be concerned with the possibility of an invasive lesion rather than carcinoma in situ. Some patients will occasionally notice a lump or growth due to the condylomatous nature of their lesions or the development of plaque-type areas in lesions that are hyperkeratotic.

The clinical appearance of lesions on the vulva is highly variable. Lesions may be multiple; this is more commonly the case in the younger patient population. In the older patient population, a single lesion is more frequently seen. The different appearance of these lesions has led in the past to the use of different terms to describe the various clinical appearances of carcinoma in situ, such as Bowen's disease or erythroplasia of Queyrat. The difference in appearance of the lesions is due to

**Figure 42-1** Carcinoma in situ. Note the pigmented lesion involving the perineal body.

differing histologic architecture and not to any difference in biological behavior. Multiple lesions are more often condylomatous in nature; this type is often associated with HPV infection. Lesions can be hyperpigmented due to excess deposition of melanin within the basement membrane of the epithelium (Fig. 42-1). Other lesions may appear thickened and white or hyperkeratotic due to an excess of keratin deposition in the superficial epithelial layers (Figs. 42-2 and 42-3). The absence of keratinization accompanied by a lack of melanin within the basement membrane and the presence of parakeratosis accounts for the red appearance of other lesions (see Fig. 42-2). All of these different lesion types are characterized by a lack of

**Figure 42-2** Carcinoma in situ. Multiple white hyperkeratotic and multiple red lesions are present.

**Table 42-3**  
In Situ Disease: Symptoms and Clinical Appearance

Symptoms
Pruritus
Bleeding
None; discovered on follow-up for prior cervical disease

White, red, or hyperpigmented

**Figure 42-3** **Carcinoma in situ.** White, hyperkeratotic lesions in the interlabial fold.

maturity of the epithelial cells going toward the surface layer; with full thickness involvement by immature cells, the classic picture of carcinoma in situ is seen.

### Diagnosis

The key to diagnosis is careful inspection of the entire vulvar epithelium. The interlabial folds and other skin creases must be fully opened and exposed to evaluate all skin surfaces. Additionally, the perineal body itself should also be carefully examined, because this disease affects squamous epithelium and can extend into the anal canal up to the dentate line. Some have advocated the use of stains as an aid in detecting in situ lesions. However, nuclear stains such as toluidine blue can be associated with false-positive results. If excoriations or breaks in the skin are present, these areas will also produce positive results. Additionally, in hyperkeratotic areas, because the stain is unable to penetrate to the cells, false-negative results are obtained. The use of a dilute acetic acid and magnification, i.e., vulvoscopy, can also yield false positives and false negatives for many of the same reasons. Therefore, careful close inspection is the most important element in diagnosis. Confirmation must be obtained by biopsy of any suspicious skin areas, which is usually easily accomplished through the use of intradermal lidocaine for local anesthesia and the use of a 4.0 or 6.0-mm Keyes biopsy punch. The punch biopsy should be taken down into the immediate subcutaneous tissues, but because the practitioner is looking to determine intraepithelial disease or the presence of early invasion, it is not necessary to go deeper into the subcutaneous tissues, which can lead to significant hemorrhaging. With a small core biopsy limited to the immediate subcutaneous tissues, hemostasis can usually be obtained through the use of silver nitrate stick or, at most, some ferric subsulfate solution and local

pressure. It would be unusual to need to resort to a suture at the biopsy site.

### Treatment

Therapy for in situ carcinoma of the vulva can generally be thought of as falling into one of two techniques<sup>3</sup> (Table 42-4). These consist of either excisional therapy or use of topical agents, such as 5-fluorouracil or trichloroacetic acid, or other techniques such as laser vaporization or the ultrasonic surgical aspirator.

Excisional therapy consists of wide local excision of single lesions or several lesions in the case of extensive multifocal disease. This therapy may even necessitate the use of a skinning vulvectomy, the removal of all of the involved vulvar skin down to the level of the dartos fascia but sparing the subcutaneous tissues and thereby preserving the architecture, and through the use of a split-thickness skin graft to give an aesthetic result.

Topical agents or other destructive techniques are alterations that may be used when the risk of invasion is low. With any of these methods, an attempt should be made to obtain an approximately 1.0-cm margin around the lesions to prevent local recurrence.

Choice of therapy will often depend on the patient's age, the desire to maintain as normal an anatomic appearance as possible, and the location of the disease. Disease in the nonhair-bearing areas, where the skin is quite thin, is readily amenable to laser vaporization and other destructive techniques. With minimal destruction of the underlying dermis, healing is rapid and usually cosmetic. However, in hair-bearing areas, where the epithelial abnormality can extend into the hair follicles and therefore into the deeper subcutaneous tissues, use of these destructive therapies necessitates penetration into the deeper levels of the dermis, which may result in scarring that actually produces a worse cosmetic outcome than excisional therapy. Where concern about the possibility of underlying invasive cancer exists, it would be best to defer to excisional therapy to allow complete histologic evaluation of the entire specimen and margins. Chafe and colleagues reported on the risk of invasion in patients treated with wide local excision.<sup>4</sup> In a group of 69 patients thought to have intraepithelial disease only who underwent wide local excision, invasive disease was found in 13 patients, or 18.8%. In eight of the 13 patients, this was found to be micro-invasion of less than 1.0 mm. However, four patients had invasion greater than 1.0 mm; an additional patient was found to have a verrucous carcinoma of the vulva.

Laser vaporization.  
CUSA.

#### Excisional

Wide local excision.  
Skinning vulvectomy with or without split-thickness skin graft.

With therapy, approximately 90% of patients will be rendered disease-free after a single therapeutic session. Regardless of the mode of therapy employed, approximately 10% of patients will "recur" and therefore must be subject to long-term follow-up. These recurrences most likely are actually the occurrence of new disease in an adjacent area of skin, especially in those patients who had adequate margins of resection at therapy. Under close follow-up, it is unlikely that patients will develop invasive disease. A previous report by Buscema and colleagues, which studied 102 patients followed for up to 15 years, revealed that only 4 patients subsequently developed invasive disease under observation after therapy.<sup>5</sup> Of these patients, 2 were postmenopausal, and two were receiving immunosuppression therapy for autoimmune diseases. It would appear that in those patients with lowered immunity, increased surveillance for the possible development of invasive disease is warranted.

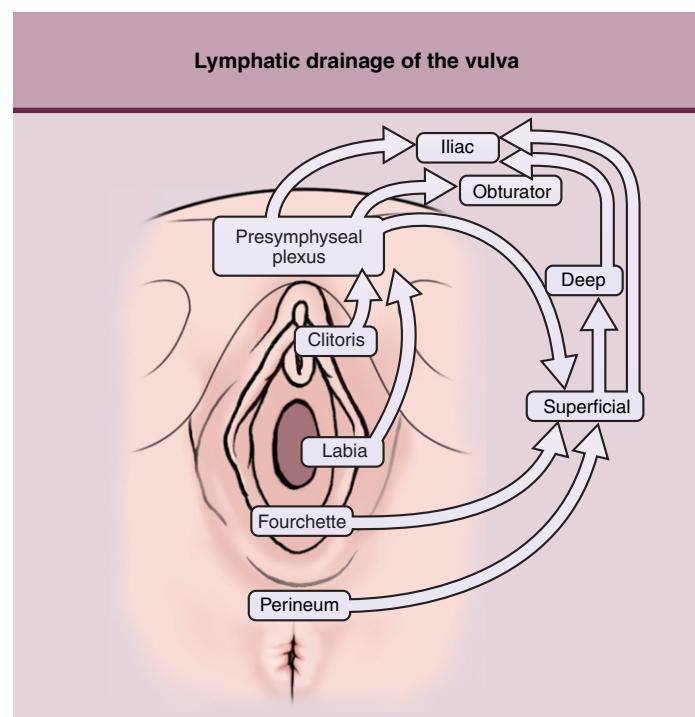

## INVASIVE VULVAR CANCER

### Natural History and Pattern of Spread

Stanley Way addressed the American Gynecologic Society in the early 1960s, stating that failure to adequately treat vulvar cancer was due to incomplete removal of the primary lesion and/or a totally inadequate attack on the draining lymph nodes. As a result of his work along with that of others, standard care for vulvar cancer became an en bloc radical vulvectomy with bilateral inguinal-femoral lymphadenectomy and bilateral pelvic lymphadenectomy to completely excise the primary lesion, the skin at risk for recurrence, and all of the draining lymph node groups. The large skin excisions were also necessary due to the large size of the primary lesions and in many cases the associated clinically positive inguinal nodes that were commonly seen at the time. However, as experience accumulated and large series of cases were carefully examined, the natural history of the disease along with its mechanisms of spread became clearer, eventually allowing for improvements in the care and management of patients with vulvar cancer.

The primary mechanism of disease spread is via direct extension. The lesions tend to expand concentrically along mucosal surfaces and by invasion into the dermis and then deeper underlying structures. As lesions expand, they may also encroach on adjacent structures, notably the urethra, vagina, or anus; this is reflected in the staging system, with increasing stage being assigned, based first on the overall size and then on involvement of adjacent structures.

Secondary spread of vulvar cancer occurs via the draining lymphatics (Fig. 42-4). The vulvar skin actually migrates during fetal development from the lower abdomen into its final position. The primary lymphatic drainage follows along the external pudendal vessels to the inguinal lymph nodes. This group of nodes, also commonly referred to as the inguinal-femoral nodes, consist of the first level of lymph nodes, which are those above the cribriform fascia, commonly referred to as the superficial inguinal nodes (Fig. 42-5), and the femoral lymph nodes, which are located below the cribriform fascia and medial to the femoral artery and overlying the femoral vein. Lymphatic drainage then proceeds cranially through the inguinal ligament to the ipsilateral pelvic lymph nodes. An extensive anastomotic network surrounds the midline structures, theoretically allowing

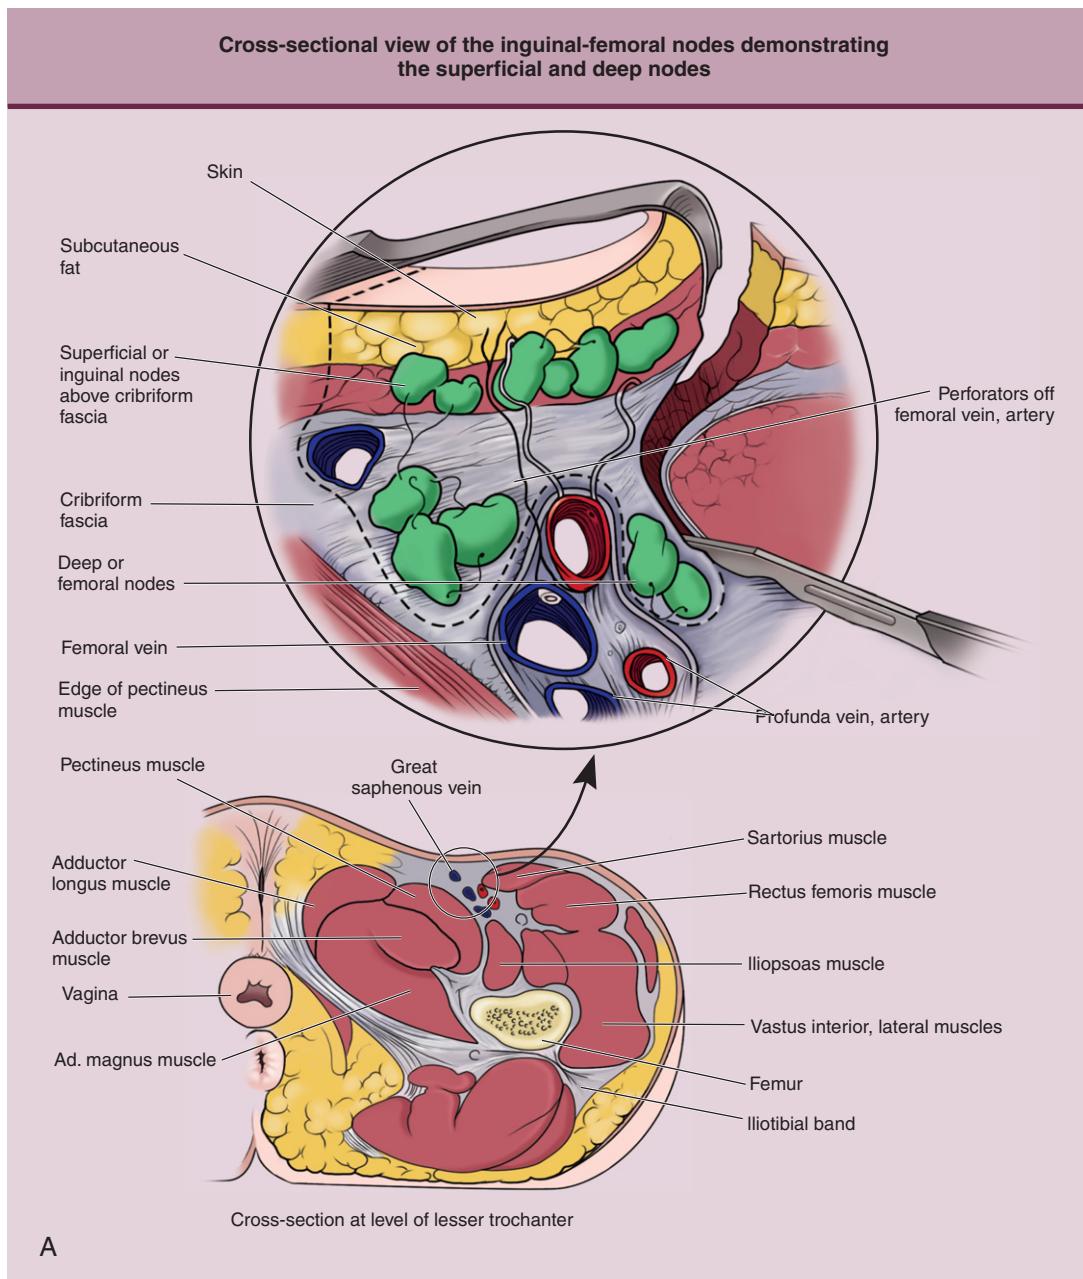

**Figure 42-4 Potential lymphatic pathways from the vulva.**

(From Plentl AA, Friedman EA: Lymphatic System of the Female Genitalia. Philadelphia: WB Saunders, 1971, p. 25 with permission.)

for drainage from either side to the contralateral inguinal-femoral lymph node group. However, extensive clinical experience has demonstrated that involvement of the contralateral nodes is extremely rare, unless there is primary involvement of the draining ipsilateral inguinal-femoral lymph nodes. Lesions that involve or approach the midline can, however, spread to either side with equal ease. Additionally, although it is theoretically possible for direct spread to occur to the pelvic lymph nodes along the dorsal artery and vein and internal pudendal vessels, which are direct branches of the anterior division of the internal iliac vessels, clinical experience has also found that direct involvement of the pelvic lymph nodes rarely occurs, even with midline lesions, unless there has been initial involvement of the inguinal-femoral lymph nodes on either side.

The current staging system for vulvar cancer utilizes surgical findings that reflect the spread pattern of the disease as it is now understood (Table 42-5). Stage increases based on the increasing size of the lesion and the involvement of adjacent structures. Stage also increases with any inguinal-femoral lymph node involvement, with further increases for either bilateral inguinal-femoral node involvement, or secondary pelvic lymph node involvement. In addition, stage increases with distant disease spread, which is rarely seen.

Various clinical parameters have been held out as prognostic factors for patients with carcinoma of the vulva. These have included size of the lesion, depth of invasion of the lesion, location, and status of the inguinal-femoral or pelvic lymph nodes.<sup>6-9</sup> When a factor is designated as prognostic, it is important to consider what it is prognostic for (Table 42-6). Although there is at least indirect correlation with all of the above factors and risk of recurrence or death, the most important factor in

**Figure 42-5 A, Anatomic landmarks for the inguinal-femoral nodes.** The node lies medial to the sartorius, lateral to the adductor longus, and above the pectenous muscles.

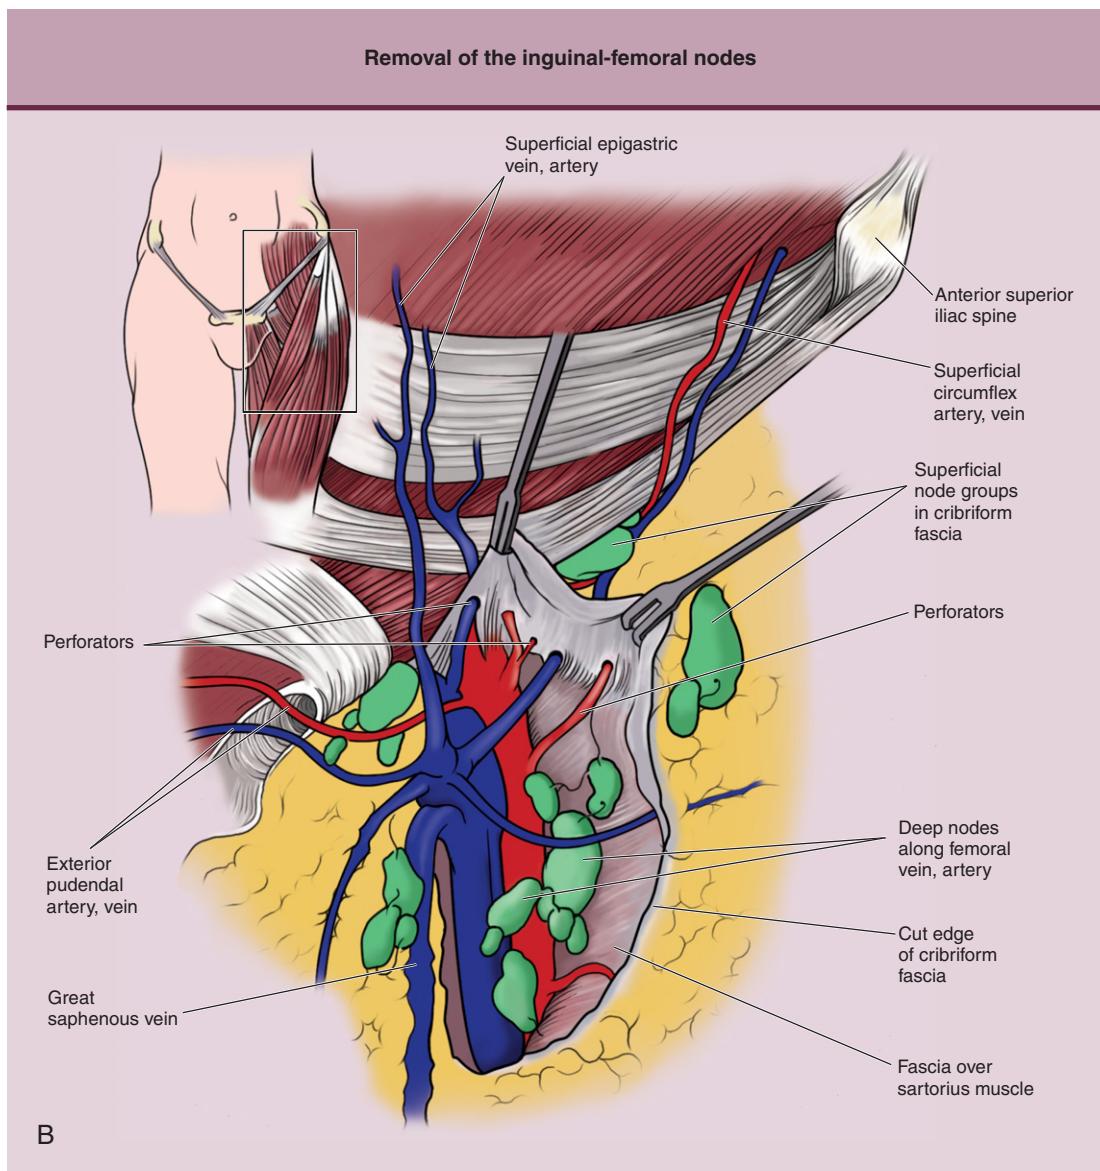

*Continued*

predicting survival is the status of the inguinal-femoral lymph nodes. Additionally, the number of involved nodes is also highly predictive for survival. Patients who have more than two positive inguinal-femoral nodes show a marked decrease in survival relative to those patients with two or fewer positive nodes. The other clinical prognostic factors are indirectly associated with risk of recurrence; increasing size, increasing depth, and lesion location (bordering or involving the clitoris, urethra, or anus) may be associated with an increased risk of spread to the inguinal-femoral nodes.

The primary draining node group, the ipsilateral inguinal-femoral nodes, predicts for the possibility of spread to the pelvic

node group or to the contralateral groin. Patients with two or more positive nodes are more likely to have microscopic spread to the other node groups.<sup>10</sup> As a result of this further spread along the lymphatic chains, they are also more likely to develop pelvic recurrences or distant disease that is unlikely to be amenable to further salvage therapies currently available (Table 42-7).

With the knowledge that the status of the inguinal nodes predicts not only the possibility of metastasis to the pelvic lymph nodes, but also an increased risk of pelvic recurrence and distant disease, the value of pelvic lymphadenectomy as a therapeutic procedure was questioned. This is especially important in light of the fact that additional node dissection can result in severe

**Figure 42-5, cont'd B, View of the cribriform fascia separating the deep from the superficial nodes.** The deep nodes can be seen around the femoral vessels.

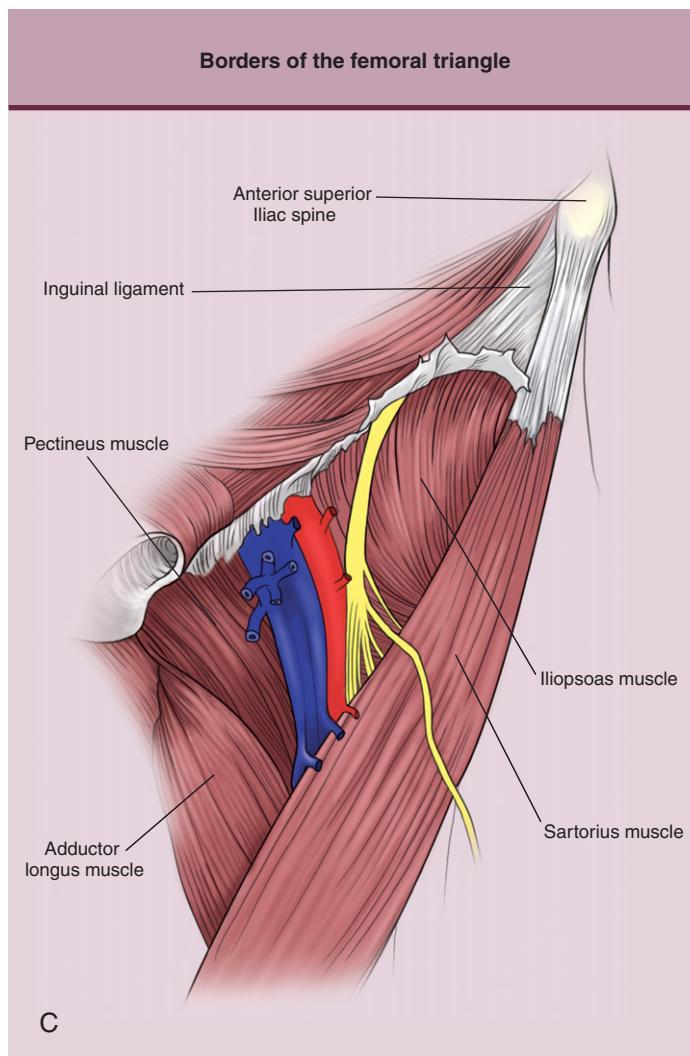

increased morbidity, such as lymphedema and lymphangitis, added operative time, and carries the immediate risk of the surgical procedure itself. The Gynecologic Oncology Group (GOG) conducted a prospective randomized trial to evaluate the role of pelvic lymphadenectomy versus postoperative radiation therapy to potentially involved nodes in patients at risk.<sup>11</sup> Patients who were found to have positive inguinal-femoral nodes were randomized intraoperatively to either pelvic lymph node dissection or to postoperative radiation therapy to the pelvic lymph nodes after wound healing. Results showed that survival was significantly improved in the group that received radiation therapy (Fig. 42-6). The radiation therapy patients had fewer complications and significantly less lymphedema and other postoperative complications. This demonstration of both a survival benefit and significantly lower morbidity with postoperative radiation therapy led to the discontinuation of standard

pelvic lymphadenectomy. All patients with positive inguinal nodes are currently treated with adjuvant postoperative radiation therapy to the pelvic nodes.

#### Treatment of the Inguinal-femoral Lymph Nodes

In treatment of invasive vulvar cancer, it is imperative that the inguinal-femoral nodes, as the primary draining nodes, be evaluated. Bilateral node dissection is indicated for lesions that approach the midline. For well-lateralized lesions, dissection of the contralateral inguinal-femoral nodes is indicated only if there is evidence of involvement of the nodes in the ipsilateral groin. Most clinicians currently would perform an ipsilateral node dissection only at the time of initial treatment and then a contralateral node dissection at a later date if indicated.

As part of the previous standard en bloc therapy, dissection of the inguinal-femoral nodes had traditionally been carried out

**Figure 42-5, cont'd C, Only the neurovascular bundle remains after complete dissection.** (From Copeland LJ, Jarrell JF: Textbook of Gynecology, 2nd ed. Philadelphia, WB Saunders, 1999, Fig. 53-4, 53-5.)

with the excision of the skin bridge and the en bloc resection of the nodes. This was done because of the belief that the tumor could permeate into the lymphatics and that therefore an attempt to excise all the intervening skin was important to remove any tumor in transit in these lymphatic channels. Excision of the skin bridge often resulted in wound breakdown, infection, and prolonged hospitalizations. As it became clear that tumor embolizes to the primary lymph nodes rather than permeating the lymphatics, a thinner and thinner bridge was excised. Eventually, this resulted in the use of separate incisions for the node dissections, without resection of any intervening skin bridge.<sup>12,13</sup> There has not been a randomized prospective trial evaluating the use of separate incisions versus an en bloc resection, but comparison of patients treated via the triple, or separate, incision approach has clearly shown significant decreases in operative time and blood loss and, most importantly, a significant decrease in the incidence of breakdown of the wounds overlying the groin, which has resulted in significantly shorter postoperative stay (Table 42-8).

**Table 42-5**  
**FIGO Staging of Carcinoma of the Vulva**

T1	Tumor confined to the vulva and/or perineum 2 cm or less in greatest dimension
T2	Tumor confined to the vulva and/or perineum greater than 2 cm in greatest dimension
T3	Tumor of any size with adjacent spread to the lower urethra and/or the vagina, and/or the anus
T4	Tumor of any size invading the upper urethra, bladder mucosa, rectal mucosa, or pelvic bone
NO	No lymph node metastasis
N1	Unilateral regional lymph node metastasis
N2	Bilateral regional lymph node metastasis
M0	No clinical metastasis
M1	Distant metastasis (including pelvic lymph node metastasis)
Stage I	T1 NO MO IA T1 ≤ 1 mm IB T1 > 1 mm
Stage II	T2 NO MO
Stage III	IIIA T3 NO MO IIIB T3 N1 MO T2 N1 MO T1 N1 MO
Stage IV	IVA T4 NO MO IVB TX N2 MO TX NX M1

<3+	5.8%	2.9%	0%	3.8%	6.7%
≥3+	33%	33%	44%	66%	88%

Attempts to eliminate inguinal-femoral node dissection have been fraught with hazard. Early detection of inguinal-femoral node metastasis would still allow for a possible cure; unfortunately, later detection of a recurrence in the groin in the inguinal-femoral node group is almost uniformly fatal. Hacker and colleagues<sup>15</sup> have shown, in a series of patients who had

**Figure 42-6** Survival curve from GOG showing improved survival for those patients treated with radiation therapy rather than pelvic node dissection. (From Homesley HD, Bundy BN, Sedlis A, Adcock L: Radiation therapy versus pelvic node resection for carcinoma of the vulva with positive groin nodes. Obstet Gynecol 1986;68:733-740.)

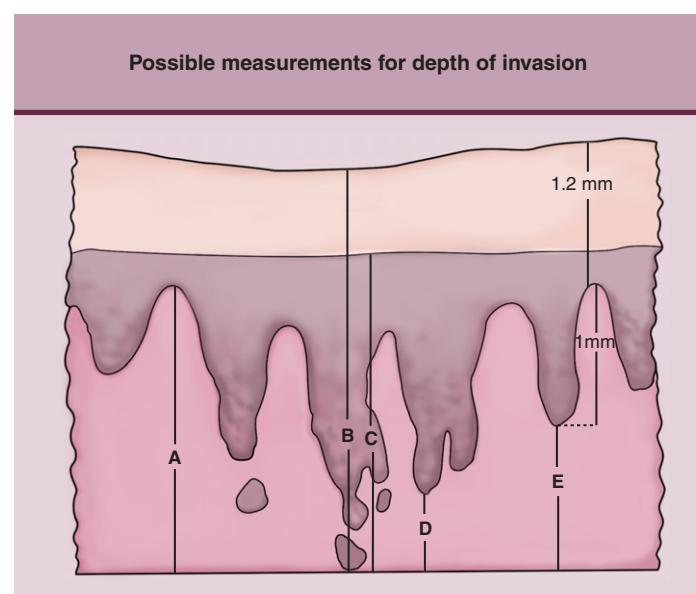

undergone node dissection for clinically nonsuspicious nodes, that approximately 10% were found to have nodal metastasis; all of these patients were able to be salvaged. However, in a group of patients in whom node dissection was omitted, there was a 10% incidence of recurrence in the groin; none of these patients could be salvaged due to development of widespread disease. Therefore, early detection of involved inguinal-femoral nodes is important to allow for treatment before dissemination of disease to the secondary node groups and subsequent systemic spread can occur. An alternative to surgical therapy is radiation therapy to the groins at risk (bilaterally for midline lesions, unilateral for lateral lesions). When the GOG compared these techniques in a randomized trial, the trial was closed early due to the improvement in outcome (lower recurrences rates in the groins) in the patients undergoing surgical excision.<sup>16</sup> However, the greater failure rate in the radiation group may have been due to a failure to deliver an adequate dose to the appropriate depth in the groin tissues.<sup>17</sup>

A group of patients for whom the incidence of node metastasis is so low that inguinal-femoral node dissection can be omitted has now been established. Although the risk of nodal metastasis increases with increasing depth of invasion, as is seen in cervical cancers, there is an 8% to 10% incidence of nodal metastasis with lesions of 3.0 mm or less invasion in vulvar cancer, which is quite different from the less than 1% incidence of metastasis with less than 3.0 mm invasion in cervical cancer. The International Society for the Study of Vulvovaginal Diseases has defined *microinvasion* as those lesions that exhibit less than 1.0 mm of stromal invasion. This depth of invasion is measured from the top of the nearest uninvolved dermal papillae, because as other points of reference can alter the measurement (Fig. 42-7).

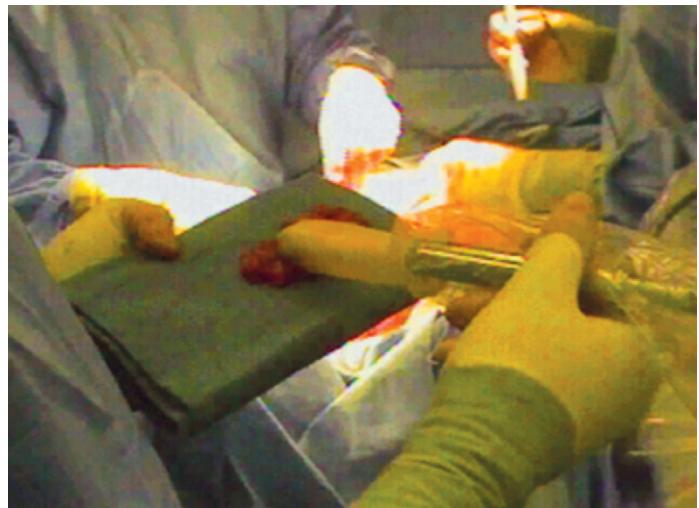

Lymph node dissection has typically been carried out through the use of a border technique, which involves defining all of the borders of dissection and then removing all of the nodes confined within those borders. The superior border of dissection is along the edge of the inguinal ligament. The medial border is defined as the lateral aspect of the adductor longus muscle, and the lateral border is along the medial aspect of the sartorius muscle. The apex of the dissection is where the adductor longus and sartorius intersect, forming the top of Hunter's canal. The superficial group of nodes lies deep to Camper's fascia and above the cribriform fascia that lies over the femoral vessels. The saphenous vein enters into the femoral vein as it passes through the fossa ovale in the cribriform fascia. The deep group of nodes lies along the medial aspect of the femoral artery and overlies the femoral vein, and drainage then extends cranially through the inguinal ligament into the pelvic node group. By carefully staying medial of the femoral artery, the clinician can avoid the femoral nerve, which lies outside the sheath. Preservation rather than transection of the saphenous vein during the dissection will allow for better collateral flow and will help prevent subsequent lymphedema.

**Figure 42-7** Possible sites from which depth of invasion could be measured. (From Wilkinson, EJ: Superficial invasive carcinoma of the vulva. Clin Obstet Gynecol 1985;28:188.)

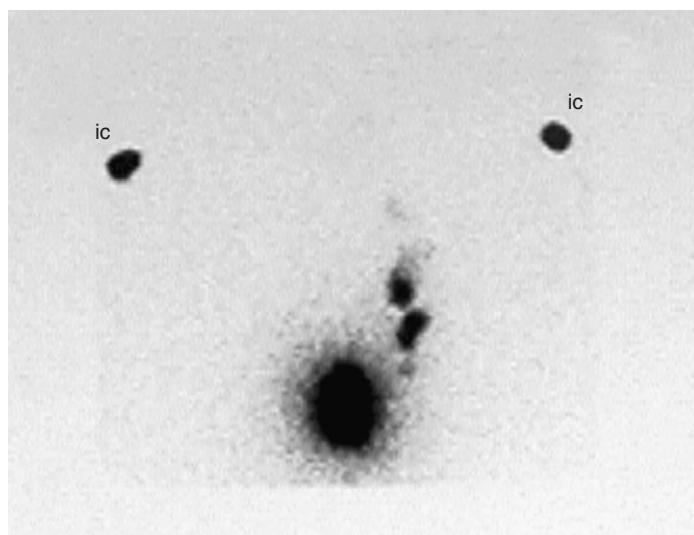

**Figure 42-8** Blue dye localized in a sentinel node in the superficial inguinal nodes.

**Figure 42-10** A gamma counter is used to confirm that the labeled node has been excised.

Recent efforts have focused on an effort to identify the sentinel node, that node which would be the first to be subject to metastasis and which could then predict for the positivity or negativity of the entire inguinal-femoral node group.<sup>18,19</sup> In theory, if this node is negative, there would be no need for a further, complete node dissection. Before surgery, the leading edge of the tumor is injected subcutaneously with either a radioactive tracer of technetium or a blue-colored lymphophilic dye, which will then follow the draining lymphatics, allowing identification of the sentinel node by either direct visual inspection, in the case of the blue dye (Fig. 42-8) or through localization of the radioactivity in the case of the technetium colloid (Figs. 42-9 and 42-10). For lesions that approach the midline, both leading edges and both groins will obviously need to be examined. In

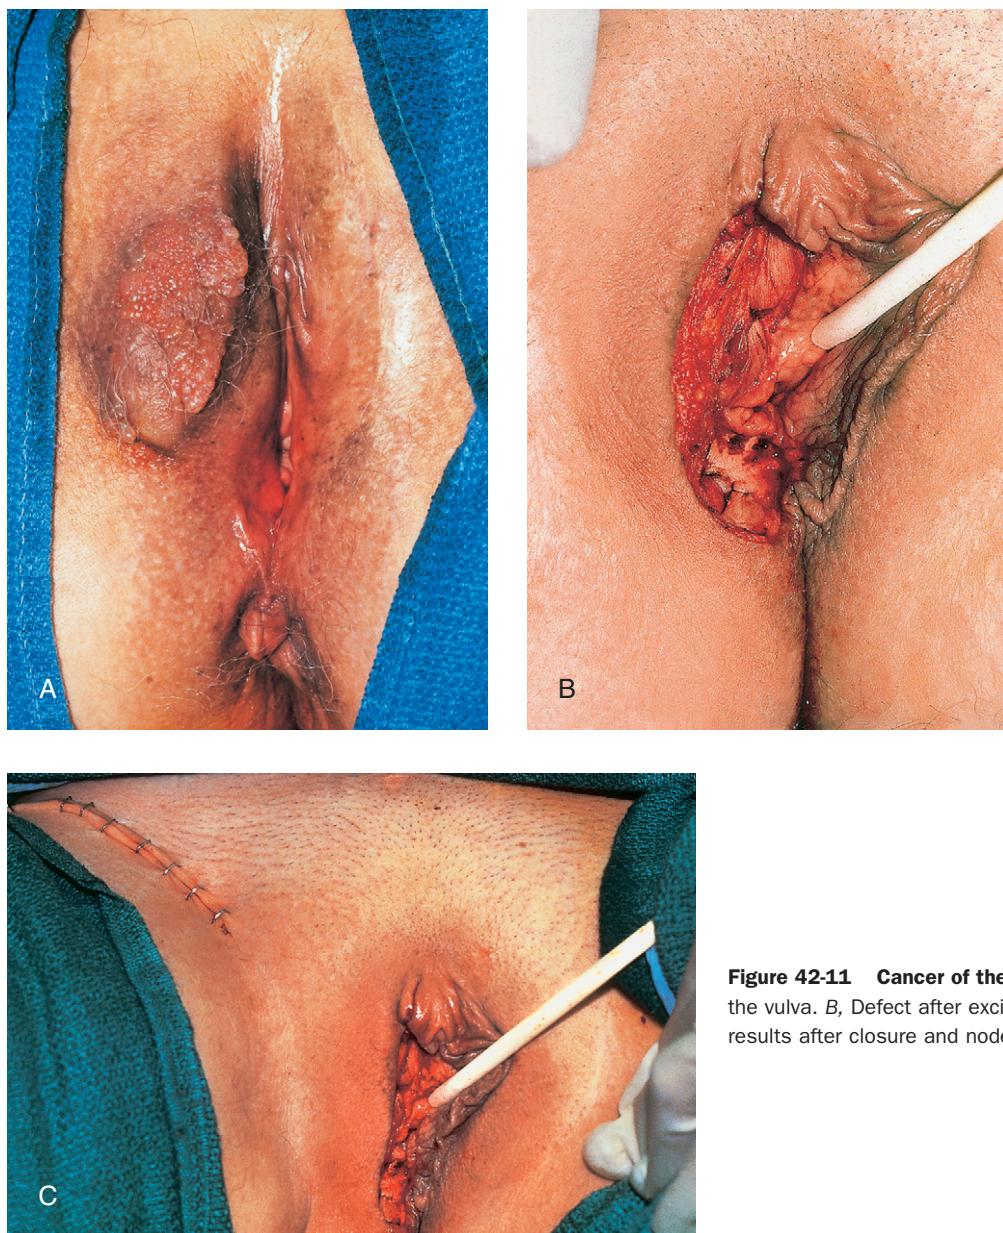

**Figure 42-9** Technetium-99 scan after injection of the vulvar lesion.

The center spot at the bottom represents excreted label. Two sentinel nodes can be seen just above and to the left of the bladder. IC, iliac crest.

almost 90% of cases that have been evaluated, the sentinel node is able to be identified, isolated, and examined. To date, most reports have also indicated good correlation between the status of the sentinel node and the status of the remaining inguinal-femoral nodes after a complete dissection. At this time, however, there is not enough data to allow for treatment decisions based on the status of the sentinel node alone. Further confirmation of its ability to predict the status of the residual nodes and absence of recurrence in the inguinal-femoral group is still required.

### Treatment of the Primary Lesion

Universal treatment of the primary lesion by radical vulvectomy resulted in resection of large amounts of normal tissue, especially in patients with smaller localized lesions. The larger defects would therefore be associated with increasing incidence of breakdown, wound infection, and long hospitalizations to allow for secondary healing of the surgical bed. Additionally, very few subclinical lesions were noted in the radical vulvectomy specimens, questioning the need for the prophylactic resection of normal vulvar tissue. In lesions that were lateralized or well situated either anteriorly or posteriorly along the vulva, initial efforts focused on a radical hemivulvectomy to remove the lesion with wide margins. Investigators also began to look at a radical local excision for smaller lesions (Fig. 42-11). In such an excision, an attempt was made to obtain margins at a minimum of 1 cm around the primary lesion, with a depth of excision extending down to the inferior fascia of the urogenital diaphragm, as with the standard en bloc radical vulvectomy.<sup>13,15,20,21</sup> Lesions that were far enough removed from either the anal mucosa, vaginal mucosa, or urethral orifice should be able to be widely resected with either the en bloc or radical local excision techniques. However, when lesions were closely approximating any of these structures, the difficulty in obtaining an adequate margin would be equivalent for either technique, and additional excision of the lateral tissues would not improve the ability to obtain an adequate margin. Retrospective evaluation of groups of patients treated by radical excision rather than the en bloc technique has

**Figure 42-11** **Cancer of the vulva.** *A*, A T1 lesion on the right side of the vulva. *B*, Defect after excision of the primary lesion. *C*, Postoperative results after closure and node dissection via separate incisions.

shown equivalent rates of local control with similar rates of local recurrence.<sup>15</sup> In fact, the best predictor of local control is the adequacy of the margin on the surgical specimen (Table 42-9),<sup>22</sup> and as previously noted this will depend on the lesion's proximity to the anal, vaginal, or urethral orifices. Extending the margins beyond a minimum of 1 cm doesn't improve local control rates and only results in larger defects.

Problems arise whenever a lesion extends to involve the vagina, urethra, or anus. This could result from a lesion arising in proximity to one of these structures or may be due to neglect of a lesion that spreads along the epithelial surface and eventually involves one of these structures. If an attempt is made to obtain an adequate margin, it would necessitate an exenteration, with subsequent loss of bowel, bladder, or sexual function. Reconstruction might return some, but certainly not all, function. To try to preserve function and anatomy, radiation therapy was given prior to surgical excision; approximately 75% of patients

had regression sufficient to allow preservation of sphincter or vaginal function.<sup>23</sup> Most patients can therefore be saved from an exenteration. However, if local recurrence occurs in the radiated area, an exenteration would offer the only possibility for a cure. In an effort to improve the local control achieved with radiation

**Table 42-10**  
**Efficacy of Synchronous Chemoradiation**

	Number	Percent
Patients	71	100%
Clinical chemoradiation	33	46%
Pathologic chemoradiation	22	31%
No exenteration	68	96%

From Moore DH, Thomas GM, Montana 65, et al: Preoperative chemoradiation for advanced vulvar cancer: a phase II study of the GOG. Int J Radiat Oncol Biol Phys 1998;42:79-85.

therapy, recent studies have focused on the addition of synchronous chemotherapy,<sup>24,25</sup> usually with platinum-containing regimens, as a radiation sensitizer, especially given the improvement that was seen in advanced squamous cancers of the cervix. In the GOG study reported by Moore,<sup>24</sup> 48% of patients had a complete clinical response to combined chemoradiation, and almost all were managed without an exenterative procedure (Table 42-10).

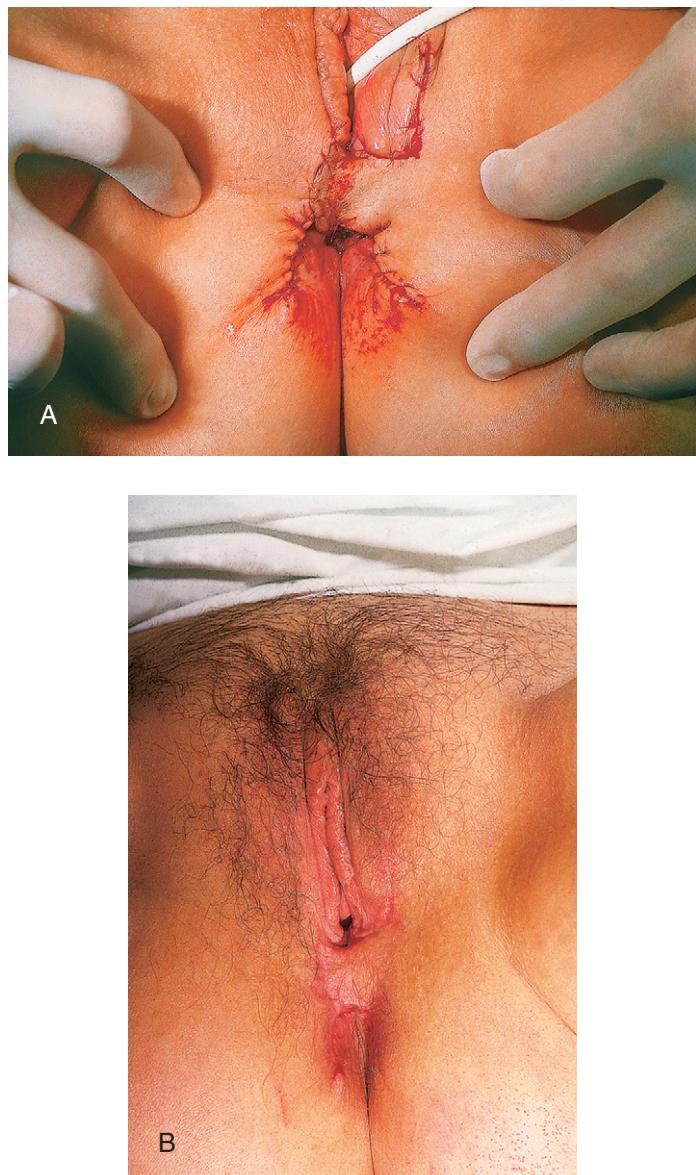

Even with a conservative approach, with an attempt to obtain adequate margins, a radical local excision can result in a large defect that is difficult to close primarily. Historically, large defects were allowed to close by secondary intention, resulting in prolonged hospitalizations. If the defect is not very large, local flaps or Z-plasties could be used to advance skin and provide a blood supply in the area to aid in closure<sup>26</sup> (Fig. 42-12). In the case of a large defect or when there has been prior radiation to reduce the size of a large lesion, a myocutaneous flap is necessary to not only fill the defect, but also bring in a new blood supply to aid in healing. Using the gracilis myocutaneous flap from the medial aspect of the thigh can allow for coverage of the vulva and also for filling in a portion of the vagina, if necessary, by rotating the flap superiorly and medially into the defect.<sup>27</sup>

## RECURRENT DISEASE

Disease recurrence can be manifest either locally, in the groins, or distally (including pelvic lymph node recurrence). Local recurrence is either due to an inadequate margin at initial therapy or new disease in another area of the vulva. The treatment of a local recurrence is guided by the same principles as the treatment of a primary lesion. Groin recurrence is almost inevitably fatal,<sup>10</sup> as previously discussed (see Table 42-7). If the groin has not been previously radiated, it might be possible to excise grossly positive nodes or use radiation to the groin for palliation. If, however, radiation has been used already or in the case of distant disease, palliative chemotherapy is the only treatment option. Chemotherapy is usually based around platinum, either alone or in combination, as with squamous cancers of the cervix.

## OTHER VULVAR NEOPLASMS

Malignant melanoma is the second most common malignancy arising on the vulva, yet it accounts for only 5% of vulvar malignancies, and these are relatively uncommon to begin with. Therefore, most experience with these lesions has come from

**Figure 42-12** **Cancer of the vulva.** A, A rhomboid flap has been used to close the perineal defect. B, Result at 3 months' postsurgery.

small series of patients accumulated over a fairly long period. Most patients will initially present with some form of growth or abnormal bleeding. An analysis of patients treated with at least a radical hemivulvectomy revealed that the 1992 American Joint Committee on Cancer (AJCC) staging correlated best with progression-free survival, followed by Breslow's staging based on thickness of the tumor.<sup>28</sup> As most patients had initially presented with advanced tumors, radical surgeries were often proposed to try to treat the lesions and the draining inguinal-femoral nodes, only to have patients fail with distant disease. This, along with the findings from the GOG study, which indicated that vulvar melanoma tends to behave similarly to other cutaneous melanomas,<sup>28</sup> has prompted a more conservative management, as with other cutaneous melanomas. The primary lesion is treated by radical local excision with reconstruction of the defect; groin node dissection may be performed

## Gynecologic Oncology

depending on the clinical status of the nodes and on Breslow's staging.

Cancer arising in Bartholin's gland can have several different appearances. Almost all patients will present with a lump appearing in the area of the gland and occasionally with bleeding. Squamous cancers can arise from the duct opening, whereas transitional cell lesions can arise from the remainder of the duct. Adenocarcinoma, including the adenoid cystic variant, can arise from the gland itself. Therapy for these lesions is also guided by the current treatment principles for squamous cancers of the vulva. The goal is for a radical resection of the primary lesion along with lymphadenectomy in the ipsilateral groin. Due to the location of the gland, deep within the vulvar tissue, overlying the urogenital diaphragm, there is a greater probability of a compromised deep margin and the need for postoperative radiation as a result.

Extramammary Paget's disease can also arise on the vulva and usually presents as a brick-red fiery lesion that is usually intensely pruritic. Most cases of Paget's disease are intraepithelial, and invasion and metastases are uncommon. However, as with Paget's disease of the breast, a significant association with the development of a second neoplasm exists. This could be an associated underlying adenocarcinoma in the vulvar tissue or, more commonly, a second neoplasm in the breast or colon (about 25% of patients).<sup>29</sup>

## KEY POINTS

- The majority of malignancies involving the vagina are metastatic lesions.
- Primary vaginal carcinoma represents approximately 1% to 2% of all gynecologic malignancies.
- Most primary vaginal carcinomas present with some type of vaginal bleeding or discharge.
- Radiation therapy is the mainstay of treatment for primary vaginal carcinomas, but because of their rarity, treatment of these tumors must be individualized.

## ANATOMY

The vagina is a tubelike muscular structure averaging 6 to 8 cm in length that is located between the uterus/cervix and the vulva, anterior to the rectum, and posterior to the bladder. The vagina is composed of three layers: an inner mucosal layer, a muscularis layer, and an outer adventitial layer. The mucosal layer is a nonkeratinizing squamous epithelium with no glands. An inner circular layer and an outer longitudinal layer of smooth muscle make up the muscularis layer. The adventitial layer is made of connective tissue that is contiguous with the other organs of the pelvis.

The vagina is composed of a rich network of lymphatic channels, and drainage to regional lymph node chains depends on location within the vagina itself. The middle to upper vaginal lymphatics anastomose with the lymphatics of the cervix and primarily drain to the pelvic lymph nodes (obturator, external iliac, and internal iliac nodes). The lower vagina drains similar to the vulva, going initially to the inguinal nodes. Lymphatics from the posterior vagina communicate to the rectal, gluteal, and sacral node chains.

## EPIDEMIOLOGY

Primary vaginal carcinoma represents only about 1% to 2% of all gynecologic malignancies. The majority of malignancies involving the vagina are metastatic lesions. These metastatic lesions most commonly arise from the cervix and vulva or occur as a result of hematogenous or lymphatic spread. There are expected to be approximately 2140 new cases of primary vaginal cancer diagnosed in 2005 in the United States.<sup>1</sup> A decreased incidence of primary vaginal carcinomas has been noted in the recent past, most likely secondary to earlier detection of premalignant conditions with cervicovaginal cytology. To be considered a primary vaginal cancer the lesion must arise in the vagina and not involve

the external cervical os or the vulva. Most of these primary vaginal carcinomas, approximately 85% to 90%, are squamous subtype. The mean age at diagnosis of the squamous subtype is approximately 60 years. Adenocarcinomas, melanomas, sarcomas, and lymphomas have also been shown to arise primarily from the vagina (Table 43-1).<sup>2-9</sup> This chapter discusses premalignant lesions of the vagina and primary vaginal carcinoma.

### Vaginal Intraepithelial Neoplasia

Vaginal intraepithelial neoplasia is much less common than intraepithelial neoplasia of the cervix or vulva. The classification of vaginal intraepithelial neoplasia is similar to that of cervical lesions: vaginal intraepithelial neoplasia 1 (mild dysplasia), vaginal intraepithelial neoplasia 2 (moderate dysplasia), vaginal intraepithelial neoplasia 3 (severe dysplasia). Some patients with vaginal intraepithelial neoplasia may present with vaginal bleeding or discharge, but the majority of patients are asymptomatic. It is most commonly found during the evaluation of an abnormal Papanicolaou (Pap) smear. An abnormal Pap smear in a patient with no abnormal cervical pathology or in a patient without a cervix should prompt investigation of the vaginal mucosa. It is more common for the proximal vagina to be involved. Most patients with vaginal intraepithelial neoplasia have a prior history of lower genital tract neoplasia, previously involving the cervix or vulva. Like cervical and vulvar intraepithelial neoplasia, vaginal intraepithelial neoplasia is also associated with human papillomavirus (HPV).

Colposcopy of the vagina is performed in a manner similar to colposcopy of the cervix, and colposcopic abnormalities of the vagina are similar to those described in the cervix. It can be quite difficult to adequately visualize the entire vagina when evaluating an abnormal Pap smear. It is usually necessary to manipulate the speculum during examination to view the entire vaginal mucosa secondary to the vaginal folds. Lugol's solution (aqueous iodine) can often aid in demarcating abnormal vaginal mucosa and can be utilized for both diagnosis and treatment (Fig. 43-1). Biopsy of an abnormal-appearing area can usually be accomplished as an office procedure without anesthesia.

The management of vaginal intraepithelial neoplasia depends on the degree of abnormality and the location of the disease. Vaginal intraepithelial neoplasia 1 is usually managed by observation. It is not uncommon for vaginal intraepithelial neoplasia 2 and 3 to involve the vagina in a multifocal nature, secondary to the HPV effect. Vaginal intraepithelial neoplasia 2 and 3 are premalignant conditions and can be treated in various ways. Traditionally, treatment modalities for vaginal intraepithelial neoplasia 2 and 3 consisted of surgical excision (vaginectomy) or vaginal irradiation. These modalities have been associated with significant morbidity, including vaginal shortening, vaginal

scarring, and problems with postoperative sexual function. More contemporary therapy has been to use CO<sub>2</sub> laser in the treatment of vaginal intraepithelial neoplasia. Chemical treatment with 5-fluorouracil can also be utilized. Cavitron ultrasonic surgical aspirator has also been used to treat vaginal intraepithelial neoplasia.<sup>10</sup>

The CO<sub>2</sub> laser treatment is favored by most. This method provides an excellent cosmetic result and enables the physician to more easily treat multifocal disease with limited morbidity. The vaginal mucosa should be treated to a depth of up to 1 mm. Larger spot sizes and the superpulse mode are used to avoid deep penetration and the conduction of excessive heat. Power settings used range between 10 and 40 watts. The potential disadvantage of using the CO<sub>2</sub> laser for the treatment of vaginal intraepithelial neoplasia is that this ablative therapy provides no tissue specimen; therefore, liberal biopsy is recommended before employing the CO<sub>2</sub> laser to rule out an invasive process.

## SQUAMOUS CELL CARCINOMAS

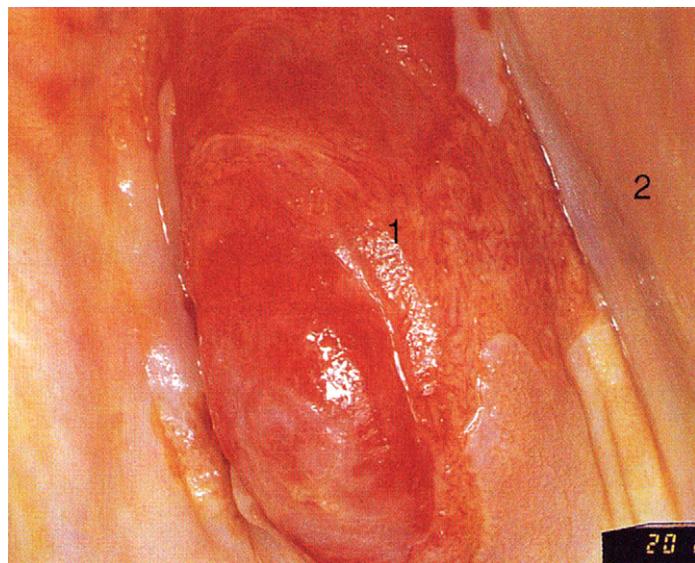

The majority of primary vaginal carcinomas are exophytic squamous lesions and present with vaginal bleeding and/or discharge (Fig. 43-2). Presenting symptoms such as pelvic pain or changes in bowel/bladder habits usually suggest a more advanced process. Most vaginal carcinomas occur in older women and arise in the upper one third of the vagina, especially the posterior wall. It is mandatory to inspect and palpate the entire vagina during a pelvic examination, especially when unexplained vaginal bleeding is present. This often involves rotating the speculum as smaller more proximal tumors at the vaginal apices may go unnoticed. Verrucous carcinoma is a rare variant of squamous cell carcinoma that can arise in the vagina. Grossly these tumors present as a cauliflower-like mass.

**Figure 43-1** *A*, The upper vagina after application of Lugol's solution. Areas labeled 1 do not stain and represent dysplastic precancerous changes. Areas labeled 2 are normal squamous mucosa of the vagina. *B*, Areas of vaginal mucosa after treatment with CO<sub>2</sub> laser (labeled 1 and 2). Untreated normal squamous mucosa of the vagina is labeled 3. (From Singer A, Monaghan J [eds]: Lower Genital Tract Precancer, Colposcopy, Pathology and Treatment, 2nd ed. London, Blackwell Science, 2000, pp 224 and 228.)

## Diagnosis

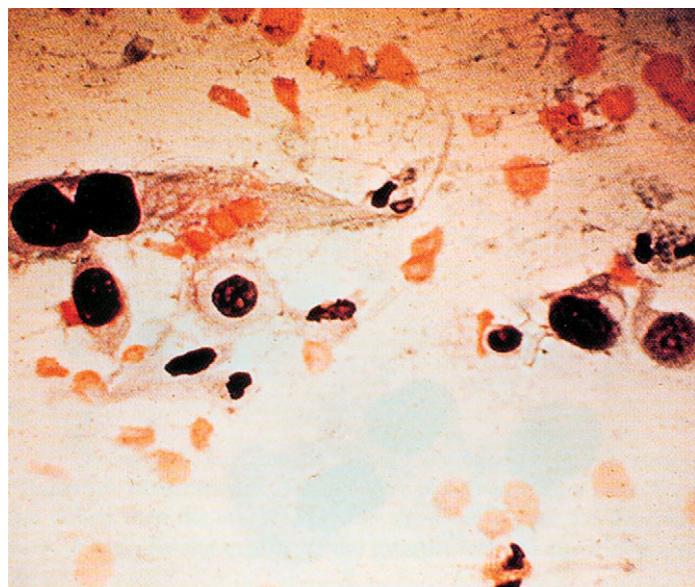

Direct biopsy of the vaginal tumor can almost always be accomplished with office punch biopsy. Abnormal cytologic findings on Pap smear (Fig. 43-3) or routine pelvic examination should prompt further evaluation. The range of patients who develop primary vaginal cancer after a previous hysterectomy

**Figure 43-2** This exophytic lesion on the right upper vaginal sidewall is a squamous cell vaginal cancer. (From Singer A, Monaghan J [eds]: Lower Genital Tract Precancer, Colposcopy, Pathology and Treatment, 2nd ed. London, Blackwell Science, 2000, pp 224 and 228.)

varies between 36% and 59%.<sup>11,12</sup> A significant number of these patients have a prior history of lower genital tract neoplasia.

Vaginal carcinoma is a clinically staged disease. International Federation of Gynecology and Obstetrics (FIGO) staging can be seen in Table 43-2. Most primary vaginal carcinomas have spread beyond the vaginal mucosa at the time of diagnosis (Fig. 43-4). Stage II vaginal carcinoma can further be subdivided into IIA (submucosal involvement without parametrial involvement) and IIB (submucosal involvement with parametrial involvement).

**Figure 43-3** This Pap smear shows highly abnormal cells suggestive of malignancy. (From Baggish M [ed]: Colposcopy of Cervix, Vagina, and Vulva: A Comprehensive Textbook. St. Louis: Mosby, 2003, p 20.)

**Table 43-2**  
FIGO Staging for Vaginal Carcinoma

Stage 0	Carcinoma in situ
Stage I	Limited to the vaginal wall
Stage II	Subvaginal tissue not involving pelvic sidewall
Stage III	Carcinoma extending to pelvic sidewall
Stage IVa	Carcinoma involves mucosa of bladder or rectum and/or extends beyond the true pelvis
Stage IVb	Distant metastasis

Once vaginal carcinoma is diagnosed, workup usually includes examination under anesthesia, cystoscopy, proctoscopy, and chest x-ray. Abdominopelvic computed tomography scan or magnetic resonance imaging are often done to evaluate for metastatic disease and to assist in treatment planning. Additional evaluation with endocervical curettage, endometrial curettage, intravenous pyelogram, barium enema, positron-emission tomography or a pretreatment laparotomy may also be beneficial in treatment planning.

The incidence of clinically positive lymph nodes at the time of diagnosis varies between 3% and 20% (Table 43-3).<sup>9,13,14</sup> Involved lymph node chains can vary and include pelvic, inguinal, or sacral/rectal, depending mostly on the location of the primary lesion.

### Risk Factors

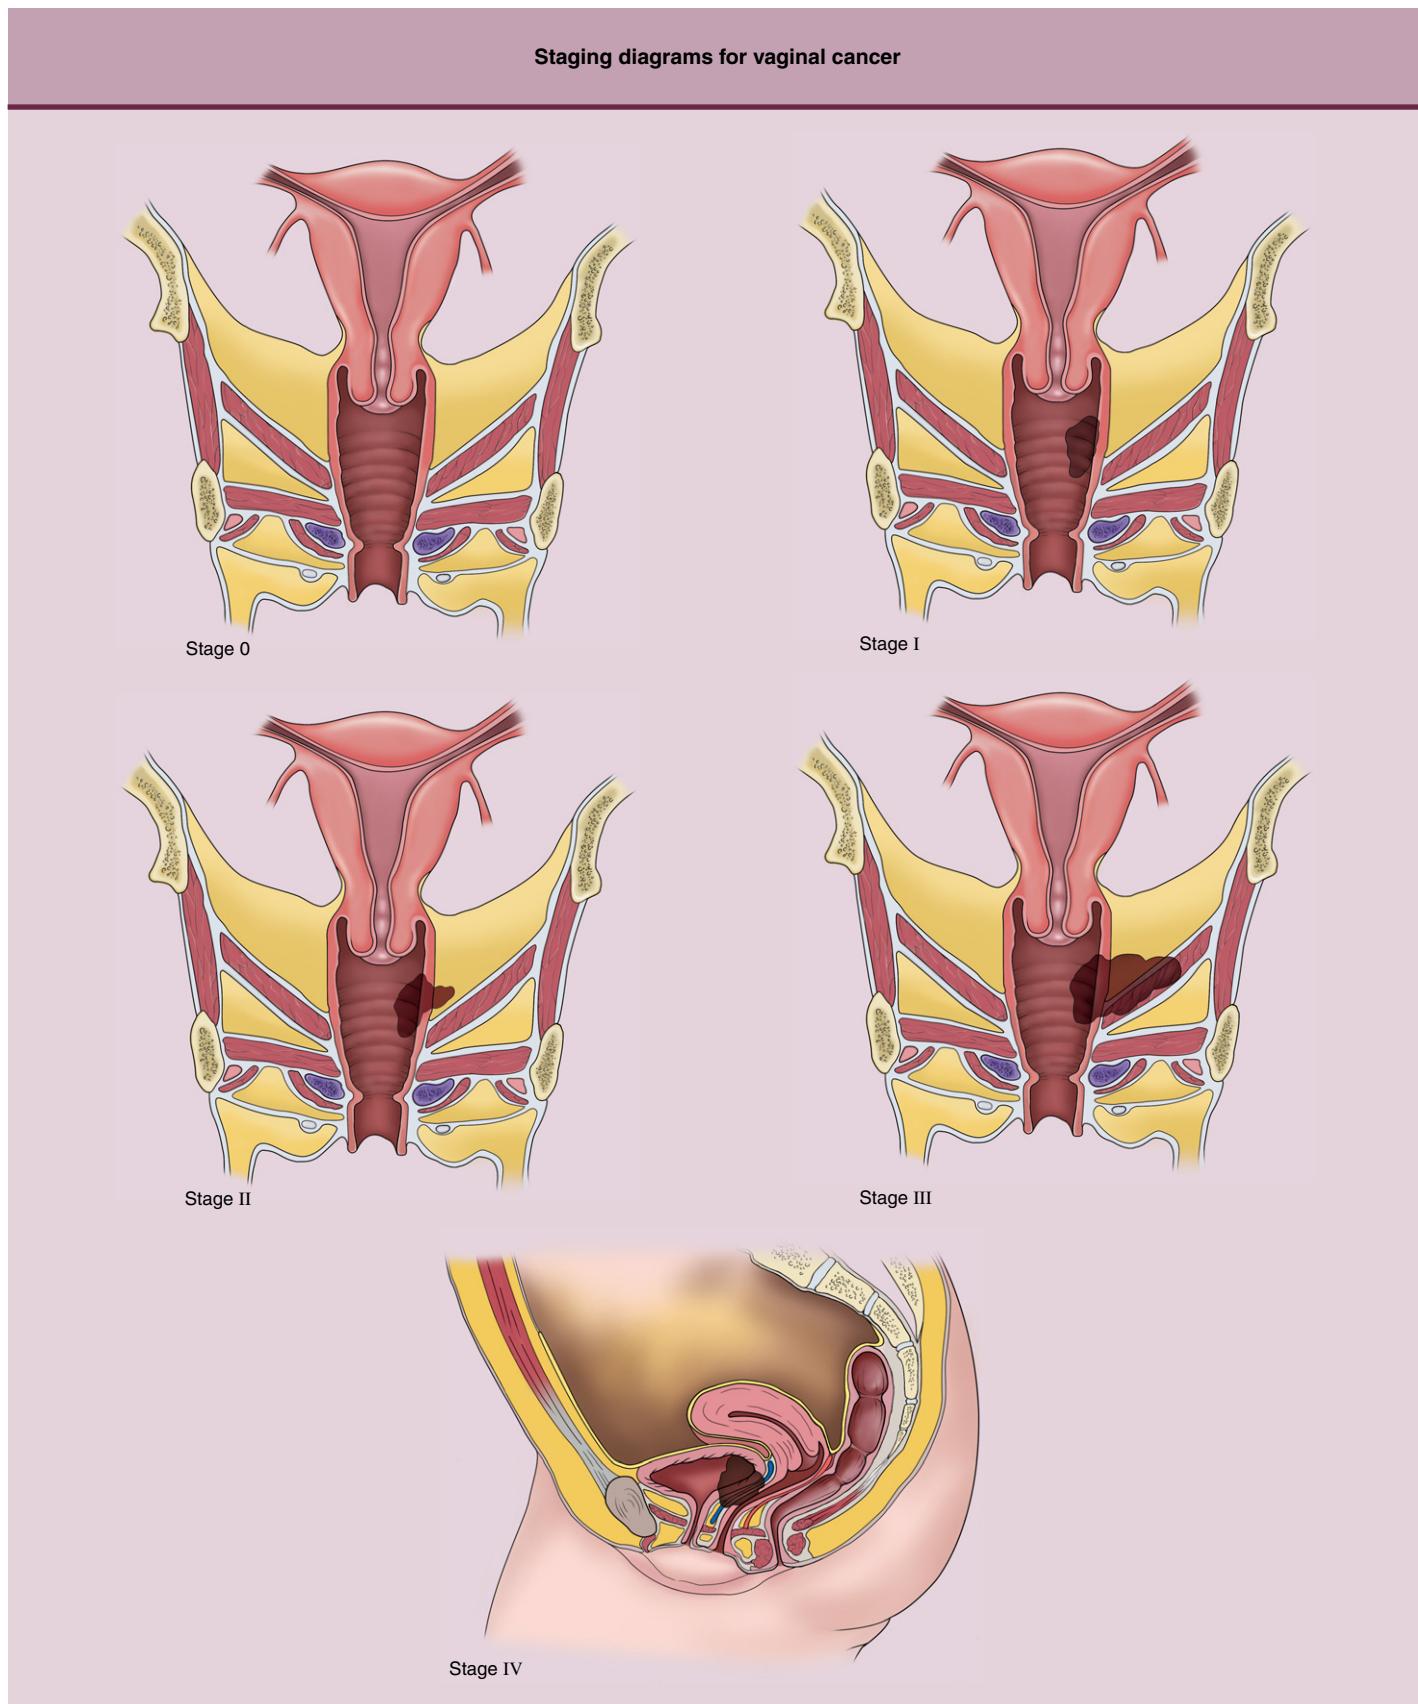

The cause of squamous cell carcinoma of the vagina is unknown. It is believed that most squamous vaginal carcinomas share the same etiology as squamous cervical carcinomas. Because of their relative rarity, primary vaginal carcinomas are much less studied than their cervical counterparts. A recent report by Daling and colleagues identified several risk factors for vaginal carcinoma similar to previously identified cervical carcinomas risk factors.<sup>15</sup> These authors reported prior HPV infection, more than five lifetime sexual partners, onset of intercourse before age 17, and smoking to be associated with primary vaginal carcinoma.

Also shown to be at risk were those patients who have undergone hysterectomy. Other potential risk factors for primary

**Figure 43-4 A schematic showing the FIGO clinical staging for vaginal cancers.** (From Disaia P, Creasman W [eds]: Clinical Gynecologic Oncology. St. Louis: Mosby, 1997, p 236.)

vaginal carcinoma include low socioeconomic status, vaginal trauma, and vaginal discharge/irritation. Prior irradiation has been considered a risk factor, but this remains controversial.

### Prognostic Factors

As with all other gynecologic malignancies, stage of disease is the most important prognostic factor in primary vaginal carcinoma. Overall survival based on stage of disease is shown in Table 43-4.<sup>2,4-6,8</sup> Primary tumors arising in the upper vagina have been shown by Chyle and colleagues to portend a better prognosis.<sup>9</sup> Others, however, have not shown this same trend.<sup>13</sup> Grade, patient age, and gross tumor appearance have not been shown to be of independent prognostic significance.

### Treatment

Radiation therapy is the cornerstone of treatment for primary squamous cell vaginal carcinoma; however, because of the low overall incidence of this disease, therapy must be individualized based on stage of disease and location of the tumor. Surgery is usually reserved for small stage I lesions or in patients with stage IVa disease or patients with a centralized recurrence, in whom a pelvic exenteration may be necessary. Some clinicians favor the use of chemoradiation with radiosensitizing agents such as cisplatin or 5-fluorouracil, extrapolating data from the treatment of locally advanced cervical cancer.

The majority of patients with primary vaginal carcinoma are treated with radiotherapy. Achieving a total tumor dose of 7000 cGy has been shown to improve local tumor control.<sup>9</sup> This most commonly involves a combination of teletherapy and intracavitary/interstitial therapy. Some small stage I and II lesions may be adequately treated with intracavitary/interstitial therapy alone. Larger ( $>2$  cm) stage I and II lesions are customarily treated initially with teletherapy to a dose of 4000 to 5000 cGy. Pelvic lymph nodes are included in this external radiation field; this technique usually decreases tumor size, such that subsequent treatment can be performed with intracavitary/interstitial implants. If the tumor is distally located in the lower vagina the

inguinal lymph nodes are more frequently involved and should be treated either with surgical excision or radiotherapy.

When surgery is utilized to treat selected stage I lesions (usually involving the upper vagina), a radical hysterectomy, partial vaginectomy, and pelvic lymphadenectomy are performed. In those patients who have undergone a previous hysterectomy a radical upper vaginectomy with pelvic lymphadenectomy is done.

Regardless of the therapy that is instituted, serious complications are seen in up to 10% to 15% of cases. These can include the following: vesicovaginal or rectovaginal fistula, rectal stricture, rectal ulceration, and radiation-induced necrosis of the vagina. Less severe and more common side effects of treatment include cystitis, proctitis, and radiation fibrosis of the vagina.

### Survival and Recurrent Disease

The overall 5-year survival rate is approximately 40% to 45% (see Table 43-4).<sup>2,4-6,8</sup> The overall survival is lower than that for cervical and vulvar cancers. This is thought to be secondary to more advanced disease at the time of diagnosis and the technical difficulty in treating these tumors.

Most recurrences from primary vaginal cancer occur within 2 years of treatment and occur in the pelvis. Pelvic exenteration can be performed in appropriate candidates with central pelvic recurrences. Chemotherapy has usually been reserved for recurrence at distant sites. The treatment results with chemotherapy for recurrent disease are generally quite poor.

## ADENOCARCINOMAS

Adenocarcinomas of the vagina are much less common than squamous carcinomas. Adenocarcinomas can affect women of all ages; however, a clear cell variant affecting younger females has been extensively described. When an adenocarcinoma of the vagina is found in a postmenopausal female consideration should be given to a metastatic process originating in the uterus, ovary, fallopian tube, colon, or rectum.

In 1971, Herbst and colleagues were the first to report an association between in utero diethylstilbestrol (DES) exposure and clear cell carcinoma of the vagina in young women.<sup>16</sup> More commonly these women were found to develop vaginal adenosis, or benign structural abnormalities such as a cervical collar, a cockscomb cervix, or a transverse vaginal septum. Herbst and Scully found that the majority of women with clear cell cancer of the vagina had a documented in utero exposure to DES. With the discontinuation of DES usage in the early 1970s this clear cell variant has become much less common.

The incidence of clear cell vagina carcinoma in those who were exposed to DES prenatally is approximately 1 in 1000. The median age at diagnosis is approximately 19 years, and more than 90% of these tumors are diagnosed early in stages I and II. The risk has been shown to be greatest in those women who were exposed in the first 20 weeks of gestation. Clear cell vaginal carcinomas are most frequently observed in the upper anterior vaginal wall, in contrast to squamous lesions, which are mostly in the upper posterior vagina.

Adenocarcinoma of the vagina is generally treated in a manner similar to squamous carcinoma of the vagina; however, because of the rarity of these tumors treatment is often

**Table 43-4**  
Overall Survival in Primary Vaginal Carcinoma

Stage	Number of Patients	5-yr Survival (%)
I	194	71
II	310	47
III	196	33
IV	78	19
Total	778	42

## Gynecologic Oncology

individualized. In younger patients who are diagnosed, high regard should be given to both vaginal and ovarian preservation. Early-stage tumors involving the upper vagina may be treated with radical hysterectomy, pelvic lymphadenectomy, and upper vaginectomy. Radiation therapy may be employed if surgical excision is local and/or less radical. In those cases in which less radical surgery is the only treatment modality employed, the risk of local recurrence is greater. The use of radiation therapy as the sole means of treatment is usually reserved for more extensive tumors and tumors involving the lower vagina.

The overall prognosis for adenocarcinoma of the vagina is directly dependent on the stage of disease. Those patients with the clear cell variant, who are generally younger and more likely to present with early-stage disease, generally have very good outcomes. The 5-year overall survival for this group of patients ranges between 75% and 80%. The outcomes for non-clear cell adenocarcinomas of the vagina not related to in utero DES exposure are generally less favorable compared to the squamous carcinomas.<sup>9</sup> As with the squamous subtypes recurrent disease is most likely to occur locally. Treatment for recurrent adenocarcinoma is also individualized and depends on location of the recurrence and the type of treatment used primarily.

## SARCOMAS

Most vaginal sarcomas arise submucosally. Many different subtypes of sarcoma have been described, including fibrosarcomas, rhabdomyosarcomas, leiomyosarcomas, endometrial stromal sarcomas, angiosarcomas, and malignant histiosarcomas. Poor prognostic factors include size greater than 3 cm, greater than 5 mitoses per 10 HPF, and cytologic atypia.<sup>17</sup> These tumors are best treated by surgical excision with adjuvant irradiation recommended for those with poor prognostic features or positive surgical margins.

Sarcoma botryoides is an embryonal rhabdomyosarcoma that affects young children. This variant of sarcoma is the most common malignancy of the vagina in children. The majority of these occur in children younger than age 5, and they often present with a grapelike vascular-appearing mass in the vagina. Historically these tumors were treated with radical surgery. More contemporary therapy now includes preoperative or post-operative chemotherapy and irradiation. The implementation of combination chemotherapy with vincristine, dactinomycin, and cyclophosphamide has improved overall survival for this tumor type.<sup>18</sup>

## MELANOMAS

Primary melanomas arising in the vagina are rare, representing approximately 0.5% to 1% of all vaginal malignancies. They are most common in the lower anterior vagina and can vary in color, size, shape, and pattern of growth. They usually present in postmenopausal females with vaginal bleeding, vaginal discharge, or a vaginal mass. As with cutaneous melanomas, several classification schemata can be used (Breslow, Chung, Clark), and tumor depth is the best predictor of overall survival.

The treatment for vaginal melanoma usually entails a radical surgical approach. For proximal lesions a radical hysterectomy,

partial vaginectomy, and pelvic lymphadenectomy can be utilized, whereas distal vaginal melanomas may require partial vaginectomy, partial or total vulvectomy, and inguinofemoral lymphadenectomy. Irradiation (both external and intracavitary) is primarily reserved for the adjuvant setting or more advanced vaginal tumors. Chemotherapy has not been shown to be effective, and the use of immunotherapy has not been proven.

Overall survival depends on the depth of invasion and is generally poor. Buchanan and colleagues found only 18 of 197 patients to survive more than 5 years from the time of diagnosis.<sup>19</sup> Recurrence is most common locally or in the lungs, and prognosis is universally poor; mean survival is approximately 8 months in these cases.

## LYMPHOMAS

Most primary vaginal lymphomas present as a submucosal mass. They are most commonly of diffuse large-cell type. Lymphomas of the vagina can be primary in origin or they may represent a metastatic process. Combination chemotherapy depending on the cell type should be utilized to treat these tumors.

## Cervical Carcinoma

Zoya Almeida-Parra, MD, Manuel Peñalver, MD, and Luis E. Mendez, MD

### KEY POINTS

- Human papillomavirus is a carcinogen directly linked to dysplasias and cervical cancer, and has been detected in greater than 90% of cancer tissues.
- The Bethesda System was revised in 2001 based on multiple studies to provide uniform nomenclature and therapeutic guidelines. The new Bethesda System subdivides atypical squamous cells (ASC) into atypical cells of undetermined significance (ASC-US) and atypical cells cannot exclude high-grade intraepithelial lesion (ASC-H).
- Management of abnormal Pap smears depends on their classification. Most abnormal Pap smears should be evaluated with colposcopic-directed biopsies. HPV testing has an important role to play in ASC-US workups but does not help with other types of abnormal Pap smears.
- Cervical cancer staging is based on size and extension of tumor. It is staged clinically rather than surgically.
- Treatment of cervical cancer depends on size of lesion. Microinvasive disease may be treated with less extensive surgery. Stage IA1 may be treated with a cone biopsy versus simple hysterectomy (after cone biopsy). The treatment for IA2 is a type II hysterectomy. Stage IB1, IB2, and IIA can be treated with either a type III hysterectomy or chemoradiation.
- Adjuvant chemoradiation is given to patients with poor prognostic factors, as determined by surgical pathology. Poor prognostic factors include lymph node involvement, lymphovascular involvement, parametrial involvement, depth of invasion, vaginal margins, and size of tumor.
- Concomitant chemotherapy, specifically cisplatin, results in a superior progression-free survival compared to radiation alone (approximately 50%).
- Surveillance for recurrence is extremely important. Irradiation is the treatment for local recurrence after surgery. Patients with local central recurrence after radiation therapy may be explored for possible exenteration. Pelvic exenterations are morbid and patient selection is important. Distal recurrence can be treated with palliative chemotherapy.

### EPIDEMIOLOGY

In the early 1970s, approximately 75% to 80% of cases of cervical cancer in the United States were invasive at the time of diagnosis. Today, most cases of cervical cancer are diagnosed at the *in situ* stage (78%). The incidence and mortality for invasive

cervical cancer has declined approximately 40% since the 1970s. This decline is due to effective cytologic screening with the advent of the Pap smear, introduced in the 1940s by Dr. George Papanicolaou. This screening test has not undergone much modification in the past 50 years (Fig. 44-1). Screening guidelines for cervical cancer are given in Table 44-1.

There were an estimated 10,520 new cases of cervical cancer for 2004, with a higher prevalence among minorities. The incidence is 12.7/100,000 among African Americans versus 8.0/100,000 among whites (Fig. 44-2). Although Pap smears for cervical cancer prevention are highly effective, use among minorities is significantly lower than among white women (85.6%). Hispanics are least likely to undergo Pap smears (82.6%), whereas 88.9% of black women reported undergoing a Pap smear.<sup>3</sup>

### ETIOLOGY

Risk factors for cervical cancer and clinical features are listed in Table 44-2. Cervical cancer is strongly linked to the human papillomavirus (HPV). HPV are small DNA viruses from the Papovaviridae family that contain 7900 base pairs (Fig. 44-3). There are more than 100 different types affecting different body areas. HPV is associated with condylomas, dysplasias, and cervical and anal cancers. The exact incidence of HPV is unknown for several reasons. Infections are many times subclinical and there is a lack of reporting of overt infections. In addition, detection techniques are difficult and complicated. HPV cannot grow *ex vivo*. Detection methods include *in situ* hybridization, southern transfer hybridization, hybrid capture, dot blot, filter hybridization, and polymerase chain reaction.

Human papillomavirus types are subdivided into low, intermediate, and high risk. The high-risk HPV types most associated with cervical cancer are 16 and 18.

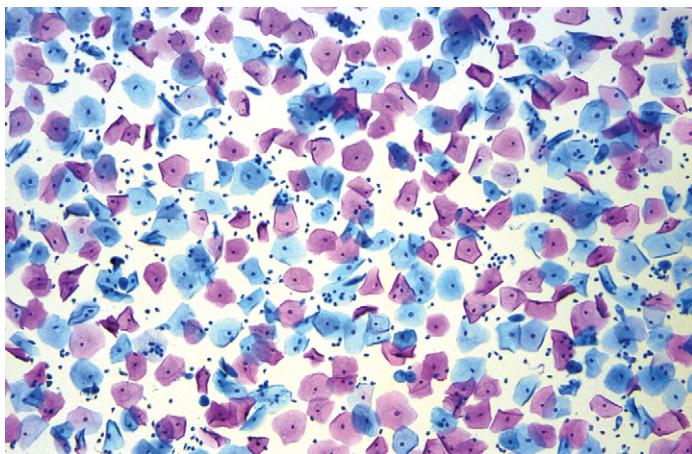

### Molecular Biology

In 1995, The World Health Organization (WHO) declared HPV as carcinogenic in humans from the biologic and epidemiologic points of view. There is strong evidence to support the role of HPV pathogenesis in cervical dysplasias and cervical cancer.<sup>4</sup> HPV DNA has been detected in greater than 90% cervical cancer tissues.

The HPV genome encodes for the following proteins<sup>5</sup>:

- 6 E (early) proteins—gene regulation and cell transformation
- 2 L (late) proteins—shell of the virus
- 1 region—regulation of DNA sequences

The HPV proteins E6 and E7 are important viral oncogenes involved in the pathogenesis of cervical cancer. These oncogenes

**Figure 44-1 Normal Pap smear used for cervical cancer screening.**

have transforming properties that interact with growth-regulating proteins. Their continued expression is necessary for malignant transformation. It is important to point out that there are different levels of oncogenicity of E6 and E7, depending on their base pairs. E7 has more oncogenic properties on HPV16 than on HPV6.

The molecular processes by which these proteins cause malignant transformation involve the p53 and retinoblastoma systems (Rb). Normally p53 is a negative regulator of cell growth. When there is chromosomal damage, p53 allows DNA repair enzymes to function. The E6 protein binds and degrades p53, thus allowing the accumulation of mutations without DNA repair and thereby causing “unchecked” cellular cycling.<sup>6</sup> Apoptosis is therefore inhibited (Fig. 44-4).

**Table 44-1  
ACOG Screening Guidelines for Cervical Cancer**

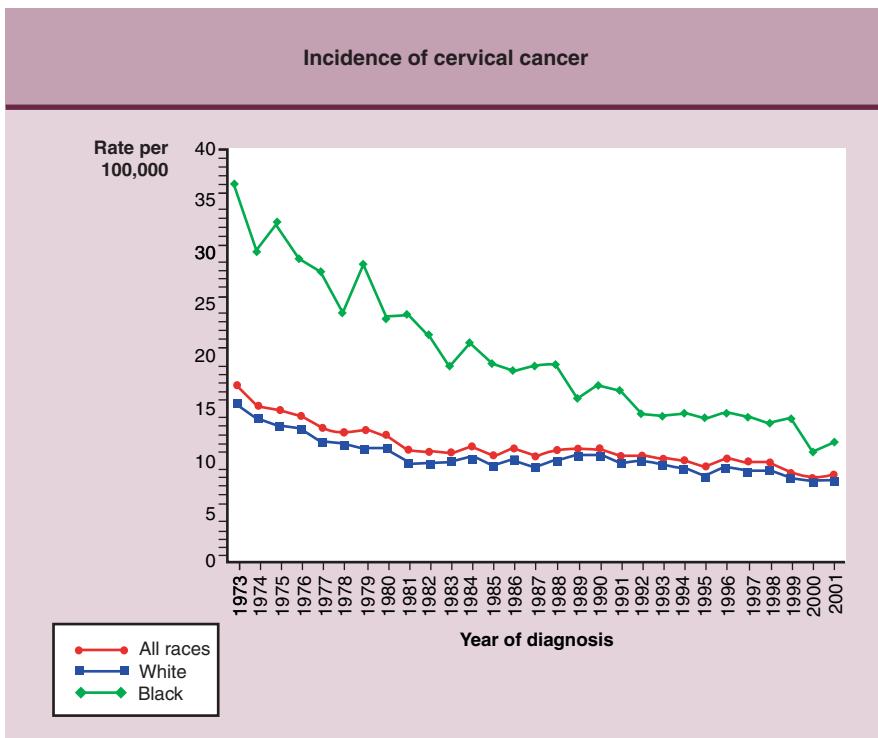

Initial screening	Should begin approximately 3 years after first sexual intercourse or by age 21, whichever comes first
Until age 30	Annual screening
At age 30 or older	<ul style="list-style-type: none"> <li>• Annual screening</li> <li>• Every 2 to 3 years, if patient has had 3 consecutive negative results</li> <li>• Combination of cytology with high-risk HPV testing; if both tests are negative, combined tests no more frequently than every 3 years, if one test is negative, more frequent testing.</li> </ul>

Exceptions:

- Women at high risk, such as those having a history of cervical cancer, immunosuppression, HIV, or cervical dysplasias, should be screened more often according to their diagnosis.
- Women with their cervix removed for benign reasons do not need annual screening. If the patient had a history of dysplasia, testing may be discontinued after three consecutive negative screening tests.

Data from American College of Obstetricians and Gynecologists.<sup>1,2</sup>

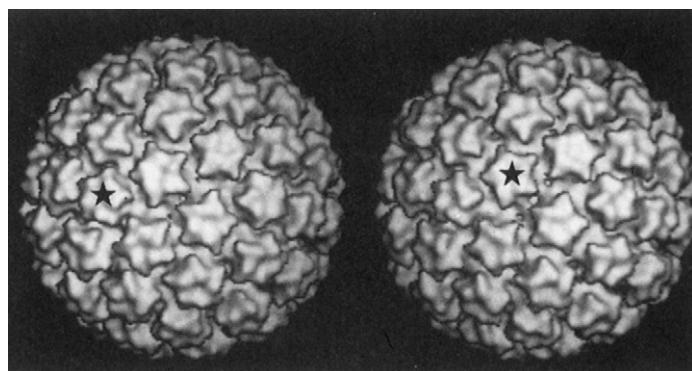

The Rb protein is involved in inducing cell apoptosis in response to DNA damage.<sup>7,8</sup> Rb binds to E2F transcription factor and inactivates E2F, which is involved with promoting the S phase of cell division. E7 bind to the Rb protein, which causes E2F to be released and allows cell division and bypasses the “check” system with p53. E6 and E7 are also involved in apoptotic inhibition and cell transformation through other mechanisms.

**Figure 44-2 Incidence of cervical cancer.**

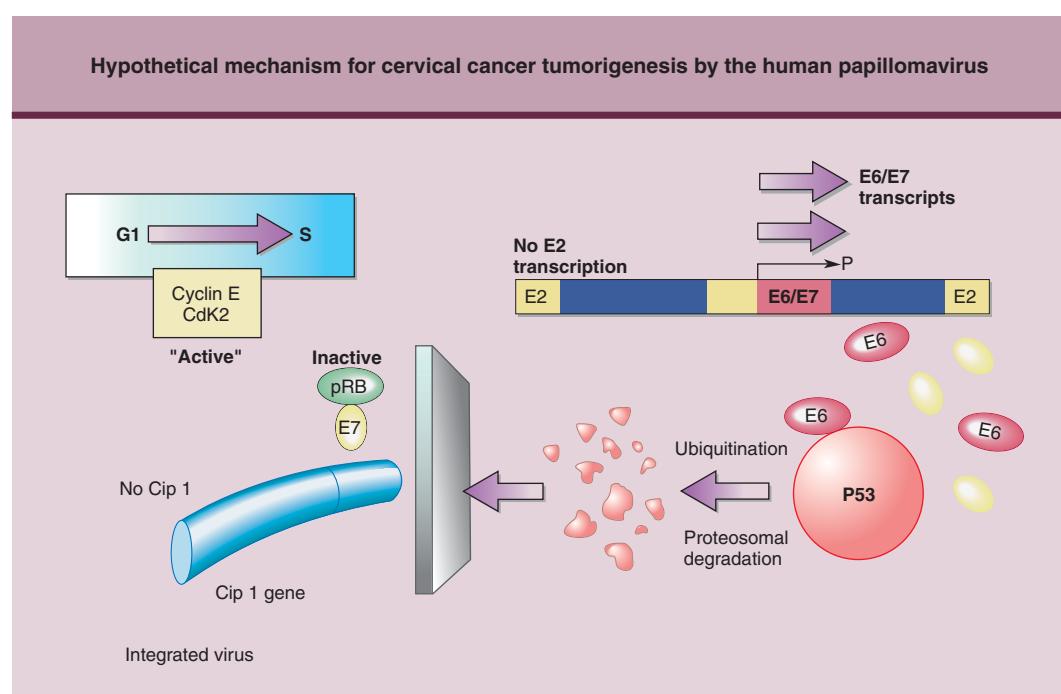

(Based on National Cancer Institute's Surveillance, Epidemiology and End Results [SEER], Facts and Figures, 2004.)

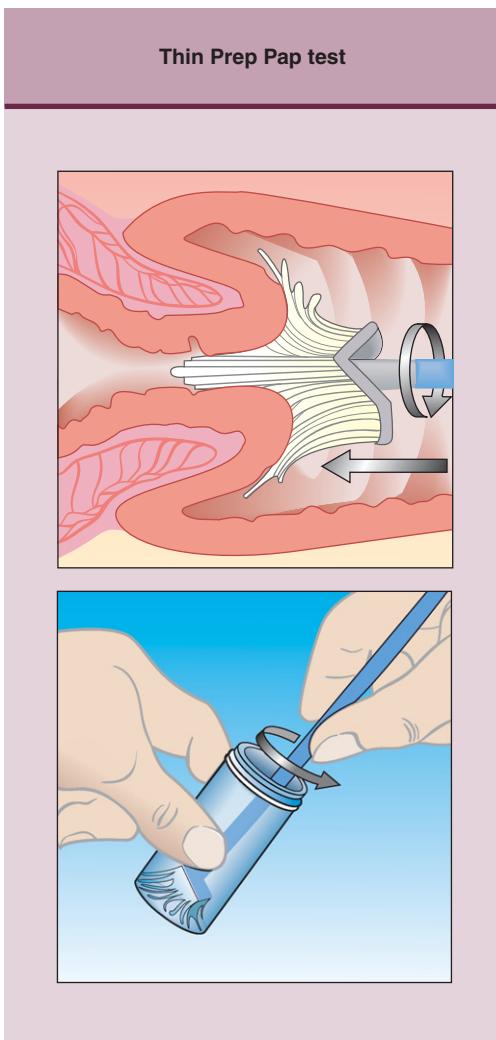

Table 44-2 Risk Factors and Clinical Features of Cervical Cancer		
Risk Factors	Clinical Features and Symptoms	
	Early Stage	Late Stage
Early age at first intercourse	No symptoms	Abdominal pain
Multiple partners	Screening with Pap smears	Unilateral leg edema/pain
Sexually transmitted diseases, HPV, HIV, HSV	Vaginal bleeding	Heavy vaginal bleeding
Oral contraception use	Postcoital bleeding	
Cigarette smoking	Abnormal discharge	
Low socioeconomic status		
Increased number of sexual partners of the current male partner

**Figure 44-4 Hypothetical mechanism for cervical cancer tumorigenesis by the human papillomavirus.**

**Figure 44-5** Liquid-based cytology, the Thin Prep Pap Test.

Endometrial cells were only reported in postmenopausal women. However, the 2001 revision notes endometrial cells present in women younger than age 40. Pertinent history is not always known when the Pap smears are read. Endometrial cells other than menses should not be present; this could indicate an endometrial abnormality.

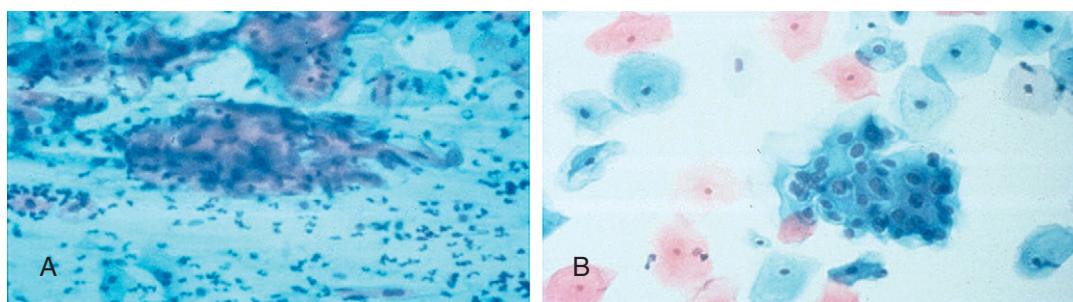

The importance of proper classification is to manage these lesions appropriately. Multiple reports are available indicating the natural history of cervical cancer precursors. Several studies

Table 44-3 Bethesda System 2001	
<b>Squamous epithelial cell abnormalities</b>	
ASC:	atypical squamous cells
ASC-US:	atypical cells of undetermined significance
ASC-H:	atypical cells, cannot exclude high-grade squamous intraepithelial lesions
LSIL:	low grade squamous intraepithelial lesions
Includes HPV, mild dysplasia, CIN I	
HSIL:	high grade squamous intraepithelial lesion
Includes moderate and severe dysplasia, CIN II, CIN III	
<b>Glandular epithelial cell abnormalities</b>	
AGC:	atypical glandular cells; specify endocervical, endometrial, or glandular cells
AGC-N:	atypical glandular cells, favoring neoplasia; specify endocervical or not otherwise specified
AIS:	endocervical adenocarcinoma in situ
Data from Solomon D, Davey D, Kurman R, et al: The 2001 Bethesda System: terminology for reporting results of cervical oncology. JAMA 2002;287:2114–2119.	

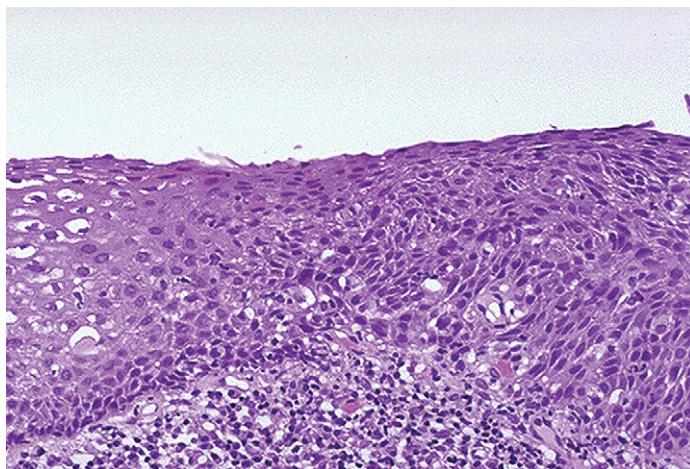

have looked at the average age of a lesion and have extrapolated that it takes more than 10 years for a dysplastic lesion to become carcinoma in situ or an invasive cancer.<sup>10,11</sup> Although many studies have determined progression of different grades of dysplasia, the more severe lesions have a higher likelihood of progression.

The category ASC (atypical squamous cells) has been divided into two categories with the purpose of detecting higher grade lesions. It has been estimated that 10% to 20% of women have underlying CIN II or CIN III and that 1/1000 may have invasive cancer. Specificity of ASC should aid in detecting CIN II and CIN III more rapidly (Fig. 44-7).<sup>12</sup>

There are different approaches to managing ASC. One alternative is to repeat the Pap smear in 4 to 6 months. Once two are negative, follow with routine Pap smear screening. If positive, colposcopy should be done. Another approach calls for HPV testing. If results are negative, the Pap smear is repeated in 12 months. If HPV results are positive, colposcopy should be done. If the colposcopy is negative, repeat Pap smears should be performed every 6 to 12 months or repeat HPV testing in 12 months. Refer for colposcopy if Pap smear or HPV testing is positive. A final option is initial colposcopy. If it is negative, repeat Pap smear in 12 months. If results of the colposcopy are positive, manage appropriately. Excisional procedures should be

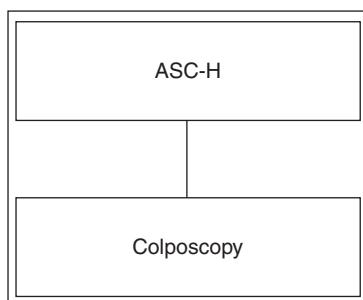

**Figure 44-6** Comparison between the conventional Pap smear (A) and the Thin Prep Pap Test (B).

**Figure 44-7 Cervical biopsy depicting moderate to severe dysplasia.**

avoided, and all immunosuppressed patients should undergo colposcopy regardless of viral load or CD4 count.

The category ASC-H (atypical squamous cells, cannot exclude high grade squamous intraepithelial lesion) should be referred for colposcopic evaluation:

The SIL categories are divided into LSIL and HSIL to differentiate the two entities. LSIL refers to a transient infection with HPV. HSIL refers to a higher risk group associated with persistent viral infection and a higher risk of progression.

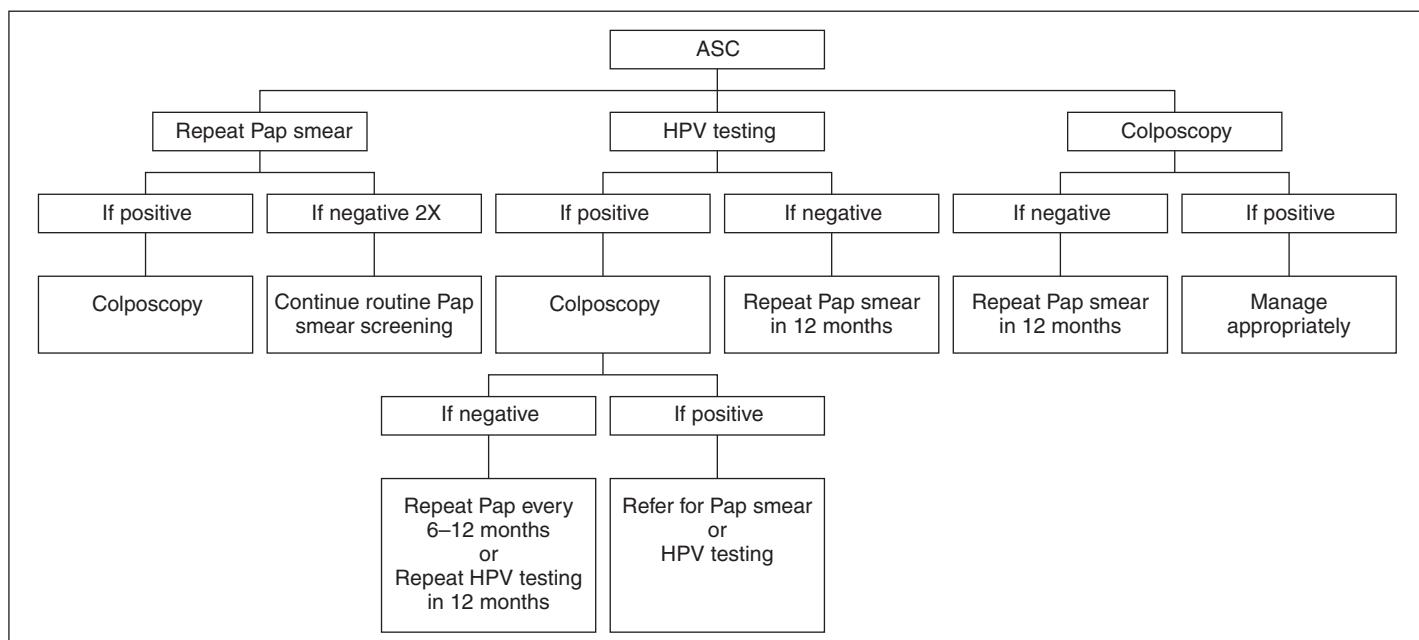

The majority of LSIL lesions will regress (47%) or persist (37%). Only 16% of patients will develop more severe lesions.<sup>13</sup> HSIL has a higher incidence of progression to CIS. From 32% to 43% of HSIL lesions will regress, 22% to 56% will progress, and lesions that are CIN III have the highest progression rate to invasive cancer (16% to 36%).<sup>14</sup> (See the flowchart at the bottom of page.)

Low-grade SIL has been managed with repeat Pap smears. Although acceptable, this approach is associated with poor compliance and the possibility for delaying diagnosis of a more severe lesion; therefore, colposcopy is recommended. HPV testing does not seem to be useful because up to 83% of women will test positive for HPV.<sup>15</sup>

High-grade SIL has been managed with colposcopy with directed biopsies. If results of the colposcopy are unsatisfactory, an excisional procedure is recommended. HPV testing for triage purposes has no role in the management of HSIL (Fig. 44-8).

Colposcopy is recommended for the management of atypical glandular cells (AGC) or endocervical carcinoma in situ (AIS). Endometrial biopsy should be performed if the woman is older than age 35 or abnormal bleeding is present. If colposcopy is negative for AGC NOS (not of significance), a repeat Pap smear should be performed every 4 to 6 months until the patient has had four consecutive negative Pap smears. If colposcopy is negative for AGC favoring neoplasia, an excisional procedure is recommended. There is not enough data to warrant HPV testing.

The 2001 revision changed the term AGUS (atypical glandular cells of undetermined significance) to differentiate this from ASCUS. There are a much higher number of high-grade diseases in this group. High-grade lesions may be seen in 10% to 39% of this group. For cases that are not sufficient to be called

**Figure 44-8 Colposcopic image of the cervix.** The transformation zone is seen completely. There are punctate lesions equivalent to CIN II seen at 8 o'clock.

AIS, a separate category has been created, atypical endocervical cells, favor neoplastic.

High-grade lesions, including CIN II, CIN III, AIS, or invasive cancer, have been found in 9% to 41% of women with AGC NOS, compared with 27% to 96% of women with AGC favoring neoplasia. Endocervical adenocarcinoma in situ is associated with AIS in 48% to 69% of cases and underlying invasive cervical carcinoma in 38% of cases.

### Microinvasive Cancer

Historically there has been much debate over the proper definition of microinvasive disease. In 1974, the Society of Gynecologic Oncologists defined *microinvasive carcinoma* as invasion with a depth of 3 mm or less. This definition was not adopted worldwide until the International Federation of Gynecology and Obstetrics (FIGO) did so in 1994 (Table 44-4).<sup>16</sup> Stage IA1 was defined as a tumor that invaded at a depth of 3 mm or less. Stage IA2 was defined as having a depth of 3 mm to 5 mm. Both stages had a horizontal spread of up to 7 mm. The purpose of this definition was to standardize treatment worldwide.

### Stage IA1

Treatment of Stage IA1 cervical cancer is conservative; it may be treated by a cone biopsy if the patient desires fertility or by an extrafascial hysterectomy if childbearing has been completed. Management is conservative secondary to the low incidence of lymph node involvement (0.5%) and low rate of recurrence (2%).<sup>17</sup>

Treatment for microinvasion on a cone biopsy depends on the margins. The surgical margins at both the endocervix and ectocervix must be negative. If there is dysplasia at the margins, a reorientation is necessary. Both Greer and colleagues and Roman and colleagues demonstrated residual disease in patients with positive margins.<sup>18,19</sup> The incidence of residual disease was 33% versus 4% if both margins were positive. If the endocervical margin was positive, 22% of women with positive margins had residual disease.

Involvement of the lymphovascular space may be present in approximately 10% of cases. Presently there is no standard treatment for these patients, although most gynecologic oncologists will agree that a more aggressive management is warranted secondary to an increased risk of lymph node positivity.

**Table 44-4**  
**FIGO Staging System for Cervical Cancer**

Stage	Qualification
0	Carcinoma in situ, intraepithelial carcinoma. Cases of Stage 0 should not be included in any therapeutic statistics for invasive carcinoma.
I	The carcinoma is strictly confined to the cervix (extension to the corpus should be disregarded).
IA	Invasive cancer identified only microscopically. All gross lesions, even with superficial invasion, are Stage IB cancers. Invasion is limited to measured stromal invasion with a maximum depth of 5 mm and no wider than 7 mm. (The depth of invasion should not be more than 5 mm taken from the base of the epithelium, either surface or glandular, from which it originates.) Vascular space involvement, either venous or lymphatic, should not alter the staging.
IA1	Measured invasion of stroma no greater than 3 mm in depth and no wider than 7 mm
IA2	Measured invasion of stroma 3 to 5 mm in depth and no wider than 7 mm
IB	Clinical lesions confined to the cervix or preclinical lesions greater than IA
IB1	Clinical lesions no greater than 4 mm in size
IB2	Clinical lesions greater than 4 mm in size
II	The carcinoma extends beyond the cervix but has not extended onto the pelvic wall; the carcinoma involves the vagina but not as far as the lower third.
IIA	No obvious parametrial involvement
IIB	Obvious parametrial involvement
III	The carcinoma has extended onto the pelvic wall; on rectal examination there is no cancer-free space between the tumor and the pelvic wall. The tumor involves the lower third of the vagina. All cases with a hydronephrosis or nonfunctioning kidney should be included, unless they are known to be due to other cause.
IIIA	No extension onto the pelvic wall, but involvement of the lower third of the vagina
IIIB	Extension onto the pelvic wall or hydronephrosis or nonfunctioning kidney
IV	The carcinoma has extended beyond the true pelvis or has clinically involved the mucosa of the bladder or rectum.
IVA	Spread of the growth to adjacent organs
IVB	Spread to distant organs

### Stage IA2

Stage IA2 cervical cancer requires more extensive surgery and is treated by a modified radical hysterectomy with pelvic lymphadenectomy. The incidence of lymph node metastasis is 7.3%, with a 3% recurrence. Pelvic lymph node dissection is sufficient, unless the lymph nodes are suspicious, which then should include dissection of the periaortic region.

If the patient desires fertility, a radical trachelectomy may be considered with nodal dissection. These are highly selected cases and patients must be counseled appropriately.

### Stage IB and IIA

Stage IB is subdivided into IB1 (tumor size <4 cm) and IB2 (tumor size >4 cm; Fig. 44-9). This subdivision was created by

**Figure 44-9 Cervical cancer Stage IB.**

FIGO in 1994 because of an increase in evidence indicating that size correlated directly with prognosis.

Generally, Stage IB1 cervical cancer is treated by a radical hysterectomy (type III). A type III hysterectomy entails removing the parametrium from where the uterine artery originates from the hypogastric artery. In addition, the upper third of the vagina is excised. There are several modifications of this technique. Removal of 2 cm of the vagina below the cervix is considered adequate margin (Fig. 44-10). For patients who are poor surgical candidates, chemoradiation therapy is another alternative.

Cervical cancer may be treated by either surgery or chemoradiation therapy. The decision is mostly institution-based or

based on the experience and comfort level of the gynecologic oncologist. The advantages of surgery are to determine prognostic factors more accurately and to preserve ovarian function and vaginal elasticity. Cure rates are equal between both groups.

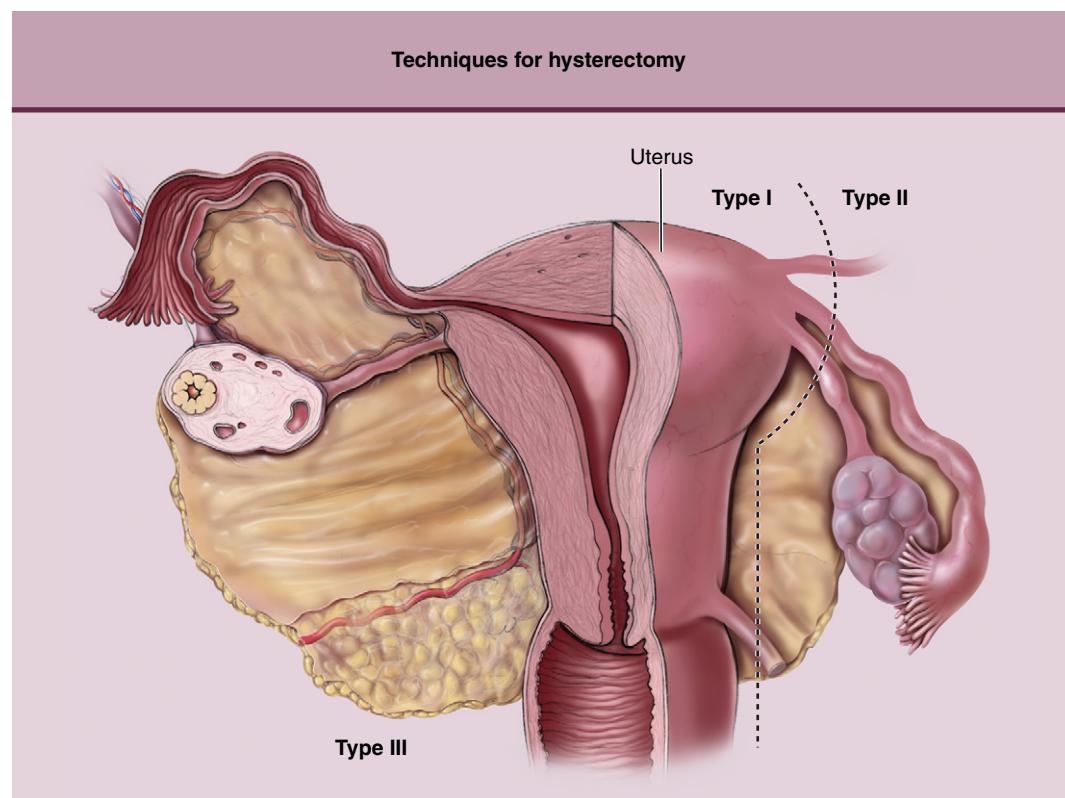

Although surgery may preserve ovarian function and vaginal elasticity, there are patients who will require adjuvant radiation therapy. Surgicopathologic prognostic factors include lymph node involvement, lymphovascular involvement, parametrial involvement, depth of invasion, vaginal margins, and the size of the tumor. These prognostic factors affect survival and thus may indicate the need for adjuvant therapy with chemotherapy and radiation.

Surgical management allows for these pathologic factors to be identified, allowing for more accurate prognosis and therapeutic recommendations. In addition, surgery affords lymph node debulking. If the patient has enlarged nodes, removing these allows the patient a better chance to respond to radiation therapy.

Complications that may occur from a radical hysterectomy are mostly related to urinary tract morbidity and bleeding. The average blood loss with a radical hysterectomy is 800 to 1500 mL.<sup>20</sup> The most common immediate postoperative complication is a urinary tract infection secondary to prolonged catheterization. In addition, many patients may have hypotonic bladder dysfunction with urine retention.

Complications occurring with radiation are related to injury to the surrounding tissues. These patients are at risk for vesicovaginal and rectovaginal fistulas. The incidence of these fistulas ranges from 0.9% to 1.6%.<sup>21</sup> In addition, many experience sexual dysfunction due to decreased caliber and vaginal elasticity. These

**Figure 44-10 Diagram indicating the extent of surgical resection for different types of hysterectomy.**

## Gynecologic Oncology

fistulas are difficult to manage and often require additional surgical intervention such as colostomy and bladder diversions and reconstructions.

Treatment for stage IB2 and IIA cervical cancers needs to be tailored to the patient's medical comorbidities and desire for sexual function preservation.

Candidates for fertility preservation are those patients with Stage IB1 cervical cancer with lesions smaller than 2 cm. If lymph nodes and lymphovascular space involvement are negative, these patients may undergo a radical trachelectomy with laparoscopic lymph node dissection. Cerclage placement should be done at the time of surgery.

In patients with bulky stage IB2 and IIA cervical cancer, many institutions prefer irradiation over surgery. One main reason to perform surgery in these patients is to "debulk" the disease. The tumor may extend beyond the radiation fields and thus not be treated optimally. These patients have a more aggressive tumor and recurrence rates of up to 30%.

### **Stage IIB to IV**

Treatment for advanced-stage cervical cancer consists of irradiation, both external beam therapy and brachytherapy, usually with radiation-sensitizing doses of chemotherapy. The extent of disease must always be evaluated, first by computed tomography and possibly by surgery for staging and resection of bulky lymph nodes that may not respond to radiotherapy. The surgical approach consists of extraperitoneal lymph node dissection to decrease morbidity and simultaneously evaluate and resect extensive nodal disease. If periaortic lymph nodes are positive, extended-field radiation is warranted.<sup>22</sup> The incidence of periaortic lymph node involvement ranges from 21% to 31%, based on stage.

Besides defining the extended field of radiation, radiation sensitizers have been proven to have an impact on treatment and survival. Several Gynecologic Oncology Group (GOG) studies have looked into different radiosensitizers such as hydroxyurea, cisplatin, and fluorouracil. Hydroxyurea was one of the first agents studied as a chemosensitizer and was found to increase the progression-free interval and survival.<sup>23</sup> A comparison between hydroxyurea and concomitant cisplatin and fluorouracil found the combination to produce superior improvement.<sup>24</sup> Rose and colleagues compared three different groups receiving radiation therapy.<sup>25</sup> Group 1 used only cisplatin; Group 2 combined cisplatin, fluorouracil, and hydroxyurea; and Group 3 used hydroxyurea only. Groups 1 and 2 showed similar progression-free survival at 24 months (64% to 77%) versus a 24% survival in Group 3. Therefore, this study proved that the cisplatin-based regimen had a superior progression-free survival. Currently, the standard is to give weekly cisplatin during radiation therapy for advanced cervical cancer.

### **TREATMENT PLAN FOR LOCALLY ADVANCED (STAGES IIB TO IVA) CERVICAL CANCER**

Treatment consists of both external beam radiation and brachytherapy. The total external beam dose is approximately 45 Gy over 4 to 6 weeks. This is then followed by one or two low-density radiation implants or serial high-density radiation.

The total amount given with brachytherapy is 85 to 90 Gy, and treatment usually lasts 6 to 8 weeks. Delays should not extend treatment past 10 weeks.

The method most commonly used is the Manchester system. This system defines two important points that will delineate the treatment area. Point A is a point 2 cm lateral and superior to the external cervical os within the plan of the implant, and Point B is 3 cm lateral with respect to point A. Point A theoretically reflects the parametria, and Point B reflects the pelvic sidewall. Other factors to take into account are the type of implant, the distance from the bladder and rectum, tumor volume, and the patient's habitus.

### **Radiation Therapy**

In general, radiation therapy is delivered in three different ways: teletherapy, brachytherapy, and interstitial therapy.

#### **Teletherapy or External Beam Therapy**

Teletherapy is defined as radiation delivered from a distance through a linear accelerator. The linear accelerator produces photon beams with accelerated electrons. Several factors influence dose distribution, including voltage of the energy beam, size of the radiation field, distance between the patient and the beam, angle of the field being treated, patient habitus, and use of other devices. To deliver appropriate treatment, computer calculations are made that account for all these factors.

The radiation plan usually will consist of two or more beams for dose distribution. The goal is to produce a homogeneous dose that will maximize treatment and minimize exposure to uninvolved tissues.

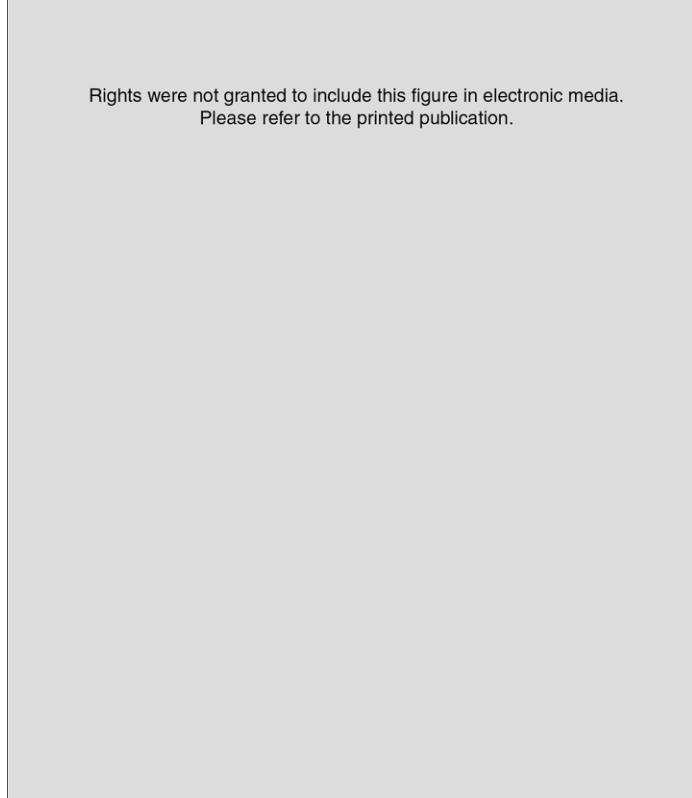

#### **Brachytherapy or Intracavitary Treatment**

Brachytherapy is radiation therapy given at a short distance, and may be given as low dose rate (LDR) or as high dose rate (HDR) treatment. Most centers will give LDR. HDR treatment consists of treatment given over minutes rather than hours and is done in an outpatient setting. Most HDR regimens consists of 5.5 to 6 Gy to point A given in five fractions. Although this kind of treatment seems more practical, there is resistance to treating patients with HDR because the optimal dosing is not quite known and there are insufficient randomized studies comparing both modalities.

Brachytherapy is an important tool for treating cervical tumors because external beam radiation is not sufficient to sterilize large tumor volumes. Most of the applications are directed toward a smaller and more specific area. Different applicators may be used, consisting of a hollow tube usually called the *tandem* and side applicators usually called *ovoids*. The applicator used most commonly is the Fletcher-Suit-Delclos, which has a pear-shaped isodose curve (Fig. 44-11).

It is essential that these applicators are properly positioned under anesthesia with radiographic confirmation. Care must be taken to avoid excessive dose to the rectum and bladder. The applicators are loaded after confirmation of placement and are usually loaded with <sup>137</sup>Cesium. The delivery dose is 40 to 60 cGy/hr. Treatment plan is 72 to 96 hours. Due to specific or unique patient characteristics, brachytherapy may be administered in two applications. This divided application does not affect the overall cumulative radiation dose.

Rights were not granted to include this figure in electronic media.  
Please refer to the printed publication.

**Figure 44-11 Tandem and ovoids for intracavitary radiation.** (From Taljanovic MS, Hunter TB: Special report: Gallery of medical devices. Part 2: Devices of the head, neck, spine, chest, and abdomen. Radiographics 2005;25:1119–1132.)

### Interstitial Radiation Therapy

With interstitial radiation therapy, the radioactive sources are placed directly into the tissue rather than in an applicator. Sources of radiation for interstitial implants are usually <sup>192</sup>iridium and <sup>125</sup>iodine. These sources can be placed as permanent seeds, temporary implants, or transperineal implants. This technique allows a high dose of radiation to be delivered within a small area. Placement needs to be accurate to avoid normal tissue damage. Transperineal implants have not been shown to be superior to intracavitary implants. Studies are equivocal for both modalities. Intracavitary implants are more practical and less painful than interstitial implants.

### Radiation Therapy Fields for Cervical Cancer

The borders of the anteroposterior (A/P) and posteroanterior (P/A) pelvic fields are the following:

- *Superior border*—a transverse line between L4 and L5. This will include the common iliac nodes. If the patient is low risk for metastatic nodal disease, the superior border may be L5–S1.
- *Inferior border*—a transverse line below the obturator foramen or ischial tuberosity (midpubis) or 2 cm below inferiormost extent of disease (if vaginal involvement is noted).
- *Lateral border*—2 cm lateral to the widest aspect of true pelvic diameter.

Note: If the lower one third of the vagina is involved, the groin nodes should be included in the treatment fields and irradiated to approximately 45 Gy at 1.8 Gy per fraction.

Custom blocking shields the small bowel and femoral heads without shielding the common or external iliac nodes (allow at least 1 cm margin). These borders help to minimize the high-dose treatment but adequately treat the tumor.

The four-field box technique is more effective and specific than the parallel technique (A/P, P/A). Lateral fields may also be important for patients who are receiving chemotherapy and should be able to preserve as much bone marrow as possible.

Specific areas may need a boost dose. In general, parametrial and/or nodal boosts will be given by A/P or P/A (>10 MV) technique. All fields will be treated on a daily basis with 1.8 Gy prescribed to Point B (a point 3 cm lateral to Point A) to bring the cumulative dose to these prescription point to 55 Gy to 70 Gy (+/-5%):

- *Parametrial/Nodal Boost*—Central blocking should measure at least 4 cm and should be tailored to the Point A isodose line from the LDR brachytherapy.
- *Nodal boosts*—These should measure at least 4 × 4 cm and maintain a margin of 1 cm from involved nodes.

### Toxicity

Side effects from cumulative radiation therapy for cervical cancer include fatigue, diarrhea, rectal irritation, urinary frequency and burning, loss of pubic hair, darkening of skin in the region within the irradiated fields, and low blood counts. Common long-term side effects include vaginal narrowing and shortening and pain during sexual intercourse. Uncommon long-term side effects may include rectal bleeding, diarrhea, rectal ulcer, urinary burning, urinary frequency, urinary bleeding, and tissue breakdown of the vagina. Rare long-term side effects include bowel obstruction, ureteral obstruction, and fistula formation between the bladder and the vagina or between the rectum and the vagina.

### Surveillance and Follow-up Care

Postradiation monthly visits are prescribed for the initial 3 months to ensure tumor regression. Should the tumor progress then surgery can be entertained. Otherwise, follow-up visits should consist of the following:

The patient should be assessed for presence of pain, bleeding, and leg edema. Bladder and rectal function should be assessed. Pap and pelvic examination should be performed every 3 months for 2 years, then every 4 to 6 months for the next year, and then every 6 months until 5 years. Routine Pap smears are important because most recurrences are asymptomatic, but will have abnormal cytology. Detection and treatment of recurrence before symptoms seem to have an improvement in survival.

The supraclavicular and inguinal nodes should be assessed for metastasis. Abdominal examination; complete visual inspection of the vagina, cervix, and urethra; and a rectovaginal examination for masses and parametrial nodularity should be performed.

Imaging is physician dependent. Computed tomography scans and chest x-rays may be useful for assessing recurrences and for treatment plans.

Tumors markers that may be used are carcinogenic embryonic antigen, CA 125, and SCA, but these are not used routinely in cervical cancer.

## **RECURRENT CERVICAL CANCER**

The majority of recurrences occur within the first 2 years after treatment (including surgery and primary radiation therapy). Perez and colleagues<sup>26</sup> reported pelvic failures as follows:

- Stage IB—10%
- Stage IIA—17%
- Stage IIB—23%
- Stage III—42%
- Stage IVA—74%

The 10-year incidence of distant metastatic disease was reported by Fagundes and colleagues<sup>27</sup> as follows:

- Stage IA—3%
- Stage IB—16%
- Stage IIA—31%
- Stage IIB—26%
- Stage III—39%
- Stage IVA—75%

The sites of recurrence were as follows:

- Lung—21%
- Bone—16%
- Periaortic nodes—11%
- Abdominal cavity—8%
- Supraclavicular nodes—7%

There are different types of recurrences. Treatment depends on location and on forms of initial treatment.

If the recurrence occurs after a radical hysterectomy, without adjuvant treatment (chemoradiation), the treatment consists of chemoradiation. If the recurrence is only at the vaginal cuff, a vaginal cylinder may be used.

Recurrences after radiation therapy are best treated by surgery only if the recurrence is in the central pelvis. This entails an exenteration, either complete or partial. The extent of the surgery depends on the location and extent of the recurrence. It may involve the bladder and/or rectum and may be above or below the levator plate.

A small group of patients may undergo a radical hysterectomy, but the morbidity is high, up to 50%. Morbidity consists of different types of fistulas, such as vesicovaginal, rectovaginal, and ureterovaginal fistula. These individuals must have a very small recurrence that is confined to the cervix to be candidates for a more conservative approach. These patients must have a lesion smaller than 2 cm with an original early-stage tumor to qualify for a radical hysterectomy. Few if any patients can be salvaged by chemotherapy.

### **Exenterations**

A pelvic exenteration is a challenging procedure for both the patient and surgeon. The patient must be prepared psychologically and should receive ostomy nursing care. Only 50% of patients who are candidates will actually undergo the procedure.

Preoperative workup includes confirmation of central recurrence, as well as complete imaging of the lungs, abdomen, and pelvis. An evaluation of renal function must be performed, as well as a sexual evaluation to include the possibility of vaginal reconstruction. Ostomy teaching must be provided. The patient must also receive psychological support.

There are essentially three parts to a pelvic exenteration: careful exploration and evaluation to make the decision to resect, the actual procedure, and reconstruction.

Exploration entails complete inspection of the avascular spaces to secure complete resection with negative margins. Aortic and pelvic node sampling are necessary to exclude disseminated disease. If any of the nodes or spaces are involved, very little benefit is achieved from such a morbid procedure.

The procedure itself depends on the extent of the disease. If the lesion only involves the cervix, a suprarelevator exenteration may be performed. However, if there is extensive vaginal involvement, the dissection must go below the levator plate. Depending on the size and location, the rectum or the bladder may be spared.

The reconstructive aspect depends on the patient's desires. Whenever possible, a low colorectal anastomosis is performed to avoid a colostomy. Urinary diversion must be considered for each patient individually. Either continent or incontinent urinary diversions may be done. The continent urinary diversions offer better quality of life if the patient is a suitable candidate. In addition, vaginal reconstruction may be performed if the exenteration is below the levator plate. This may be done with a rectus abdominis myocutaneous flap or other neovaginal techniques (Figs. 44-12 through 44-14).

Recuperation from a pelvic exenteration is extensive, with a postoperative complication rate of up to 50%, including a mortality rate of 1%. Immediate complications include postoperative bleeding, infection, pulmonary embolism, deep venous thrombosis, and renal problems. Complications that may occur later include ureteral strictures, ostomy problems, and chronic wound healing difficulties.

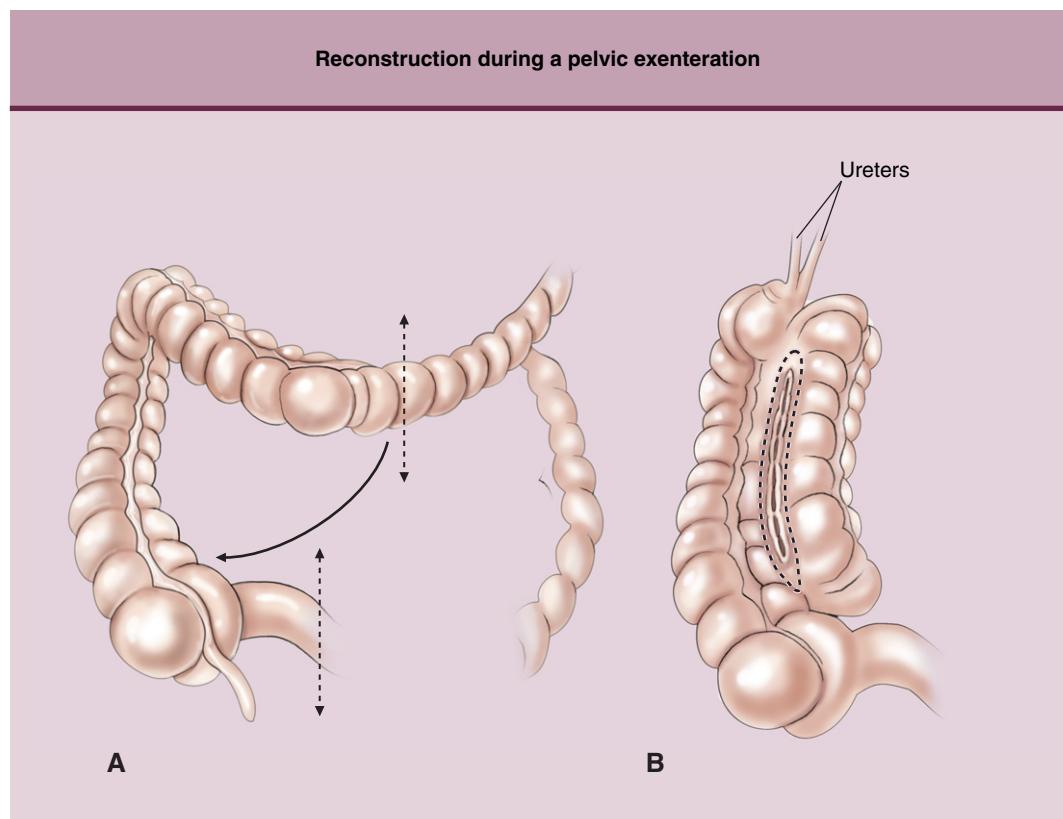

### **Radiation Therapy**

Radiation may be used for palliation in the setting of vaginal bleeding or pelvic pain. Caution must be exercised when re-irradiating an area because of increased morbidity. Radiation may be administered in large fractions to other areas of metastasis such as the brain and bony lesions that are not in the previous area of radiation.

### **Palliative Chemotherapy**

Chemotherapy in the setting of recurrence poses several problems. Most of these patients have received radiation therapy, and many of these will have received adjuvant chemotherapy. These patients have a decreased bone marrow reserve and decreased vascular supply in the pelvis due to these previous therapies. In addition, many will have ureteral stricture, which will impair their renal function or the ability to renally excrete certain chemotherapy agents.

Several different agents have been shown to have some activity against cervical cancer. The most active is cisplatin, with an overall response rate of 23%. Other agents that have some activity against cervical cancer are ifosfamide (22%), topotecan (19%), paclitaxel (17%), and vinorelbine (15%). Response rates depend on the site of recurrence. If the recurrence is outside the field of radiation, such as the lungs or liver, response rates may be up to 25%. However, if the recurrence is in the site of radiated tissue such as the pelvis, the response rate is only 5%.

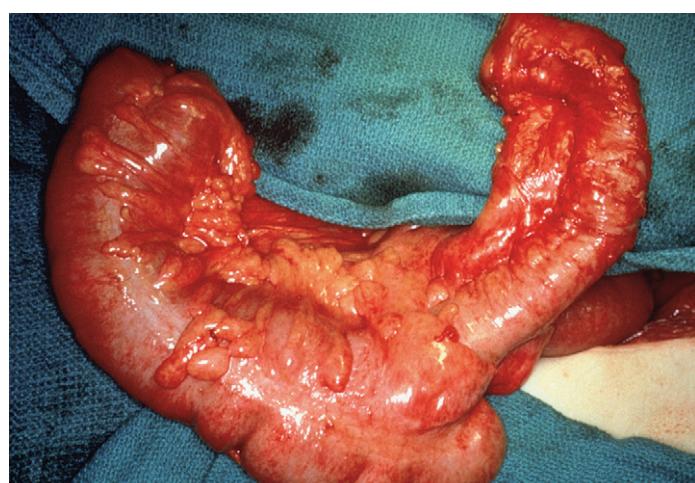

**Figure 44-12** Diagram for reconstruction during a pelvic exenteration. Approximately 12 to 15 cm of distal ileum, cecum, ascending colon, and half of the transverse colon are resected for the construction of the Miami pouch. *A*, Segment used for ileocolonic continent reconstruction: distal ileum, ascending and half of the transverse colon. *B*, Pouch seen after detubularization and reconstruction with ureters visualized.

Several GOG trials have demonstrated that the use of multi-agent chemotherapy has a better response rate and slightly improved survival rate than single agents.

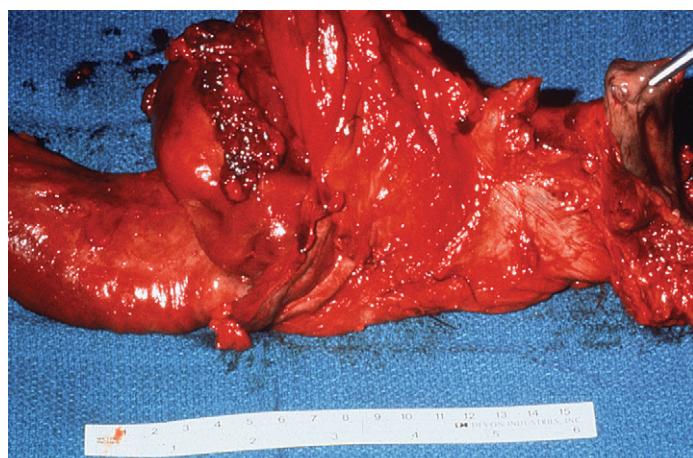

Omura and colleagues<sup>28</sup> randomized 418 patients to cisplatin alone or combined with ifosfamide or mitolactol. Response rates were higher in the cisplatin and ifosfamide group (33%) versus the cisplatin alone group (19%). Time to progression was also better in the combination group than the single-agent group (4.6 months versus 3.2 months). There was not a significant difference in overall survival.

In another GOG trial,<sup>29</sup> 280 women were randomized to receive cisplatin alone or in combination with paclitaxel. The combination group had a higher response rate (36% vs. 19%) and higher progression-free survival (4.8 months vs. 2.8 months), with no difference in overall survival.

Another GOG trial has preliminary results showing an increased overall survival in the combination group. This trial randomized 356 women to receive cisplatin alone versus in combination with topotecan versus MVAC (methotrexate, vinblastine, doxorubicin, and cisplatin). The cisplatin/topotecan

**Figure 44-13** Ileocolonic continent conduit, Miami pouch reconstruction.

**Figure 44-14** Total pelvic exenteration specimen: bladder, uterus, cervix, and rectum.

## Gynecologic Oncology

group had a higher response rate (26% vs. 13%), with a progression-free survival of 4.6 months compared to 2.9 months. The median survival difference for the cisplatin/topotecan group was 9.2 months versus 7 months.

Although several GOG trials have demonstrated a significant advantage of using combination agents versus single agents, treatment should be tailored to the patient's overall situation. Combination treatments have a higher incidence of neutropenia, renal toxicity, and peripheral neuropathy.

### BEST SUPPORTIVE CARE

In the past, palliative care was defined as care to be given during the final stages of life when treatment had failed. Currently, newer models incorporate palliative care during the initial stages of cancer treatment. In this manner, the patient has a more active role in fighting her illness. If the patient does not respond to her treatment, early introduction of palliative care may give her more autonomy and a better quality of life. It is essential for the patient to be involved from the beginning with her diagnosis, treatment plan, and decision making. Proper communication between the physician, nurses, and other caregivers is very important. In addition, psychological support should be available as well as other forms of supportive treatment.

Patients with end-stage cervical cancer may present with several different clinical presentations and symptoms, such as pain from bony metastasis, respiratory distress from lungs metastasis, and renal failure secondary to tumor growth.

Depending on a patient's wishes, tests should be done to alleviate symptoms as soon as possible. Bone metastasis can be treated with analgesics, bisphosphonates, and physical therapy. Respiratory disease may be alleviated by pleuracentesis, oxygen support, and withholding toxic treatment to give only supportive care. With regards to renal failure, involvement of the patient is essential. Some patients would rather not undergo percutaneous nephrostomies and die of uremia; others may want to continue all efforts because of fear or the need for more time. For this to be fair to the patient, complete information should be given and informed consent should be obtained. It is difficult for decisions to be made during a time of crisis. Many times, less intervention renders the patient with better quality of life.

During the final stages of illness, there should be proper support with regards to the transition toward death. Hospice care may be an option for some patients, but others may refuse. It is important to explore the patient's wishes before the final stages. In this manner, the patient has had an active role in planning her wishes as opposed to family members taking this decision from her. In addition, there must always be sensitivity to religious and culture beliefs added to any decision making.

### Pain Management

Pain has been defined by the International Association for the Study of Pain as "an unpleasant sensory or emotional experience associated with actual or potential tissue damage or described in terms of such damage." There are different forms of assessing and treating pain. One common method is the visual acuity scale, which is a simple, effective way to manage pain and assess treatment efficacy.

Pain management is adjusted to each patient's needs; a full assessment is always indicated. Other symptoms must be assessed, such as anxiety, depression, and physical tissue involvement. Once must not hesitate to use other modalities such as psychological support, integrative therapy, music therapy, and pet therapy.<sup>30</sup>

The WHO<sup>31</sup> uses a systematic ladder approach<sup>32</sup> when treating cancer pain. The first line of medications should be nonsteroidal anti-inflammatory drugs (NSAIDs) or the newer cyclo-oxygenase-2 (COX-2) inhibitors. These work by inhibiting the enzyme cyclo-oxygenase, thus reducing prostaglandins, which affect the nociceptive primary afferent neurons. NSAIDs have to be used with caution in patients with a history of gastric ulcers and renal disease. In addition, they have a ceiling effect.

The second line of drugs used to treat cancer pain is opioids, preferably agonists such as morphine. These medications do not have a ceiling. An understanding of individual pharmacodynamics of these agents, such as half-life, peak effect, and duration, is important to provide efficacious pain relief. In addition, depending on the severity of pain, different combinations may be used with NSAIDs. Presently there are alternatives to oral administration for patients who have difficulty swallowing or persistent nausea and vomiting; these routes consist of transdermal, intravenous, intraspinal, buccal, and rectal. When having difficulty managing pain, a consult from anesthesia pain experts should be obtained. In addition, patients input, perception, and wishes should always be taken into consideration.

Although many times hospice facilities manage the last moments or days of life, the physician should know how to manage this time as well and ease the pain not only for the patient, but also for the family. Agitation, anxiety, and pain may all be displayed in the final stages. Many times, patients are not able to communicate, and alleviation of symptoms may be challenging. Morphine pumps, anxiolytics, and proper hygiene care are important strategies for care in the final stages. Once again, involvement of the patient and family as much as possible provides peace and dignity to the dying patient.

## KEY POINTS

- Endometrial carcinoma is the most common gynecologic malignancy.
- The most common presenting symptom is vaginal bleeding in postmenopausal women.
- Diagnosis is made by endometrial biopsy.
- Total abdominal hysterectomy, bilateral salpingo-oophorectomy, pelvic and periaortic lymph node sampling, peritoneal washing, and omental biopsy in selected cases is the cornerstone of therapy.
- The stage of cancer is determined by the surgicopathologic findings.
- The need for adjuvant therapy (radiation and/or chemotherapy) is determined by the histologic type, tumor grade, and stage.

## EPIDEMIOLOGY, PATHOGENESIS, AND RISK FACTORS

Cancer of the uterine corpus is the most common gynecologic cancer in the United States, with approximately 40,000 cases diagnosed annually. Endometrial carcinoma is by far the most common of the uterine cancers. Other malignancies of the uterus include leiomyosarcomas, carcinosarcomas, and endometrial stromal sarcomas.

The mean and median age at diagnosis of women with endometrial carcinoma is 61 years.<sup>1</sup> Less than 5% of cases occur in women younger than age 40, and 90% occur in women older than age 50.<sup>2</sup>

### Histology

Endometrial carcinoma is divided into several histologic types; endometrioid adenocarcinoma is the most common (Table 45-1). The endometrioid adenocarcinomas can have areas of squamous metaplasia (adenoacanthoma) or areas of squamous carcinoma (adenosquamous carcinoma). In these cases the preferred histopathologic diagnosis is endometrial adenocarcinoma with benign or malignant squamous differentiation. The prognosis in cases of endometrioid endometrial adenocarcinoma with squamous differentiation is associated with the grade of the glandular component rather than the presence of a malignant squamous component. However, a malignant squamous component is usually associated with a grade 3 endometrioid adenocarcinoma; this is associated with a higher stage of cancer and a worse prognosis. Pure squamous cell carcinomas of the endometrium are extremely rare. Other histologic types, such as papillary serous and clear cell carcinomas, which are associated with a more

aggressive behavior than endometrioid carcinomas, account for 5% to 10% of endometrial cancers. These rare types of endometrial carcinoma include mucinous adenocarcinoma, secretory adenocarcinoma, and transitional cell carcinoma. The uterine papillary serous carcinomas must be distinguished from the endometrioid carcinomas with papillary architecture. The latter, also known as a villoglandular adenocarcinoma, is a well-differentiated endometrioid adenocarcinoma. In general, villoglandular endometrial adenocarcinoma is associated with a good prognosis, and uterine papillary serous carcinomas are not.

Estrogen induces mitotic activity of the endometrial epithelial and stromal cells. Under estrogenic influence the endometrium proliferates and the glandular epithelium becomes pseudostratified. Persistent estrogen stimulation unopposed by progesterone leads to endometrial hyperplasia. Depending on the architectural complexity of the glands, the hyperplasia is described as simple or complex (Fig. 45-1). The hyperplasia is further stratified by the presence or absence of cytologic atypia. Therefore, endometrial hyperplasia is classified as simple hyperplasia with or without atypia or complex hyperplasia with or without atypia (Fig. 45-2). In untreated patients endometrial hyperplasia can progress to adenocarcinoma. This has been reported to occur in 1% of cases of simple hyperplasia without atypia, 3% of complex hyperplasia without atypia, 8% of cases of simple hyperplasia with atypia, and 29% of complex hyperplasia with atypia.<sup>3,4</sup> Endometrial adenocarcinoma frequently coexists with endometrial hyperplasia. Furthermore, 20% to 50% of patients who undergo a hysterectomy a few weeks after endometrial sampling shows atypical simple or complex endometrial hyperplasia are found to have endometrial adenocarcinoma in the hysterectomy specimen.<sup>5</sup>

It has been suggested that there are two types of endometrial carcinoma, type I and II (Table 45-2). Type I are estrogen-induced, well-differentiated, superficially invasive tumors. They frequently coexist with endometrial hyperplasia, respond to treatment with progestins, and are associated with a good prognosis. Type II endometrial carcinoma may not be associated with unopposed estrogen stimulation of the endometrium. It occurs in women older than those who develop type I. It is characterized by poorly differentiated tumors (i.e., grade 3) or aggressive histologic types (e.g., papillary serous, clear cell) that deeply invade the myometrium. Type II endometrial carcinoma is associated with a poorer prognosis than type I.

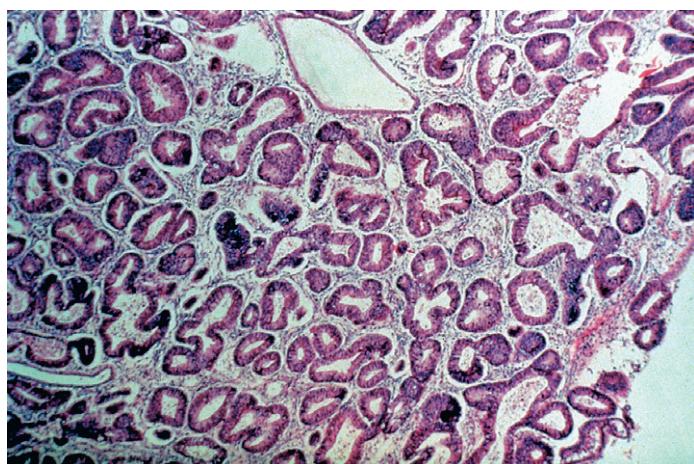

### Risk Factors

More than 75% of endometrial carcinomas are type I. Many of the identified risk factors for endometrial adenocarcinoma are associated with an excess of unopposed estrogen. Obesity of 13 to 22 kg over ideal body weight is associated with a threefold

Table 45-1

Histologic Types of Endometrial Carcinoma

- Clear cell
- Endometrioid
- Mucinous
- Papillary serous
- Secretory
- Squamous
- Transitional cell

**Figure 45-1 Simple endometrial hyperplasia.** Glandular proliferation is present; there are more glands and they are closer together than seen in normal proliferative endometrium. Plenty of endometrial stroma is still present between the glands. Some of the glands are mildly convoluted; most are round, but a few are dilated.

Table 45-2

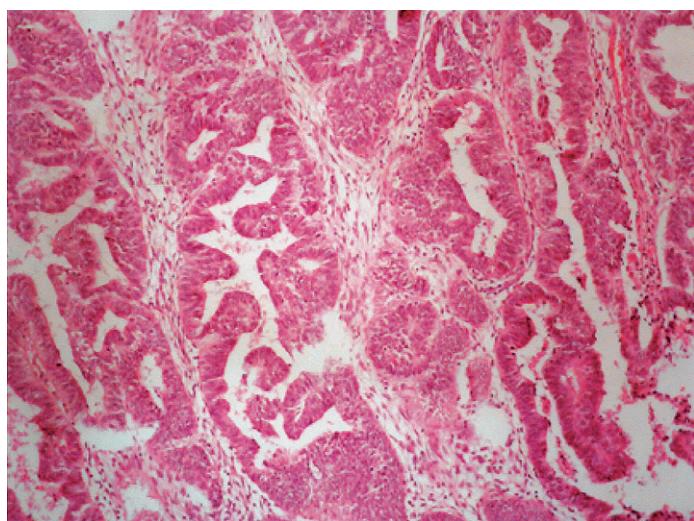

Types I and II Endometrial Carcinoma

**Type I**

- Grade 1–2
- Superficial or no myometrial invasion
- Coexisting endometrial hyperplasia
- Perimenopausal
- Induced by estrogen
- Responds to progestins
- Good prognosis

**Type II**

- High grade (grade 3, papillary serous, clear cell)
- Deep myometrial invasion
- Postmenopausal women
- Not induced by estrogen
- Does not respond to progestins
- Poor prognosis

**Figure 45-2 Complex atypical endometrial hyperplasia.** The glands are hyperplastic, with complex infolding of the glandular epithelium into the gland's lumen. Back-to-back glands with little intervening endometrial stroma are seen on the right. The nuclear atypia is not well appreciated at this magnification.

increase in the relative risk of developing endometrial adenocarcinoma<sup>6</sup>; the increase in relative risk is 10-fold in women who are 23 kg overweight. Peripheral conversion of androstenedione to estrone by the fibroblasts in the fat accounts for the increased risk. Nulliparity is associated with a twofold increase in the relative risk of developing endometrial adenocarcinoma. This is probably related to the absence of progesterone in women who are infertile secondary to anovulation resulting in unopposed estrogen stimulation of the endometrium.

Other situations associated with the development of endometrial adenocarcinoma include hypertension (1.5-fold increase in relative risk), diabetes mellitus (1.8-fold increase in relative risk), use of unopposed estrogen replacement therapy (fourfold increase in relative risk), and the presence of complex atypical endometrial hyperplasia (29-fold increase in relative risk).<sup>7</sup> Endometrial adenocarcinoma is found in 5% to 15% of women with ovarian tumors that produce estrogen (e.g., granulosa-theca cell tumor). Ten percent of women with ovarian adenocarcinoma are found to have a synchronous endometrial adenocarcinoma. In more than 50% of these cases the histologic type of both tumors is endometrioid, making it difficult for the pathologist to distinguish between metastasis or the presence of two primary cancers.<sup>8–10</sup>

The use of tamoxifen also increases the risk of developing endometrial adenocarcinoma and carcinosarcoma. In the North American breast cancer clinical trials, the use of 20 mg/d of tamoxifen resulted in a 7.5-fold increase in the relative risk of developing endometrial adenocarcinoma.<sup>6</sup> In women taking placebo the annual incidence of endometrial adenocarcinoma was 0.2/1000; in women who took tamoxifen it was 1.6/1000. Since the expected mortality from endometrial adenocarcinoma is 15% (i.e., 0.24/1000 women taking tamoxifen), annual screening of the thousands of women who take tamoxifen could potentially prevent death from endometrial adenocarcinoma in only a small fraction of them. Routine screening for endometrial carcinoma in women taking tamoxifen is not recommended. However, endometrial sampling should be done in women who experience vaginal bleeding while on tamoxifen.<sup>4</sup>

Endometrial adenocarcinoma is more common among members of families with hereditary nonpolyposis colorectal

cancer (HNPCC).<sup>4,11</sup> HNPCC is also known as Lynch syndrome and is subdivided into Lynch I and Lynch II. The Lynch I syndrome is characterized by early-onset (median age, 46 years) colorectal cancer that shows a predilection (60% to 70%) for the proximal colon and has a high rate of multiple primary colorectal carcinomas. The Lynch II syndrome has all of the preceding features, but in addition includes a number of extracolonic cancers (endometrial, ovarian, small intestine, gastric, pancreas, transitional cell carcinoma of the ureter and renal pelvis), the most common of which is endometrial adenocarcinoma.

Mutations of DNA mismatch repair genes in chromosome 2p (hMSH2) and chromosome 3p (hMLH1) account for 90% of HNPCC cases. This disturbance in DNA mismatch repair leads to genetic instability in somatic cells.

The lifetime risk for developing endometrial carcinoma for HNPCC gene carriers may be as high as 30%. It is recommended that, starting at age 30, women from HNPCC families undergo annual endometrial sampling.<sup>12</sup> These women should also undergo a colonoscopy every 2 years from age 20 to 35 and annually thereafter. At present, it is also recommended that starting at age 30 they undergo annual transvaginal sonographic examination of the ovaries and serum CA 125 determination. Prophylactic oophorectomy should be considered if preserving fertility is not an issue.

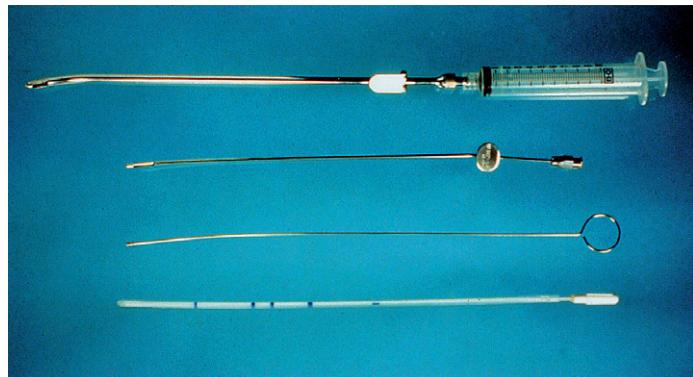

A number of studies have shown that full-term pregnancies and the use of oral contraceptives provide a degree of protection from endometrial carcinoma. A linear inverse relationship exists between the number of full-term pregnancies and the relative risk of developing endometrial carcinoma.<sup>13,14</sup> The use of oral contraceptives has been consistently associated with an approximately 50% reduction in the relative risk of developing endometrial carcinoma.<sup>15</sup>

The risk factors for type II endometrial carcinoma have not been as thoroughly studied as those for type I. Studies of patients with uterine papillary serous carcinoma and clear cell carcinoma do not show an association with estrogen use, obesity, diabetes mellitus, or hypertension.<sup>16,17</sup>

## DIAGNOSIS

Abnormal uterine bleeding (e.g., menometrorrhagia, postmenopausal bleeding) is the typical presenting symptom in women with endometrial hyperplasia or carcinoma. Some patients may complain of bloody-tinged, sometimes purulent (in cases of carcinoma) vaginal discharge. Rarely, the diagnosis is made while investigating a Papanicolaou smear showing abnormal glandular cells. On occasion the endometrial hyperplasia or carcinoma is found in a uterus removed for some other condition.

In a woman with postmenopausal bleeding, sampling of the endometrial cavity is mandatory; it should be strongly considered in women older than age 40 who have abnormal menses or intermenstrual bleeding. This could be done by traditional dilatation and curettage (D&C). However, a number of endometrial sampling devices that do not require cervical dilatation and that are appropriate for the clinical office setting (Fig. 45-3)<sup>18</sup> offer the same sensitivity for detecting endometrial hyperplasia or adenocarcinoma as D&C.<sup>18</sup> Office endometrial sampling has now become routine for the evaluation of women with abnormal uterine bleeding. Dilatation and curettage samples about 50%

**Figure 45-3 Several endometrial sampling devices.** A, Novak curette attached to a syringe. B and C, Hofmeister curet, a thinner, metal curette with stylet. D, the plastic Pipelle (Unimar, Wilton, CT) or similar device is the most popular endometrial sampling device in use today. It is 3 mm in diameter and 25 cm long. After the operator inserts the Pipelle into the endometrial cavity to the fundus, the inner plastic stylet is withdrawn. This creates suction. As the Pipelle is slowly withdrawn and rotated, endometrium is suctioned into the hollow of the device.

of the endometrial cavity, but the most commonly used suction endometrial sampling devices sample less than 15%. Therefore, a D&C should be performed if the endometrial biopsy detects hyperplasia. A neighboring adenocarcinoma may have been missed by the limited sample obtained by the endometrial aspiration device.

Hysteroscopy does not offer better sensitivity for detecting endometrial hyperplasia or adenocarcinoma than an endometrial biopsy. However, if the endometrial biopsy is negative or inconclusive and the patient continues to experience vaginal bleeding, hysteroscopy should be considered. Hysteroscopy is better than D&C at detecting endometrial polyps and submucosal fibroids.<sup>19</sup> Sonohysterography can also detect these lesions, but hysteroscopy/D&C might still be necessary since endometrial hyperplasia or cancer can be found, although infrequently, in endometrial polyps.<sup>20</sup>

The probability of finding endometrial cancer in the endometrial curettings from a woman with postmenopausal bleeding is age dependent. The frequency of endometrial cancer in women age 50 to 59 with postmenopausal bleeding is 9%; in women age 60 to 69, 16%; in women age 70 to 79, 28%; and in women older than age 80, 60%.<sup>21</sup> Although some have tried to predict the presence of endometrial adenocarcinoma in women with postmenopausal bleeding based on the risk factors discussed previously, the models proposed are not sufficiently sensitive.<sup>22</sup> In the rare situation in which endometrial sampling cannot be accomplished, transvaginal ultrasonography is of value. At a threshold of 5 mm for endometrial thickness, the negative predictive value of transvaginal sonography is 99%. However, the positive predictive value for detecting any abnormality is only 9%.<sup>23</sup>

## TREATMENT

### Endometrial Hyperplasia

After excluding an estrogen-producing tumor as the cause of endometrial hyperplasia, treatment with progestins can prevent

## Gynecologic Oncology

the development of endometrial adenocarcinoma. For treatment purposes patients with endometrial hyperplasia can be divided into those with atypical hyperplasia (who are at higher risk for developing carcinoma) and those without atypia. Women with simple or complex endometrial hyperplasia without atypia are treated with either cyclic (e.g., medroxyprogesterone 10 mg/d the first 14 days of every month) or continuous (e.g., megestrol 20 mg bid) progestins. However, laboratory data suggests that the cyclic administration may be more effective.<sup>24</sup> The successful treatment of endometrial hyperplasia using a progestin-releasing intrauterine device (IUD) has also been reported.<sup>25</sup> An endometrial biopsy obtained after 3 to 6 months of therapy should reveal a normal endometrium with pregestational changes. After resolution of the hyperplasia, women at risk for pregnancy who do not desire one are placed on oral contraceptives, if not contraindicated. Those who are anovulatory and desire to become pregnant can undergo ovulation induction. Those who are not at risk for pregnancy can continue on cyclic progestin therapy. The disappearance of withdrawal bleeding after 14 days of progestin would indicate that there is no longer enough circulating estrogen to stimulate the endometrium and progestin therapy can be discontinued.

As stated previously, women with atypical endometrial hyperplasia (simple or complex) are at risk for harboring a coexistent adenocarcinoma. If they have completed their family, a hysterectomy should be considered. If they want to preserve their uterus or have comorbid conditions that significantly increase the risk of surgical complications, treatment with continuous progestins is instituted. Megestrol acetate (20 to 40 mg bid) is one option. Alternatives include the use of depot medroxyprogesterone or a progestin-containing IUD.<sup>25</sup> The endometrium is sampled 3 to 6 months after the initiation of therapy. If the hyperplasia persists and the patient is at high risk for surgical complications, a pelvic magnetic resonance imaging (MRI) study will help exclude a coexistent endometrial adenocarcinoma with myometrial invasion. If the MRI shows a normal junctional zone, intracavitary radiation (i.e., brachytherapy) could be considered.

Surgery is the cornerstone of therapy for endometrial carcinoma. Most patients with endometrial cancer undergo surgical staging. The pretreatment evaluation, when surgery is to be performed by a gynecologic oncologist, can be limited to a chest radiograph and routine blood studies. Pretreatment studies such as cystoscopy, sigmoidoscopy, intravenous pyelogram, and barium enema have been found to be unnecessary.<sup>26</sup> Preoperative computed tomography (CT) has a poor positive predictive value (50%) and poor sensitivity (57%) for detecting lymph node metastasis.<sup>26</sup> The CT findings seldom alter the treatment plan.

### Presurgical Evaluation of Carcinoma

Patients with stage IA or IB, grade 1 endometrial adenocarcinoma are at low risk of having lymph node metastasis. In these patients there is little to gain by doing a lymphadenectomy and there are some risks associated with it. These patients can have their surgery performed by a gynecologic generalist. A preoperative pelvic MRI can determine the absence of myometrial invasion.<sup>27–29</sup> In addition, the probability of finding extrauterine disease with a serum CA 125 of less than 20 U/mL is close to 0%.<sup>30</sup> Therefore, a preoperative MRI and a CA 125 in a woman with clinical stage I, grade 1 endometrial adenocarcinoma can

identify patients that can be treated with a hysterectomy only (i.e., normal junctional zone on gadolinium-enhanced MRI, CA 125 < 20 U/mL). In this select group of patients a transvaginal hysterectomy can be considered.<sup>30</sup>

### Staging Endometrial Carcinoma

The International Federation of Gynecology and Obstetrics (FIGO) staging of endometrial carcinoma in use today was adopted in 1988 (Table 45-3). It requires surgery and careful pathologic evaluation of the removed tissues. The clinical staging classification used before 1988 is an alternative if the patient cannot be surgically staged (Table 45-4).

Table 45-3 FIGO Staging of Endometrial Carcinoma	
Stage	Description
I	Confined to the body of the uterus
IA	No myometrial invasion
IB	Involves myometrium to <50%
IC	Involves the myometrium to 50% depth or more
II	Involves the uterus and the cervix
IIA	Cancer in the cervix is no deeper than the endocervical glands
IIB	Cancer in the cervix invades the stroma below the endocervical glands
III	Cancer invades the uterine serosa, adnexa, retroperitoneal nodes, or vagina and/or positive peritoneal cytology
IIIA	Positive peritoneal cytology, uterine serosal and/or adnexal involvement with cancer
IIIB	Cancer present in the vagina
IIIC	Cancer present in the pelvic and/or periaortic lymph nodes
IV	Intra-abdominal metastasis, metastasis outside of the abdomen and pelvis to include to the inguinal nodes and/or rectal or bladder mucosa invasion by the cancer
IVA	Rectal and/or bladder mucosa invasion by the cancer
IVB	Intra-abdominal metastasis (e.g., metastasis to omentum) metastasis to inguinal nodes, distant metastasis (e.g., metastasis to lungs)

The stage also includes the tumor grade

Grade 1	5% or less of the tumor is solid
Grade 2	6% to 50% of the tumor is solid
Grade 3	>50% of the tumor is solid

In cases of significant nuclear atypia, the cancer is upgraded one grade. In patients who cannot undergo surgery, the clinical staging system in place before 1988 is used.

Table 45-4 Clinical Staging of Endometrial Cancer in Use Before 1988*	
Stage	Description
I	Confined to the uterus
IA	Uterus sounds to ≤8 cm
IB	Uterus sounds to >8 cm
II	Cancer extends to the cervix
III	Cancer involves other pelvic organs, other than the bladder or rectum
IVA	Invasion into bladder and/or rectal mucosa
IVB	Distant metastasis

\*This classification is used for patients who cannot undergo surgicopathologic staging.

The surgicopathologic staging classification correlates better than clinical staging with the risk for nodal metastasis and prognosis. For each stage, the grade of the tumor is included. The FIGO grading system for endometrial adenocarcinoma is based on the architectural features of the tumor. In grade 1 endometrial adenocarcinomas, 5% or less of the tumor is solid. Grade 2 tumors are 6% to 50% solid, and grade 3 tumors are more than 50% solid. In tumors with a squamous cell carcinoma component (i.e., adenosquamous), the grading is based on the glandular component. Tumors with significant cytologic atypia are upgraded one grade higher than their architectural grading would suggest. In papillary serous and clear cell carcinomas nuclear grading takes precedence, but these histologic types are usually considered grade 3.

In patients with surgicopathologic stage I disease, the endometrial carcinoma is confined to the corpus. If there is no myometrial invasion it is stage IA. If invasion is limited to the inner half of the myometrium (<50%), it is stage IB. If the carcinoma invades the outer half of the myometrium ( $\geq 50\%$ ), it is stage IC. There is a direct correlation between the depth of myometrial invasion and the proportion of patients found to have pelvic or periaortic nodal metastasis (Table 45-5).<sup>31</sup> Eleven percent of patients with deep myometrial invasion and grade 1 endometrial adenocarcinoma have pelvic node metastasis. Pelvic node metastases are found in 19% of patients with grade 2 deeply invasive tumors and in 34% with grade 3 deeply invasive tumors. Periaortic node metastases are found in 6% of patients with deep myometrial invasion and grade 1 adenocarcinoma. They are found in 14% of patients with deeply invasive grade 2 adenocarcinomas and in 23% of patients with deeply invasive grade 3 tumors. However, metastases to the pelvic or periaortic lymph nodes are negligible in patients with grade 3 tumors with no myometrial invasion.

Stage II tumors involve the uterine corpus and the cervix. If the tumor does not invade any deeper than the normal location of the endocervical glands it is classified as stage IIA. If there is cervical stromal invasion below the endocervical glands it is classified as stage IIB. Patients with stage IIA endometrial adenocarcinoma have a better prognosis than patients with stage IIB.

**Table 45-5**  
**Percentage of Patients with Pelvic and Periaortic Node Metastasis**  
**in Endometrial Carcinoma\***

	Grade 1 (N=180)		Grade 2 (N=288)		Grade 3 (N=153)	
	Pelvic (%)	PA (%)	Pelvic (%)	PA (%)	Pelvic (%)	PA (%)
Depth of Invasion						
None (N=86)	0	0	3	3	0	0
Inner 1/3 (N=281)	3	1	5	4	9	4
Mid 1/3 (N=115)	0	5	9	0	4	0
Out 1/3 (N=139)	11	6	19	14	34	23

PA, periaortic nodes.  
\*Based on histologic grade and depth of myometrial invasion.  
From Creasman WT, Morrow CP, Bundy BN, et al: Surgical pathologic spread of endometrial cancer. Cancer 1987;60:2035-2041.

Stage IIIA endometrial carcinoma includes a heterogeneous group of patients. These patients may have invasion of the carcinoma to the uterine serosa, involvement of the adnexa, or positive peritoneal washings. Patients with one of these findings and those with two or three of them are still classified as having stage IIIA endometrial carcinoma. However, the prognosis worsens as the number of factors that would classify a patient as having stage IIIA disease increases. Among women with stage IIIA endometrial adenocarcinoma, those with positive peritoneal cytology have a better prognosis than those with adnexal metastasis or uterine serosal involvement.<sup>32</sup>

In 1981, Creasman and collaborators reported on 167 patients with clinical stage I endometrial cancer.<sup>33</sup> Malignant cells were identified in the peritoneal washings of 15% of these patients. Patients with positive peritoneal cytology had a poorer probability of survival than those with negative washings. This was true in the presence or absence of identified extrauterine cancer. However, not all patients underwent systematic surgical staging. At the Roswell Park Cancer Institute women with stage I endometrial adenocarcinoma received a prehysterectomy intrauterine radioactive implant. Of 93 patients reported by Yazigi and colleagues<sup>34</sup> in 1983, 10 had positive peritoneal cytology. There was no statistically significant difference in survival probability between patients with negative or positive peritoneal washings. In 1992, Kadar and collaborators reported on 269 women with clinical stage I or II endometrial adenocarcinoma who underwent systematic surgical staging. Thirty-four (13%) were found to have positive peritoneal cytology.<sup>35</sup> No difference in the probability of survival was found between patients with positive or negative peritoneal cytology who had no extrauterine metastasis. However, the cumulative 5-year survival of patients with extrauterine metastasis (e.g., metastasis to periaortic lymph nodes) and positive peritoneal cytology was 13%, whereas it was 73% if the cytology was negative. This correlates with Gynecologic Oncology Group (GOG) data that showed that in women with clinical stage I and II endometrial adenocarcinoma who underwent surgical staging, recurrences occurred in 64 (11%) of 611 with negative washings and in 25 of 86 (29%) of those with positive washings.<sup>36</sup> However, recurrences occurred in only 6 (19%) of 32 women with positive peritoneal cytology without other risk factors. The preceding data suggest that the presence of positive peritoneal cytology is of most clinical significance in patients with endometrial adenocarcinoma who have extrauterine spread.

Endometrial carcinoma that invades the bladder or rectal mucosa is classified as stage IVA. If intra-abdominal, extra-abdominal, or inguinal lymph nodes metastases are present, the disease is classified as stage IVB. Extrapelvic peritoneal metastases are found in approximately 10% of patients with clinical stage I, grade 2 or 3 endometrioid adenocarcinoma or high-risk histologic types (i.e., papillary serous, clear cell).<sup>37</sup> In most, the metastases are macroscopic. This highlights the importance of careful exploration of the entire peritoneal cavity.

### Treatment of Endometrial Carcinoma

Although surgery is the cornerstone of therapy for endometrial cancer, patients who are not surgical candidates can be effectively treated with radiation. To obtain results similar to those obtained in patients who undergo primary surgical therapy, both

## Gynecologic Oncology

external beam (teletherapy) and intracavitary irradiation (brachytherapy) should be used.<sup>38</sup> Pretreatment evaluation with CT and/or MRI is performed. Patients with grade 1 adenocarcinoma, no myometrial invasion on MRI, and a CA 125 of less than 20 U/mL can be treated with brachytherapy only. Women with well-differentiated endometrial adenocarcinoma who are not fit to undergo brachytherapy or women who are young and desire to preserve their fertility can be treated with progestins.<sup>39</sup> An MRI of the pelvis and a serum CA 125 determination are obtained before taking this approach. Approximately 70% of women with a grade 1 endometrial adenocarcinoma who are treated with progestins will have a complete response.<sup>39</sup> Megestrol acetate (80 mg bid) is one treatment option. Sampling of the endometrium is done after 3 to 6 months of therapy.

Most women with endometrial cancer are treated primarily by total abdominal hysterectomy and bilateral salpingo-oophorectomy. The abdomen is opened through a low vertical midline incision that can be extended above the umbilicus if periaortic lymph node dissection is to be performed. On entering the abdomen, pelvic washings are obtained utilizing at least 200 mL of saline. Laparoscopic-assisted vaginal hysterectomy (LAVH) and bilateral salpingo-oophorectomy is an alternative to laparotomy. If LAVH is done, peritoneal washings are obtained early in the procedure. If necessary a laparoscopic pelvic and/or periaortic node dissection can be done.

Although the status of the pelvic and periaortic lymph nodes is considered in FIGO staging, most patients with endometrial adenocarcinoma do not undergo lymphadenectomy. The National Cancer Institute's Survival, Epidemiology, and End Results (SEER) database has 23,258 women with "stage I" endometrial adenocarcinoma treated between 1998 and 2000. Only 6371 (27%) underwent lymph node dissection.<sup>40</sup> Lymphadenectomy is routinely performed by only 54% of gynecologic oncologists in North America who took part of a survey in 1994.<sup>41</sup> This is so because the need for adjuvant therapy directed at the pelvic lymph nodes can be determined by the grade of the tumor and the depth of myometrial invasion. One study showed that no patient with stage IA or IB, grade 1 or 2 endometrial adenocarcinoma with greatest surface dimension of 2 cm or less had positive lymph nodes or died of cancer.<sup>42</sup> It has been shown that when adjuvant whole pelvis irradiation is limited to patients at risk for pelvic node metastasis, the recurrence rate is 10%.<sup>43</sup> The cumulative 5-year survival of patients with endometrial adenocarcinoma at low risk of pelvic node metastasis treated with surgery only is not statistically different from that of patients who are at higher risk of pelvic node metastasis and who receive adjuvant whole pelvis irradiation after surgery.<sup>44</sup> In addition, 38% of patients who do not receive postsurgical adjuvant irradiation and who develop a recurrence are salvaged by radiation therapy.<sup>45</sup> This means that even if 10% of patients with low-risk endometrial adenocarcinoma were to recur, the cure rate for this group of patients would be at least 93%.

The GOG showed that 9% of women with clinical stage I endometrial adenocarcinoma have pelvic node metastasis.<sup>31</sup> Ninety-five percent of the pelvic node metastasis occurs in patients with deeply invasive tumors or grade 2 or 3 adenocarcinomas. Pelvic node metastasis is found in 5% or less of patients with grade 1 or 2 adenocarcinoma that does not invade the myometrium or in which the invasion is limited to the inner

third (see Table 45-5). In contrast, 11% of patients with grade 1 endometrial adenocarcinomas that invaded to the outer third of the myometrium have pelvic node metastasis. Therefore, adjuvant whole pelvis irradiation should be considered for patients with stage IC endometrial adenocarcinoma of any grade.

Some advocate the performance of pelvic and periaortic lymphadenectomy in all patients with endometrial adenocarcinoma grossly confined to the uterus<sup>46</sup>; others suggest that it is not necessary to perform the lymphadenectomy in patients with stage IA or IB, grade 1 adenocarcinoma.<sup>47</sup> Orr and colleagues<sup>46</sup> reported on 69 patients with stage IC endometrial adenocarcinoma who underwent pelvic and periaortic lymphadenectomy and did not receive radiation. Their cumulative 5-year survival was 93%. Larson and colleagues<sup>47</sup> performed pelvic and periaortic lymphadenectomy in 123 patients with clinical stage I, grade 2 or 3 endometrial adenocarcinoma, or stage I, grade 1 with invasion to the outer half of the myometrium. Of these patients, 105 (85%) had negative nodes and a median follow-up of 39 months. Their cumulative 5-year survival was 91%. Of the 18 patients with metastasis to the lymph nodes, 5 had estrogen receptor-positive tumors and received 320 mg of megestrol acetate daily. Thirteen had estrogen receptor-negative tumors and were treated with chemotherapy (cyclophosphamide, doxorubicin, and cisplatin). With a median follow-up of 51 months, the cumulative 5-year survival of these 18 patients is 85%.

Orr and colleagues<sup>46</sup> did not show a clinically significant increase in the morbidity associated with performing a pelvic and periaortic lymphadenectomy. In contrast, investigators from Duke University did show that women with endometrial adenocarcinoma who underwent pelvic lymph node sampling sustained increased blood loss and transfusions, longer operative time, and increased morbidity.<sup>48</sup> In addition, Lewandowski and colleagues<sup>49</sup> showed an increase in intestinal complications in patients who received whole pelvis radiation after pelvic and periaortic lymphadenectomy. Eleven percent of patients who received whole pelvis radiation after total abdominal hysterectomy, bilateral salpingo-oophorectomy, and pelvic and periaortic lymphadenectomy developed intestinal complications. Intestinal complications were not reported among women who received postoperative whole pelvis radiation and who did not undergo lymphadenectomy.

Periaortic node metastases are present in 5% of women with clinical stage I endometrial adenocarcinoma.<sup>31</sup> Ninety-four percent of patients with periaortic node metastasis have grade 2 or 3 tumors or grade 1 adenocarcinomas that invade deeply into the myometrium. Less than 5% of patients whose tumors do not penetrate any deeper than the inner one third of the myometrium have periaortic node metastasis (see Table 45-5).

The Postoperative Radiation Therapy for Endometrial Carcinoma (PORTEC) study group randomized patients with endometrial carcinoma after total abdominal hysterectomy and bilateral salpingo-oophorectomy without lymph node dissection to receive 4600 cGy to the pelvis or to observation.<sup>50</sup> This is the only published randomized trial with long-term follow-up that studies the value of adjuvant pelvic radiation therapy in patients with endometrial carcinoma with intermediate risk factors. The PORTEC trial was limited to women with stage IC, grade 1 or 2 endometrial adenocarcinoma or stage IB, grade 2 or 3 disease.

Patients with stage IC, grade 3 tumors were not included. Patients with stage IA, any grade, or stage IB, grade 1 carcinoma were also excluded.

In this group of patients with endometrial adenocarcinoma with intermediate risk of recurrence who did not undergo a lymphadenectomy the actuarial 8-year survival rate is no different for the adjuvant radiation therapy group and the observation group, 71% and 77%, respectively. The 8-year actuarial locoregional failure rate was higher in the observation group (15%) than in the adjuvant radiation group (4%). Most recurrences in the observation group occurred in the vagina (32 of 41). Of the patients in the observation group with vaginal recurrences, 30 received treatment for the recurrence with curative intent. Twenty-six of the 30 achieved a complete response and 20 were without disease at last follow-up. The actuarial 5-year survival rate after vaginal recurrence in the observation group and in the radiation therapy group is 65% and 43%, respectively.

A similar study by the GOG, with a median follow-up of 69 months, randomized surgically staged women with stage IB, IC, and II (occult disease) endometrial adenocarcinoma to adjuvant whole pelvis irradiation or observation.<sup>51</sup> This study also shows no difference in survival. The estimated 4-year survival was 86% in the observation group and 92% in the radiation arm ( $P = 0.557$ ).

The PORTEC study found that the rate of locoregional failure was significant (>10%) only among women older than age 60 and among those with grade 2 deeply invasive tumors and stage IB, grade 3 tumors. In a retrospective study, investigators from the Mayo Clinic identified lymphovascular invasion (LVI) as another significant risk factor for local failures.<sup>52</sup> Others have shown that tumor size (>2 cm) is also a significant risk factor.<sup>53</sup> Therefore, patients with stage IB, grade 3 tumors who are age 60 or older, have tumors with LVI, and/or tumors larger than 2 cm may benefit from adjuvant whole pelvis irradiation, especially if the periaortic nodes are histologically negative.

Based on the preceding data, the therapeutic approach to endometrial adenocarcinoma that offers the best therapeutic index (minimizes morbidity and maximizes cure rate) is the following (Tables 45-6 and 45-7). On entering the abdomen peritoneal cytology is obtained. A total hysterectomy and bilateral salpingo-oophorectomy is performed. An omental biopsy is obtained in cases of papillary serous or clear cell carcinoma. Lymphadenectomy is not performed in patients with grade 1 tumors that on gross examination and/or frozen section of the uterine specimen show less than 33% myometrial invasion.

In selected patients (not obese, low surgical risk) with grade 2 or 3 tumors or deeply invasive grade 1 carcinomas, a bilateral pelvic lymphadenectomy and periaortic node sampling is performed. If metastases in lymph nodes are found (i.e., stage IIIC), chemotherapy with cisplatin and doxorubicin has been recently found to offer a survival advantage over whole abdominal radiation.<sup>54</sup> An ongoing GOG study could show that the addition of chemotherapy to a smaller radiation field (whole pelvis with or without periaortics) improves the probability of survival.<sup>38</sup>

In patients with deeply invasive grade 1 adenocarcinomas and patients with grade 2 or 3 adenocarcinoma, periaortic node dissection might discover extrapelvic disease. Adjuvant whole pelvis radiation is given to patients who have stage IC adeno-

**Table 45-6**  
**Guidelines for Adjuvant Therapy of Endometrial Cancer after Total Abdominal Hysterectomy, Bilateral Salpingo-oophorectomy, and Periaortic Node Dissection Without Pelvic Node Dissection**

Stage	Adjuvant Therapy	Rationale
IA grade 1–3	None	Positive nodes, recurrence rate <5%
IB grade 1 & 2	None	Locoregional failure <5%
IB grade 3 <60 yo no LVI <2 cm*	None or WP XRT	Low locoregional failure (but based on limited data)
IB grade 3 >60 yo LVI >2 cm	WP XRT	Locoregional failure, pos. pelvic nodes >10%
IC grade 1*	Individualize, consider WP XRT	Locoregional failure—7% 11% positive pelvic nodes with outer third myometrial invasion
IC grade 2–3	WP XRT	Locoregional failure—15% >10% positive pelvic nodes
As above, with positive periaortic (stage IIIC)	Chemotherapy  Consider whole pelvis and periaortic irradiation followed by chemotherapy	Better survival probability with chemotherapy than with WAR  Under investigation

LVI, lymphovascular invasion; WAR, whole abdominal radiation; WP XRT, whole pelvis radiation.

\*In these patients, pelvic lymphadenectomy could offer the best therapeutic index.

carcinoma of any grade or stage IB, grade 3 adenocarcinoma and who were considered poor candidates for a pelvic lymphadenectomy (see Table 45-6). The addition of intravaginal radioactive implant (i.e., brachytherapy) to adjuvant whole pelvis irradiation has been shown to increase the rate of therapy-induced toxicity and has no impact on local control or the probability of survival.<sup>55</sup> If periaortic node metastasis is discovered, chemotherapy with cisplatin and doxorubicin or carboplatin and paclitaxel can be given. Alternatively, these patients can be entered in a clinical trial. One such trial randomizes patients to receive cisplatin and doxorubicin versus cisplatin, doxorubicin, and paclitaxel after whole pelvis irradiation with or without radiation to the periaortic area, as indicated.<sup>38</sup>

**Table 45-7**  
**Guidelines for Adjuvant Therapy of Endometrial Carcinoma after Total Abdominal Hysterectomy, Bilateral Salpingo-oophorectomy, and Pelvic and Periaortic Lymphadenectomy**

Stage	Adjuvant Therapy
IA-C, grade 1–3	None (consider vaginal brachytherapy in grade 3 or with LVI)
IIA-B, grade 1–3	Vaginal radiation implant
IIIC and IVB	Chemotherapy
IIIA, IIIB, IVA	See text

LVI, lymphovascular invasion.

Patients with stage I papillary serous carcinoma have a poorer survival probability than patients with endometrioid adenocarcinoma.<sup>4</sup> Their survival probability seems to improve if they are treated aggressively following surgery with radiation and platinum-based chemotherapy.<sup>56</sup> Patients with advanced or recurrent uterine papillary serous carcinoma respond to carboplatin and paclitaxel better than to any other chemotherapy combination.<sup>57</sup> The combination of carboplatin and paclitaxel is increasingly being used in these cases.

Patients with clinically obvious cervical involvement by the endometrial adenocarcinoma (i.e., stage IIB) can be treated with a radical hysterectomy, bilateral salpingo-oophorectomy, bilateral pelvic lymphadenectomy, and periaortic node dissection.<sup>58</sup> In most cases a preferable alternative is to deliver preoperative external-beam whole pelvis radiation and one intrauterine radioactive implant followed 6 weeks later by an extrafascial total abdominal hysterectomy, bilateral salpingo-oophorectomy, and periaortic node dissection.<sup>38</sup> If extrapelvic metastases are found, chemotherapy (e.g., cisplatin and doxorubicin, carboplatin and paclitaxel) is given. Patients with occult stage IIA or IIB endometrial carcinoma found in the hysterectomy specimen receive postoperative adjuvant radiation therapy if a pelvic lymphadenectomy was not done. An intravaginal radioactive implant can be done in patients with occult stage IIA or IIB endometrial adenocarcinoma who were treated by simple hysterectomy and bilateral pelvic lymphadenectomy.<sup>59</sup> This approach can decrease the rate of local recurrences.

Patients with stage IIIA endometrial adenocarcinoma based only on positive peritoneal cytology could be treated with megestrol acetate 160 mg to 320 mg daily.<sup>60</sup> Patients with stage IIIA endometrial adenocarcinoma based on adnexal and/or serosal involvement are treated with chemotherapy (e.g., doxorubicin and cisplatin, carboplatin and paclitaxel). In these patients the entire abdominal cavity is at risk for recurrence. The use of chemotherapy has been found to offer a survival advantage over whole abdominal irradiation.<sup>54</sup> Patients with vaginal metastasis (stage IIIB) receive pelvic irradiation (external beam and intravaginal implant) followed by a hysterectomy and periaortic node dissection. Radiation to the inguinal nodes is given in cases of metastasis to the distal third of the vagina. Chemotherapy is given if more advanced disease is found at the time of the hysterectomy. Another approach, depending on the size and location of the vaginal metastasis, is to perform the surgical staging first and, if more advanced disease (i.e., stage IIIC or IVB) is found, to treat the patient with chemotherapy with or without radiation for control of the vaginal lesions.

Patients with intra-abdominal metastasis (i.e., stage IVB) who are surgically rendered free of macroscopic disease can be treated with whole abdominal radiation, chemotherapy, or hormonal therapy (megestrol and/or tamoxifen). Recent data shows that treatment with cisplatin and doxorubicin results in improved disease-free survival and overall survival than treatment with radiation.<sup>54</sup> Patients with extra-abdominal metastasis or with residual intra-abdominal disease can be treated with chemotherapy (e.g., doxorubicin and cisplatin, carboplatin and paclitaxel) or hormones (megestrol and/or tamoxifen). A recently published GOG study showed a 33% (CI, 21% to 46%) response rate with tamoxifen 40 mg/d given without break and medroxyprogesterone 200 mg/d or 100 mg twice a day, orally, for one

week.<sup>61</sup> Another study of patients with recurrent or advanced endometrial adenocarcinoma showed a 27% (CI, 17% to 38%) response rate with megestrol (160 mg/d for 3 weeks) followed by tamoxifen (40 mg/d for 3 weeks).<sup>62</sup> Patients with positive inguinal nodes (stage IVB) and no extrapelvic disease could receive whole pelvis and inguinal irradiation. Alternatively, they could be treated with chemotherapy. Most patients with known stage IVB endometrial adenocarcinoma will still benefit from undergoing a hysterectomy.<sup>63</sup> Selected patients with stage IVA (i.e., bladder or rectal invasion) endometrial adenocarcinoma may benefit from a pelvic exenteration. However, because these patients tend to be older, obese, and with multiple comorbidities, most are treated with pelvic irradiation with or without surgery. The surgery may be a diverting colostomy or urostomy if a fistula develops. In patients with stage IVA endometrial adenocarcinoma that have periaortic node metastasis, chemotherapy, periaortic irradiation, and/or hormonal therapy are also used.

### Treatment of Recurrences

If a recurrence occurs, treatment will depend on the site or sites of recurrence and on the previous therapy. In patients with clinical stage I carcinoma, the vagina is the most frequent site of recurrence.<sup>50,51</sup> A confirmed isolated vaginal recurrence can be treated by surgical excision followed by whole pelvic and intravaginal radiation. If pelvic radiation was used at the time of primary therapy, an intravaginal radiation implant can be used after surgical excision of the recurrence. The actuarial 5-year survival rate after treatment of a vaginal recurrence is approximately 50%.<sup>50</sup> Pelvic sidewall recurrences and extrapelvic recurrences are associated with a low probability of 5-year survival. If no prior radiation therapy has been given, a pelvic recurrence or a periaortic recurrence can be treated with radiation, chemotherapy, or a combination of the two. A patient receiving radiation therapy can receive cisplatin at a dose of 50 mg/m<sup>2</sup> every 21 days concomitant with radiation. Once radiation therapy is completed, several courses of carboplatin and paclitaxel are given. Doxorubicin, an active agent against endometrial carcinoma, can result in increased radiation-induced skin toxicity. Patients who have previously received radiation to the area of the recurrence are treated with chemotherapy. The combination of carboplatin and paclitaxel has shown a high response rate when used to treat women with advanced-stage or recurrent endometrial carcinoma.<sup>57</sup> Topotecan at a dose of 1.5 mg/m<sup>2</sup>/d for 5 days on a 21-day cycle has shown activity in the treatment of recurrent endometrial carcinoma.<sup>64</sup> However, this dose and schedule are associated with unacceptable bone marrow toxicity. A lower dose of 1 mg/m<sup>2</sup> in patients who had not received prior radiation and 0.8 mg/m<sup>2</sup> for those with a history of prior radiation is being investigated. Hormonal therapy may also be effective. Megestrol at a dose of 160 to 320 mg/d has been used, with complete responses observed, especially in patients with lung metastases.<sup>65</sup> Estrogen increases the expression of progesterone receptors. A combination of progesterone and tamoxifen may result in a higher response rate, as previously discussed.<sup>61,62</sup>

### FOLLOW-UP

Most endometrial carcinoma recurrences occur within the first 2 years after therapy. For this reason, patients undergo a pelvic

examination with or without vaginal cytology every 3 months during the first 2 years. An annual chest radiograph should be considered. The yield is higher if the chest radiograph is obtained 2 years after therapy. Most recurrences are detected when the clinical evaluation is directed by the patient's symptoms.<sup>66</sup> In years three, four, and five a pelvic examination is performed every 6 months and vaginal cytology is obtained at least annually. Thereafter, the patient is examined annually. In patients considered at risk for intraperitoneal recurrences (e.g., stage IIIA adenocarcinoma, uterine papillary serous carcinoma), serum for CA 125 levels is periodically sent.<sup>67</sup> This follow-up scheme has not been shown to have a statistically significant impact on the salvage rate of patients with endometrial cancer recurrence. However, it offers the patient psychological support during a period of great anxiety. It also allows the clinician to screen for other cancers (e.g., breast, colon) and to offer other health maintenance services (e.g., smoking cessation, serum lipid determinations, calcium supplementation).

### Management of Menopausal Symptoms

After treatment of endometrial adenocarcinoma, some women may need estrogen replacement therapy for the treatment of vaginal atrophy. Estrogen replacement therapy most likely has no impact on the probability of survival in women who had early-stage endometrial adenocarcinoma. However, a GOG prospective randomized clinical trial that attempted to answer this question was closed before achieving its accrual goal of 2108 patients. An analysis of 1234 evaluable patients (618 randomized to receive estrogen, 616 randomized to receive placebo) was presented at the 35th annual meeting of the Society of Gynecologic Oncologists.<sup>68</sup> The median follow-up for all patients was 30.8 months. Of the 618 patients randomized to receive estrogen, only 12 (1.9%) experienced a recurrence. Of the 616 patients randomized to receive placebo, 9 (1.5%) developed a recurrence. Therapies other than estrogen are available for the management of menopausal changes other than genital atrophy. Hot flashes can be managed with progestins, clonidine, or venlafaxine. Osteoporosis can be prevented with raloxifene or bisphosphonates, in addition to calcium supplementation and weight-bearing exercise.

### Endometrial Carcinoma Survival

Most women with endometrial adenocarcinoma in the United States have stage I disease at diagnosis. Data for 1994 and 1995 reported from 1578 hospitals to the American College of Surgeons' Commission on Cancer show that 63% of patients

had stage I disease, 7.4% stage II, 10.5% stage III, and 6% stage IV (<http://web.facs.org/ncdbbmri>). The reported 5-year survival is stage I, 81%; stage II, 61%; stage III, 39%; and stage IV, 11%. The probability of 5-year survival by substage according to international statistics is shown in Table 45-8.

# Chapter 46

## Uterine Sarcomas

Valena Soto-Wright, MD, and Robert McLellan, MD

### KEY POINTS

- Uterine sarcomas are a rare group of heterogeneous uterine tumors that comprise less than 4% of all uterine cancers.
- Most uterine sarcomas present with common gynecologic symptoms of abnormal bleeding and pelvic pain that result in the recommendation for surgical intervention.
- Despite the use of Pap tests, endometrial biopsies, and ultrasound, the majority of cases are diagnosed by final surgical pathology.
- Unlike other Stage I gynecologic cancers (endometrial, cervical, vulvar, ovarian), where 5-year survival is about 90%, patients with Stage I uterine sarcoma have less than 50% 5-year survival.

Uterine sarcomas are a heterogeneous group of malignancies that arise from the mesenchymal tissue within the uterus. These tumors may consist of mesenchymal tissue alone or in combination with benign or malignant epithelial tissue (adenosarcoma, carcinosarcoma). Uterine sarcomas are rare, comprising 3% to 5% of all malignancies arising from the uterus. These malignancies behave in a variety of fashions, and their management is often poorly understood, because many studies in the peer review literature combine the various subtypes of uterine carcinoma in the reporting data. Uterine sarcomas are aggressive malignancies with a 5-year survival rate of less than 50% in patients with clinical Stage I disease.

### EPIDEMIOLOGY, RISK FACTORS, AND PATHOGENESIS

Uterine sarcomas are rare, with an annual worldwide incidence of 0.5 to 3.3 cases per 100,000 women per year.<sup>1,2</sup> The Surveillance, Epidemiology, and End Results program (SEER) provides the most accurate data in the United States with a range of 1.2 to 2.3 cases per 100,000 women. Harlow's analysis of the SEER data demonstrates that carcinosarcoma occurs in 0.8 cases/100,000 women, followed by leiomyosarcoma (0.64 cases/100,000 women), endometrial stromal sarcoma (0.19 cases/100,000 women), and unclassified sarcomas (0.05 cases/100,000 women), respectively.<sup>3</sup>

Uterine sarcomas are about twice as common in black women relative to white women. The more common endometrial adenocarcinoma occurs more often in white women. Although few reports suggest a history of pelvic radiation in leiomyosarcoma

or endometrial stromal sarcoma, exposure to pelvic irradiation appears to be a risk factor for the development of carcinosarcoma and adenosarcoma. In multiple series of carcinosarcoma, antecedent radiation was identified in up to 29% of cases.<sup>4-10</sup> Although some of these reports have described sarcomas that arise in an irradiated field behaving in a particularly aggressive fashion, the small number of reported cases do not allow reliable conclusions to be drawn regarding their behavior. Data regarding age of menarche, menopause, and parity as risk factors are inconsistent in the literature.

In 1978 tamoxifen (Nolvadex) was introduced for the treatment of breast cancer. As of April 2001, 43 cases of uterine sarcoma were reported among breast cancer patients treated with tamoxifen in the United States, and a further 116 women in other countries developed sarcomas.<sup>11,12</sup> The median duration of tamoxifen use in these patients was 5 years, with the primary histology being carcinosarcoma. Although data regarding risk factors and staging was not complete, 27 of 86 patients on whom such data were available had FIGO Stage III or IV disease according to International Federation of Gynecology and Obstetrics (FIGO) staging criteria. Long-term follow-up of women enrolled in tamoxifen trials suggests an increased incidence of uterine sarcoma of 0.17 cases per 1000 women per year. The advanced stage of uterine sarcomas associated with tamoxifen use is in marked contrast to the early stage of uterine adenocarcinomas that have been reported in tamoxifen users.

Uterine sarcomas are derived from mesoderm and may arise in uterine smooth muscle, endometrial stroma, or blood and lymphatic vessel walls. The International Society of Gynecological Pathologists (ISGYP) has adopted the classification system outlined in Table 46-1 that divides sarcomas into two groups.<sup>13</sup> The first represents pure nonepithelial uterine sarcomas; the second represents mixed epithelial and non-epithelial sarcomas. The descriptive terms *homologous* and *heterologous* refer to sarcomas containing tissue elements indigenous to the uterus and sarcomas with tissue elements such as bone or cartilage that are not normally found in the uterus (i.e., chondrosarcoma), respectively. There appear to be no difference in the clinical behavior of homologous and heterologous müllerian sarcomas. The term *malignant mixed müllerian sarcoma* is equivalent to carcinosarcoma. For practical purposes, the four most common uterine sarcomas in order of decreasing frequency are carcinosarcoma, leiomyosarcoma, endometrial stromal sarcoma, and adenosarcoma. The natural history of sarcomas varies based on the histologic subtypes outlined by the ISGYP classifications system.<sup>13</sup>

**Table 46-1**

## CLINICAL FEATURES

### Carcinosarcoma

Carcinosarcomas (mixed müllerian sarcomas) are the most common type of uterine sarcomas, representing 43% of all sarcomas in one study.<sup>14</sup> These tumors consist of endometrial adenocarcinoma in association with malignant mesenchymal tissue (Fig. 46-1). The debate regarding the histogenesis of these tumors has focused on whether the origin is from a common multipotential stem cell versus distinct malignant mesenchymal and epithelial cells. Immunohistochemical staining of carcinosarcoma and poorly differentiated uterine carcinoma show extensive overlap, suggesting a common cell of origin. It has also been observed that metastases of carcinosarcoma are frequently composed of only the carcinomatous component. Compared to adenocarcinomas these tumors grossly appear more fleshy and bulky. The classic presentation of painful postmenopausal bleeding associated with the clinical finding of friable tumor prolapsing through a dilated cervix should raise concern for a presumptive diagnosis of carcinosarcoma.

Doss and colleagues<sup>5</sup> reported that gross tumor at the cervical os was present in 36 of 49 patients presenting with carcinosarcoma. Abnormal vaginal bleeding occurs in 95% of patients presenting with carcinosarcoma, and about 30% of patients describe pain.<sup>14–16</sup> Up to 50% of patients will have the clinical finding of uterine enlargement or a palpable pelvic mass.<sup>4,16,17</sup> A study by Doss and coauthors showed that a mean interval of 3.7 months passed from the onset of symptoms to the subsequent diagnosis of early-stage carcinosarcoma.<sup>5</sup> Hematogenous and lymphatic metastases are common in carcinosarcoma. Doss and colleagues reported on 18 patients with carcinosarcoma and lymphatic metastasis: 6 periaortic, 6 pelvic, 3 supraclavicular, and 1 each of inguinal, colonic, or mesenteric.<sup>5</sup> Fleming, in a summary of 10 previously reported autopsy studies, showed that widespread intra-abdominal and pelvic disease was commonplace for women who died of uterine sarcoma.<sup>18</sup> Tubo-ovarian metastases are also frequent when intra-abdominal metastases are present. In 14 patients with extra-

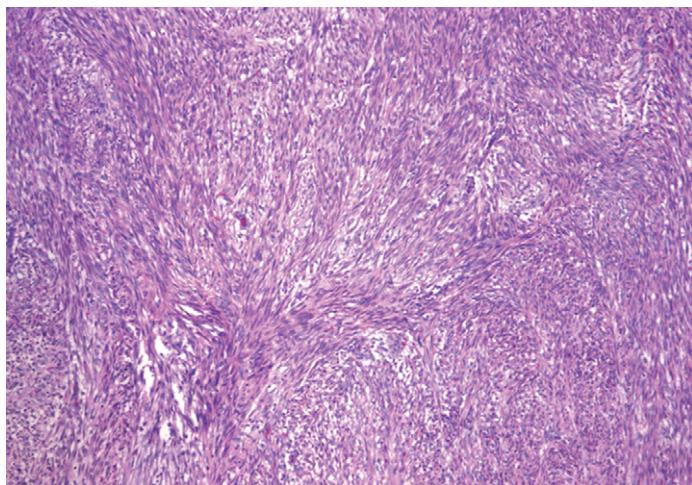

uterine disease, 10 were found to have adnexal metastases in a study by Norris and colleagues.<sup>19</sup> Of the 14 patients with intra-abdominal and adnexal metastases, only 2 had vaginal wall metastasis. A relatively high rate of pulmonary metastatic disease has also been noted in autopsy studies.<sup>18,20</sup>

### Leiomyosarcoma

Leiomyosarcoma is the second most common form of uterine sarcoma, accounting for about 1% of all uterine carcinomas. In premenopausal women, leiomyosarcoma is more common than carcinosarcoma. Leiomyosarcoma is a malignancy thought to arise de novo from uterine smooth muscle. Grossly, leiomyosarcoma has been described as a whitish gray or pale pink cancer similar in appearance to a benign leiomyoma. Like benign leiomyomas, areas of the leiomyosarcoma may show cystic or hemorrhagic degeneration or areas of coagulative necrosis.

Dinh and Woodruff reported a series of 43 cases of leiomyosarcoma; the carcinoma was a solitary lesion in 45% of the women studied but also was associated with multiple myomas in 42% of cases.<sup>21</sup> They emphasize that in the remaining 13% of cases the leiomyosarcoma was not recognized grossly but only identified as an infiltrative process in the final hysterectomy specimen. The location of the sarcoma was thought to be prognostic based on 5-year survival rates for submucosal, intramural, and subserosal sarcomas, which ranged from 80% to 100%, in contrast to a 5-year survival rate of 25% for sarcomas occurring de novo in the myometrium without a definite mass. Patients in their series with extrauterine disease had a 33% overall 5-year survival. Favorable prognostic features included premenopausal status of the patient, confinement of the tumors within a myoma, low mitotic count, absence of necrosis, and presumed hyalinization in adjacent tissue. Forty-one of the 43 patients were followed up 2 or more years. The overall 5-year survival was 73%.<sup>21</sup>

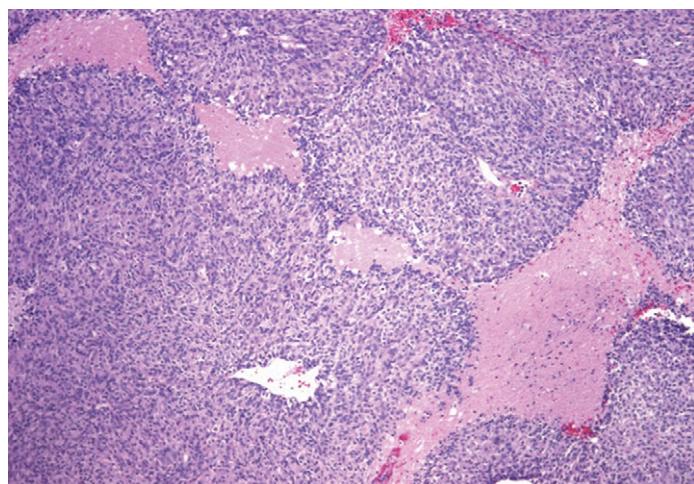

The histopathology of leiomyosarcoma, according to the classic paper by O'Connor and Norris,<sup>22</sup> is based on the mitotic count and the degree of atypia of tumor cells, with no attention paid to the cellularity of the neoplasm. Figure 46-2 demonstrates

**Figure 46-2 Leiomyosarcoma.** Interlacing pleomorphic spindle-shaped smooth muscle cells containing hyperchromic nuclei.

the cellular pleomorphic spindle-shaped smooth muscle cells with hyperchromatic nuclei and numerous mitotic figures characteristic of leiomyosarcoma. Tumors with 1 to 4 mitoses/10 high-power field (HPF), independent of the degree of atypia, are grouped as leiomyoma. Tumors with 5 to 9 mitoses/10 HPF with grade 1 atypia are of uncertain malignant potential. A similar mitotic count but with grade 2 or 3 atypia or any tumor with 20 mitoses/10 HPF is considered a malignant leiomyosarcoma. An alternative approach that takes into consideration the mitotic count, degree of atypia, and the presence or absence of coagulative necrosis has been advocated by Hendrickson and Kempson at Stanford.<sup>23</sup> Figure 46-3 demonstrates a leiomyosarcoma with coagulative necrosis, which the Stanford group feels is both of diagnostic and prognostic significance. In this more complex diagnostic schema, which includes coagulative necrosis, five categories exist; it remains unclear if this approach will be validated by better prognostic or therapeutic outcomes of clinical significance in the future.

Leiomyosarcoma most commonly presents with abnormal bleeding, with symptoms often attributed to the presumed

**Figure 46-3 Leiomyosarcoma with coagulative necrosis.**

diagnosis of leiomyoma. The clinical pearl that a presumed uterine leiomyoma rapidly increasing in size (defined as a doubling in size over 3 to 6 months of observation) should raise concern regarding possible leiomyosarcoma has not been substantiated by recent review. In a study of 1332 women admitted for myomectomy or hysterectomy for presumed uterine leiomyoma, the incidence of sarcoma was 0.23%. Furthermore, among the 341 women with rapidly enlarging leiomyoma, only 0.27% had uterine sarcoma.<sup>24</sup> More commonly, the rapid increase in size is due to cystic or hemorrhagic degeneration of a benign leiomyoma rather than malignant growth. Because leiomyosarcoma arises from the myometrium, the ability to diagnose this tumor preoperatively may be elusive.

The clinical characteristics of 208 patients with uterine leiomyosarcoma outlined in Table 46-2 are reported in a retrospective series at the Mayo Clinic from 1976 to 1999 conducted by Giuntoli and colleagues.<sup>25</sup> The age at diagnosis for women with leiomyosarcoma ranged from 23 to 89.3 years, with a median of 50.9 years. Abnormal bleeding, a pelvic mass, or pain occurred in 56%, 54%, and 22% of the patients, respectively. The median uterine sarcoma measured 9 cm. Most patients (130 of 208, 62%) had Stage I disease. Notably, Stage IV disease on the basis of lung metastasis was the second most common stage, occurring in 41 patients (20%). This reflects the propensity for hematogenous and lymphatic spread other than the direct peritoneal extension more commonly seen in epithelial gynecologic cancer.

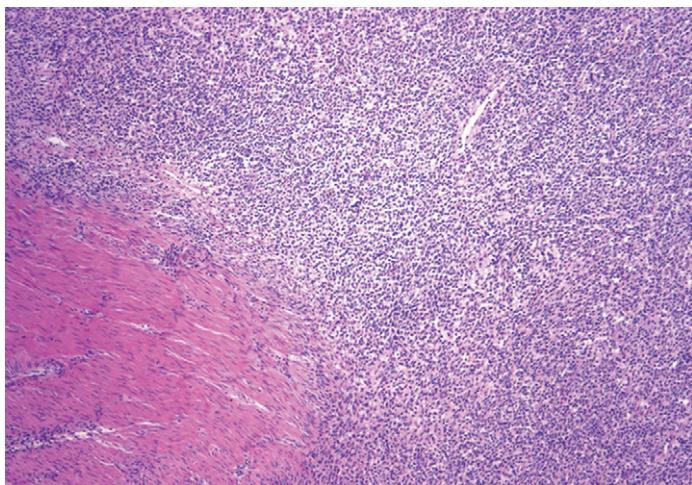

### Endometrial Stromal Sarcoma

Endometrial stromal sarcoma is composed of cells resembling the endometrial stroma in the proliferative phase of the menstrual cycle (Figs. 46-4 and 46-5). The tumor typically grows into the endometrium and is usually diagnosed by endometrial sampling. Traditionally, endometrial stromal sarcoma has been divided into low-grade and high-grade stromal sarcomas on the basis of less

**Table 46-2**  
**Characteristics of 208 Patients with Leiomyosarcoma of the Uterus**

Characteristic	Value

Modified from Giuntoli RL 2nd, Metzinger DS, DiMarco CS, et al: Retrospective review of 208 patients with leiomyosarcoma of the uterus: prognostic indicators, surgical management and adjuvant therapy. *Gynecol Oncol* 2003;89:460–469.

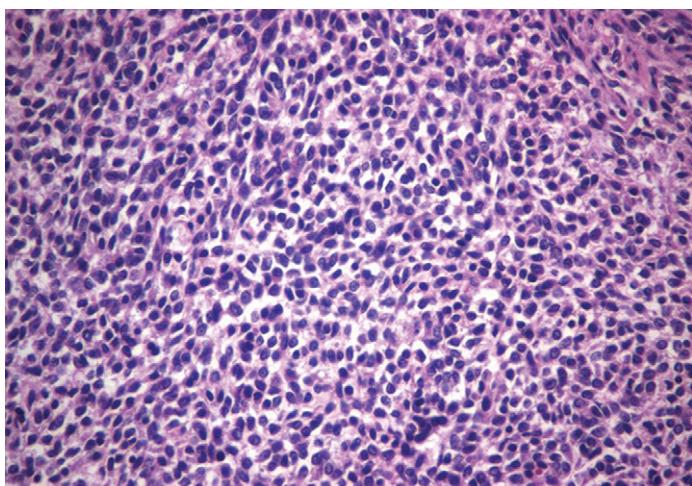

**Figure 46-4** **Endometrial stromal sarcoma.** Tumor infiltrating through myoma.

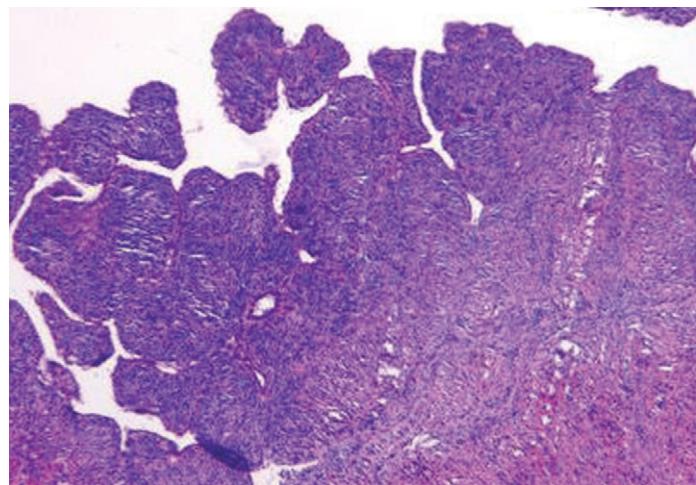

than 10 mitoses/10 HPF or greater than 10 mitoses/10 HPF, respectively. Within the high-grade endometrial stromal sarcoma group, many of the tumors had anaplastic cells that did not show endometrial stromal differentiation. Debate exists whether this subgroup of tumors with anaplastic cells would be better classified as poorly differentiated sarcoma.<sup>26,27</sup>

Endometrial stromal sarcoma is observed mainly in premenopausal women. Amant and coworkers reported on a series from 1990 to 2002; it involved 16 women with a median age of 34 (range, 18 to 53 years). In 6 of 15 (40%) of the women the original diagnosis was missed and was established only after consultation with a pathologist with a special interest in gynecologic pathology.<sup>28</sup> Lesions to be considered in the differential diagnosis of endometrial stromal sarcomas include cellular leiomyoma, cellular intravenous leiomyomatosis, and adenomyosis with sparse glands, metastatic carcinoma, and lymphoma.

Endometrial stromal sarcomas may be associated with an indolent growth pattern, with lung metastases often occurring late. Low-grade endometrial stromal sarcomas may be rich in

**Figure 46-5** **Endometrial stromal sarcoma.** The higher magnification shows small uniform cells with bland nuclei.

**Figure 46-6** **Adenosarcoma.** Papillary structures with cystic spaces covered by endometrial-type epithelial cells.

estrogen and progesterone receptors and generally respond to progestins. Complete response to the aromatase inhibitor aminoglutethimide (500 mg q.i.d.) has been reported.<sup>29</sup> Removal of the ovaries is recommended for endometrial stromal sarcoma, because the recurrence rate in patients with retained ovaries was 100% (6 of 6) compared to 6 of 13 in those who underwent initial oophorectomy.<sup>30</sup>

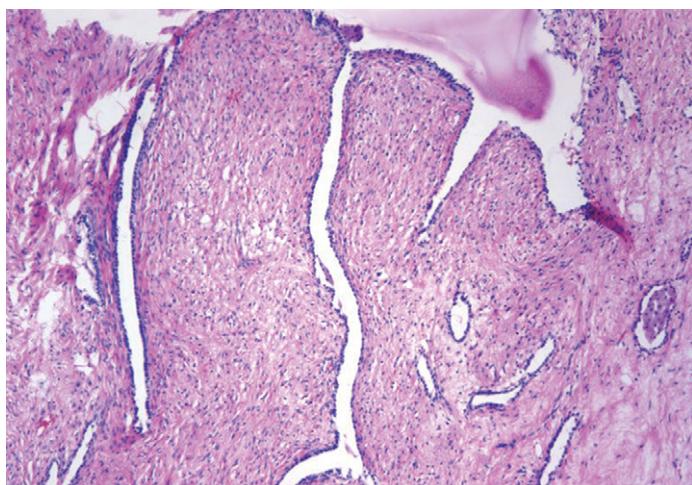

### Adenosarcoma

Adenosarcoma is a mixed form of uterine sarcoma characterized by the presence of benign glandular epithelium mixed with a sarcomatous stroma. Histologically broad papillary structures, clefts, glands, and cystic structures are lined by endometrial-type epithelium with minor areas of focal cytologic atypia (Fig. 46-6). The stromal component is condensed beneath the surface epithelium, forming a “cambium layer” that most often resembles endometrial stromal sarcoma or less commonly leiomyosarcoma.

Adenosarcomas are considered a low-grade malignancy but do recur about 20% of the time after surgical therapy. Figure 46-7 demonstrates recurrent metastatic adenosarcoma to the lung after progestational therapy 6 years after the patient’s primary tumor was excised. This patient remains alive with disease 8 years from her original diagnosis and 2 years from the first documented lung recurrence.

### DIAGNOSIS

Most women with uterine sarcomas present with abnormal bleeding and pelvic pain. Initial evaluation may include Papanicolaou (Pap) smear, pelvic ultrasound, and/or endometrial biopsy, depending on the age of the patient. The sensitivity of these tests in diagnosing uterine sarcoma is poor and varies with the histologic subtype of uterine sarcoma. Carcinosarcoma, due to its malignant glandular component arising in the endometrial cavity, is much more likely to be diagnosed by endometrial biopsy than leiomyosarcoma, which arises from the myometrium.<sup>31</sup> The majority of women with leiomyosarcoma have not had a preoperative endometrial biopsy.<sup>14</sup> Of those women with

**Figure 46-7 Metastatic pulmonary adenosarcoma after medroxyprogesterone acetate therapy.**

leiomyosarcoma biopsied, only 25% to 50% of cases were diagnosed correctly before hysterectomy. Most women with leiomyosarcomas are diagnosed after hysterectomy performed for the management of presumed leiomyoma. Many women have had additional testing, such as computed tomography (CT) scan or magnetic resonance imaging (MRI), but in disease confined to the uterus the findings are not specific and may not raise concern regarding a possible malignancy. MRI findings suggestive of uterine sarcoma include a heterogeneous medium and high-signal intensity within a uterine mass or hematometra with high-signal intensity on T<sub>1</sub> and T<sub>2</sub>.<sup>32</sup>

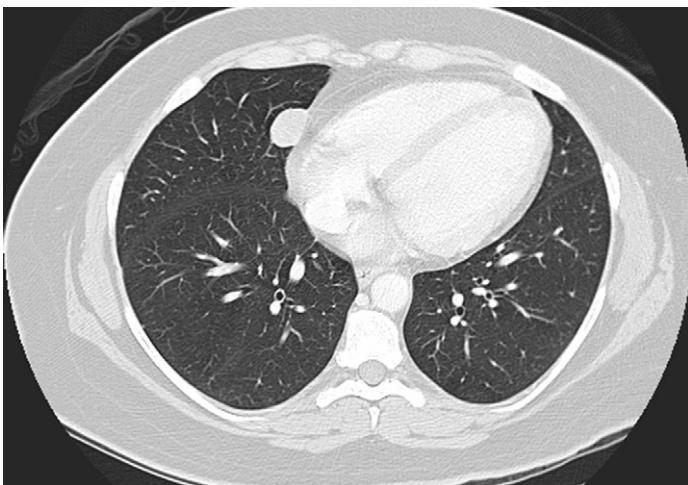

In women with a diagnosis of uterine sarcoma made preoperatively, evaluation should focus on determining the extent of disease. A careful history may identify patients with pulmonary or abdominal symptoms suggestive of metastatic disease. A complete physical examination is indicated, with special attention given to a careful lymph node survey, including the supraclavicular lymph nodes, auscultation of the chest, and palpation of the abdomen and inguinal-femoral nodes. Gynecologic examination should include inspection of the entire vaginal vault and cervix, bimanual examination, and rectovaginal examination. Rectovaginal examination and occult blood testing may identify otherwise occult involvement of the rectovaginal septum by direct tumor extension. Preoperative radiographic studies include a posteroanterior (PA) and lateral chest x-ray. A CT scan of the abdomen and pelvis may identify extrauterine disease, such as lymphatic or peritoneal metastases. Chest CT scan may be useful postoperatively when pathological diagnosis is confirmed because both carcinosarcoma and leiomyosarcoma metastasize to the lung. Punnonen reported 14 isolated pulmonary recurrences in 21 patients diagnosed with recurrent leiomyosarcoma.<sup>33</sup> Women with isolated pulmonary metastasis from leiomyosarcoma are candidates for thoracotomy, with 5- and 10-year survival of 43% and 35%, respectively.<sup>34,35</sup>

Figure 46-8 demonstrates the importance of preoperative chest radiography, PA and lateral. An 11-mm right upper lobe nodule is seen on the PA view, but only on the lateral film is a second, retrocardiac lesion identified. The patient underwent a total hysterectomy and bilateral salpingo-oophorectomy for

presumed leiomyoma. Her intraoperative findings, however, were worrisome for uterine sarcoma; final surgical pathology demonstrated a high-grade endometrial stromal sarcoma involving the uterus, with metastatic disease present to the adnexa bilaterally. Postoperative metastatic workup included a chest and abdominal pelvic CT scan. The chest CT scan identified the right upper lobe 11-mm nodule but also clearly defined a 2-cm mass abutting the right side of the heart that was only a subtle finding on the lateral chest x-ray (Fig. 46-9). The abdominal pelvic CT scan shown in Figure 46-10 demonstrates a 5.5-cm soft tissue mass at the level of the left common iliac bifurcation that was felt to represent necrotic lymphadenopathy versus metastatic implant of soft tissue sarcoma to the peritoneal surface. Figure 46-11 demonstrates the fluoro-2-deoxy-D-glucose (<sup>18</sup>FDG) positron emission tomography (PET) scan of the patient with endometrial stromal sarcoma whose chest x-ray and CT scans have been shown in Figures 46-9 and 46-10, respectively. <sup>18</sup>FDG is an analog of glucose that engages in cellular metabolism, allowing a distinction to be made between benign and malignant tissues. The whole-body scan demonstrates increased uptake at two sites in the lung in addition to the left periaortic nodes, left external iliac nodes, and right external iliac nodes, correlating well with the CT scan findings. The rarity of uterine sarcomas limits assessing the sensitivity or specificity of PET scan, but in soft tissue sarcoma of other sites, Schwarzbach and colleagues reported a sensitivity and specificity of 91% and 88%, respectively.<sup>36</sup> PET scans have also been shown to be of value in staging, restaging, and prognosis in soft tissue sarcomas.<sup>37</sup>

**Figure 46-8 Lateral chest radiograph with a retrocardiac lesion not seen on PA view, representing metastatic high-grade endometrial stromal sarcoma.**

**Figure 46-9** Chest CT scan documenting 2-cm metastatic pulmonary nodule of high-grade endometrial stromal sarcoma.

This diagnostic workup reflects the aggressive nature of the majority of uterine sarcomas and the importance of meticulous preoperative evaluation.

## TREATMENT

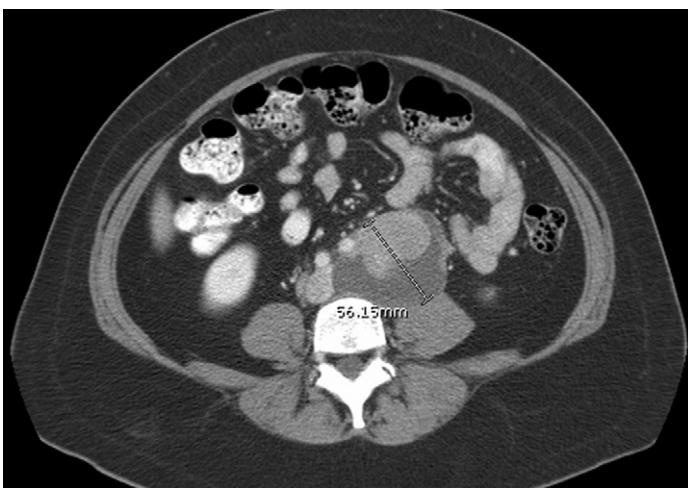

Surgery is the only treatment for curative intent in patients with carcinosarcoma. The traditional procedure consists of an exploratory laparotomy through a midline abdominal incision. Peritoneal washings for cytology are obtained followed by careful inspection and palpation of the diaphragm, liver, spleen, stomach, small and large bowel, omentum, peritoneal surfaces, and retroperitoneal structures. When a thorough laparotomy is performed, extrauterine disease may be found in 12% to 40% of patients with carcinosarcoma who otherwise had clinical findings to suggest disease confined to the uterus.<sup>4,5,8,10,38</sup> The pattern of spread may mimic poorly differentiated endometrial cancer with direct serosal extension, metastasis to the fallopian tube or ovary, and intraperitoneal dissemination.<sup>39</sup> The

**Figure 46-11** FDG-PET scan. Metastatic high-grade endometrial stromal sarcoma with increased uptake in the left periaortic nodes and left iliac nodes.

Gynecologic Oncology Group, in a prospective surgical staging study, reported that 17% of all patients with carcinosarcoma had pelvic and/or periaortic nodal disease.<sup>40</sup> Accordingly, in patients with no evidence of extrauterine disease nodal sampling should be considered because additional prognostic information may be gained. Although cytoreductive surgery has not been shown to improve survival in patients with carcinosarcoma, if intestinal obstruction is present from metastatic disease, palliative bypass is appropriate.

As in carcinosarcoma, patients with leiomyosarcoma are treated with curative intent with extrafascial abdominal hysterectomy with a bilateral salpingo-oophorectomy. When leiomyosarcoma is diagnosed on final pathology after myomectomy for presumed benign fibroids, total hysterectomy should be considered. Berchuck and colleagues reported three patients who had myomectomy followed by hysterectomy, with two of the three having residual leiomyosarcoma in the final hysterectomy specimen.<sup>41</sup> Fertility-sparing surgery for young, nulliparous women has been reported by Lissoni and colleagues.<sup>42</sup> After myomectomy, all patients had normal hysteroscopy, pelvic ultrasound, abdominal pelvic CT scan or MRI, and normal chest radiography. Of the eight women studied, with a median follow-up of 42 months, three live births were recorded, but one patient died of recurrent disease. Patients must be informed of the risks of fertility-sparing surgery and the limited data available to support a conservative approach. In young patients who have had hysterectomy for leiomyosarcoma, the role of bilateral salpingo-oophorectomy has been analyzed in a case-control series

**Figure 46-10** Abdominopelvic CT scan with 5.5-cm soft tissue mass at the left common iliac bifurcation.

by Giuntoli.<sup>25</sup> Of 25 women with functioning ovaries in whom one or both ovaries had been preserved compared to similarly staged women whose ovaries had been resected, no significant difference in disease-specific survival was noted.

In patients with a diagnosis of leiomyosarcoma established at the time of surgery, generally bilateral salpingo-oophorectomy has been performed. Prospectively acquired surgical staging data from Memorial Sloan-Kettering Cancer Center documented 3.9% (4 of 1080) and 8.1% (3 of 37) incidence of ovarian and nodal metastasis, respectively.<sup>43</sup> No patients with Stage I or II disease had positive lymph nodes. (The presence of gross extrauterine disease was the only factor predictive of nodal involvement.) In the retrospective series by Giuntoli and colleagues, lymph node involvement was reported in 11% (4 of 39) with leiomyosarcoma. Three of the four patients had extrauterine disease, but the remaining patient had no clinically suspicious nodes or extrauterine disease.<sup>25</sup> Therefore, although lymph node dissection provides prognostic information, it is not felt to be therapeutic and may be omitted unless required by treatment protocol.

Palliative radiation therapy has been employed when patients present with symptomatic locally advanced disease with or without known metastatic disease that cannot be resected with adequate surgical margins. The Radiation Therapy Oncology Group (Protocol #8502) demonstrated in a Phase II trial that a split-course radiation schedule effectively relieved symptoms with minimal short- or long-term complications. The schedule consisted of 3.7 Gy of external beam radiation delivered twice daily for 2 days, followed by a 2- to 4-week rest before a similar repeat course. This regimen may be repeated twice for a total pelvic dose of 44.4 Gy.

### Adjuvant Treatment

Radiation, chemotherapy, and combined chemoradiation have all been reported as adjuvant or postoperative treatment for women with uterine sarcoma. The European Organization for the Research and Treatment of Cancer (EORTC) reports the only randomized trial in the peer-reviewed literature for adjuvant therapy of uterine sarcoma.<sup>44</sup> The trial evaluated observation versus postoperative adjuvant pelvic radiotherapy. Enrolled patients had undergone a minimum of total abdominal hysterectomy with bilateral salpingo-oophorectomy and cytology. The trial took 13 years to accrue 124 patients reflecting the rarity of uterine sarcomas and the need for collaborative multicentered trials. All histologic types were permitted with 103 LM, 91 CS, and 28 endometrial stromal sarcomas. Patients were randomized to pelvic radiation or observation. There was no effect on overall survival or progression-free survival. A decrease in local recurrence was noted in patients with CS who received radiotherapy without any benefit noted for treated patients with LMS. Similar to the EORTC data, most authors describe decreased local recurrence but have not demonstrated improved overall survival. This may reflect the extent of unrecognized microscopic disease or metastatic disease outside the pelvic treatment fields that remains after laparotomy. Extended field or whole abdominal radiation may prevent abdominal/pelvic recurrence but it is unknown if this influences survival.<sup>45,46</sup> Future study designs of adjuvant therapy will need to consider the histologic subtypes of sarcomas based on the EORTC trial data.

### Chemotherapy

To improve survival in women with uterine sarcoma, active chemotherapeutic agents are needed to prevent both local and systemic recurrence. No studies to date have shown efficacy for adjuvant chemotherapy despite the known recurrence rate of 50% for clinical Stage I disease. Because 90% of uterine sarcomas are either carcinosarcoma or leiomyosarcoma, meaningful trial data are available for only these histologic subtypes. Chemotherapy is employed for patients with metastatic or recurrent disease with drug choice guided by histology, based on data from GOG trials (Table 46-3).

The most active single agent against carcinosarcoma identified, with a response rate of about 32%, is ifosfamide. Sutton and colleagues reported a response rate of 5 complete and 4 partial responders among 28 patients who had not received prior chemotherapy, receiving a 5-day schedule of ifosfamide at a dose of 1.5 mg/day every 4 weeks.<sup>47</sup> The GOG reported a response rate of 34.8% in a Phase II trial of ifosfamide in 23 patients with carcinosarcoma.<sup>47</sup> The GOG also identified cisplatin as an active agent, but with a response rate of only 19% in 63 previously untreated patients with carcinosarcoma.<sup>48</sup> The GOG compared combination therapy with ifosfamide and cisplatin to single-agent ifosfamide in a Phase III trial in 194 evaluable patients with carcinosarcoma.<sup>49</sup> Despite an overall response rate of 54% and 36%, respectively, and median progression-free survival of 6 months and 4 months, respectively, which favored combination therapy, the cost of increased morbidity, particularly myelosuppression, has limited the use of this combination.

The GOG conducted a Phase II trial evaluating the clinical activity of paclitaxel in patients with persistent or recurrent carcinosarcoma of the uterus.<sup>50</sup> All patients had failed previous treatments, 15 patients had received previous radiation therapy, and 33 patients had failed prior chemotherapy. All patients had histologically confirmed carcinosarcoma with measurable disease. Eight of 44 patients responded to paclitaxel administered at a dose of 170 mg/m<sup>2</sup> (135 mg/m<sup>2</sup> in those patients with prior radiation therapy). Four patients (9.1%) had a complete response and four had a partial response. Neutropenia was the most common toxic effect. The authors concluded that Paclitaxel had moderate activity in patients with carcinosarcoma of the uterus. Currently the GOG is accruing patients for a Phase III trial comparing ifosfamide with or without paclitaxel in the treatment of recurrent carcinosarcoma (GOG #161).

The use of chemoradiation for patients with optimally debulked advanced carcinosarcoma is the subject of GOG

**Table 46-3**  
**Recommendations for Chemotherapy in Advanced or Recurrent Uterine Sarcomas**

Histology	Recommendation
Carcinosarcoma	Ifosfamide or ifosfamide/cisplatin
Leiomyosarcoma	Doxorubicin
Other histologies	Data inconclusive

Modified from Rubin SC (ed): Chemotherapy of Gynecologic Cancers, 2nd ed. Philadelphia, Lippincott Williams & Wilkins, 2004, Table 4.9, p 18.

## Gynecologic Oncology

#150, a Phase III randomized trial, which uses whole abdominal radiation with combination ifosfamide and cisplatin.

In contrast to carcinosarcoma, leiomyosarcoma has only modest response to ifosfamide and negligible response to cisplatin. The highest response rates in leiomyosarcoma, about 25%, are achieved with doxorubicin.<sup>51,52</sup> Phase II trials continue to focus on identification of active drugs for leiomyosarcoma. More recent data has documented that combination chemotherapy with gemcitabine and docetaxel in leiomyosarcoma patients showed an overall response rate of 53%, including three complete responders.<sup>53</sup> In this study 50% of patients previously treated with doxorubicin with or without ifosfamide responded. Grade 3 or 4 neutropenia developed in 27% of patients despite the use of granulocyte colony-stimulating factor.

In summary, the use of chemotherapy in uterine sarcoma in recurrent or metastatic disease is palliative, not curative. Experimental protocols may be considered versus palliative care programs based on the patient's performance status. Although a number of active agents have been identified, a large study of 1042 uterine sarcoma patients reported to the Cancer Registry of Norway from 1956 to 1992 showed no improvement in 5-year survival after the introduction of chemotherapy into treatment protocols.<sup>54</sup> The rarity of uterine sarcomas and the difference in clinical response between the two major histologic types has limited randomized trial data to guide therapy. In view of these obstacles and the lack of highly active regimens in advanced disease no trials for chemotherapy in the adjuvant setting are currently under way.

## PROGNOSIS

Malignant uterine sarcomas are aggressive tumors with a poor prognosis. Surgical stage is the most important prognostic variable. Even if the tumor is Stage I at presentation, the overall 5-year survival is only 50%. If extrauterine disease is present, 5-year survival is about 20% with little change despite post-operative treatment. Among the three main histologic subtypes of uterine sarcoma, sites of disease recurrence and survival rates are similar after correcting for stage of disease.<sup>21,48</sup>

## KEY POINTS

- Primary fallopian tube carcinoma is relatively rare (0.1% to 1% of all female genital tract malignancies).
- Treatment for fallopian tube carcinoma is similar to that for ovarian carcinoma. Initial treatment is surgical staging (peritoneal washings and biopsies, omentectomy, pelvic/ periaortic lymphadenectomy). For advanced disease, tumor debulking to less than 1 cm residual disease followed by chemotherapy is advocated.
- Chemotherapy includes six cycles of a platinum-based compound combined with paclitaxel. Newer agents active in epithelial ovarian cancer may have comparable efficacy in fallopian tube carcinoma.
- Survival appears to be higher than for ovarian cancer, probably because fallopian tube carcinoma is usually detected at an earlier stage.
- Women with genetic susceptibility to ovarian and breast cancer (especially *BRCA1* carriers) are at increased risk for fallopian tube carcinoma. In women undergoing prophylactic surgery to prevent ovarian cancer, careful gross and microscopic assessment of the fallopian tubes may be indicated.

Primary carcinoma of the fallopian tube is relatively rare, accounting for approximately 1% of all female genital tract malignancies. Etiologic factors are largely unknown, but are probably similar to those for epithelial ovarian cancer. Histologically, most fallopian tube carcinomas are pure adenocarcinomas. The most commonly identified histology is serous, although other epithelial subtypes (e.g., endometrioid, clear cell, transitional cell, carcinosarcoma) have been reported. In this chapter, we outline the clinical presentation and current management of fallopian tube carcinoma. Recently, case reports and a few epidemiologic studies have demonstrated a link to fallopian tube carcinoma in women at increased risk for hereditary breast and ovarian carcinoma. In light of this, an algorithm that addresses risk, current guidelines for surveillance, and the role and type of prophylactic surgery under investigation is provided.

## EPIDEMIOLOGY

Primary fallopian tube carcinoma accounts for 0.1% to 1.1% of all genital malignancies,<sup>1</sup> with a prevalence of about 3.6 per million women per year.<sup>2</sup> According to data derived from the

Surveillance, Epidemiology, and End Results (SEER) program, from 1973 to 1984, incidence rates in the United States have remained stable, and age-specific incidence follows a pattern similar to that for ovarian and endometrial tumors. In the United States, whites were found to have a slightly higher, although not a statistically different, incidence rate per million women (3.5 vs. 3.1; RR, 1.14; 95% CI, 0.7 to 1.8).<sup>3</sup> In contrast, a study from the Finnish Cancer Registry (1953–1997) reported a 4.5-fold increase in incidence, from 1.2 per million women in 1953 to 1957 to 5.4 per million women in 1993 to 1997.<sup>4</sup> As has been shown for ovarian cancer, higher living standards may be a contributing factor; women of higher socioeconomic classes have a 1.8-fold higher incidence rate (95% CI, 1.2 to 2.6) than women within the lowest classes. Also like ovarian cancer, comparing women from rural versus urban areas and unemployed women versus women in academic or clerical occupations, rates are approximately 50% higher in the latter groups.<sup>4</sup>

In the United States, based on SEER data, considerable differences in population-based incidence rates occur by geographic region, from as low as 2.7 per million women up to 6.5 per million women. This may be a reflection of true regional differences; more likely, it is due to differences in the frequency of misclassification of fallopian tumors as ovarian neoplasms.<sup>4</sup> In the Finnish study, incidence rates per million white women compared to other ethnicities were slightly higher (5.4 vs. 3.3) and were otherwise similar, other than that the peak in age-specific rates in Finland was in women between ages 60 and 64, compared to between ages 70 and 74 in the United States.<sup>3,4</sup> Many factors may account for the trend in higher rates overall and in more socioeconomically advantaged women; these include better detection, improved awareness, better access to gynecologic oncology specialty care, and earlier diagnosis. In advanced and inoperable cases, it is often difficult and sometimes impossible to discriminate between an ovarian and a fallopian tube primary carcinoma. Because the ovaries, uterus, and fallopian tubes are all of müllerian origin, neoplasms arising in any of these sites are histologically identical. Thus, especially in advanced cases, because fallopian tumors mimic these more common neoplasms both histologically and in patterns of spread, the likelihood of misdiagnosis is increased.<sup>4,5</sup>

According to a number of epidemiologic studies, the prognosis for fallopian tube carcinoma may be better than that for ovarian cancer. In the United States (SEER data, 1990–1997) primary fallopian tube carcinoma patients stage for stage were found to have a better 5-year relative survival than ovarian cancer patients diagnosed in the same time period (Table 47-1).<sup>3</sup> Similar results have been reported by the Austrian Cooperative

Table 47-1

**Relative Survival (5-Year) for Fallopian Tube Carcinoma Compared with Epithelial Ovarian Cancer [SEER, 1990–1997]**

Study Group for Fallopian Tube Carcinoma (Stage I/II, 50%; Stage III/IV 19%),<sup>5</sup> the Norwegian Radium Hospital (Stage I, 73%; Stage II, 37%; Stage III, 29%; Stage IV, 12%),<sup>6</sup> and by the International Federation for Gynecology and Obstetrics (FIGO: Stage I, 69%; Stage II, 58%; Stage III, 20%; Stage IV, 22%).<sup>7</sup> On the other hand, Rosen and colleagues, in a nationwide retrospective analysis of Stage I and II fallopian tube carcinoma versus ovarian cancer, reported that survival was worse for the fallopian tube carcinoma patients (5-year survival, 50.8% vs. 77.5%).<sup>8</sup>

## CLINICAL FEATURES

### Clinical Signs and Symptoms

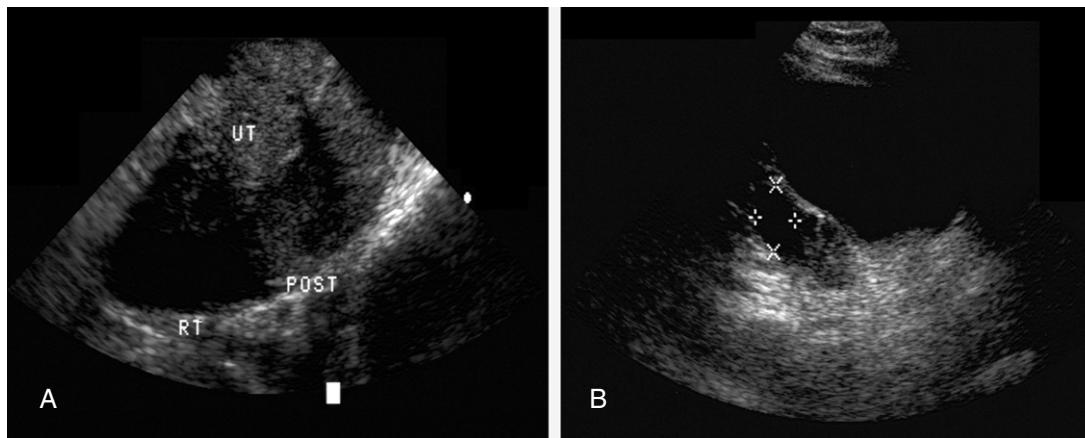

The most common symptoms associated with fallopian tube cancer are abdominal pain, abnormal vaginal bleeding, and an abdominal or pelvic mass. The classic presentation is colicky abdominal pain, often relieved with passage of a profuse watery vaginal discharge, and a mass on examination, a triad of symptoms termed *hydrops tubae profluens*, considered pathognomonic for fallopian tube carcinoma. According to most series, however, this presentation is found in only 5% to 10% of patients. The most common symptoms include abnormal vaginal bleeding (42% to 62%), abdominal pain (28% to 48%), and watery vaginal discharge (20%).<sup>1,5,9–11</sup> An abdominal mass discovered on ultrasound or computed tomography (CT) scan (33%) is a more common presentation than incidental finding of a pelvic mass on examination (5%)<sup>9</sup>; in 14% of cases, ascites is suspected based on radiographic studies or examination.<sup>6</sup> Rarely (about 1% of cases), patients present with acute abdomen with torsion and/or intra-abdominal bleeding.<sup>1,11</sup> About 15% to 20% of patients experience no symptoms.<sup>1,6</sup>

### Biological Markers, Cervical Cytology, and Radiographic Studies

Few reports address the utility of CA 125 either for screening or predicting outcome in patients with fallopian tube cancer.<sup>12–14</sup> In one series, CA 125 levels were elevated in 70% of all cases, but in only 20% of those with Stage I disease<sup>12</sup>; other studies

indicate that CA 125 levels in Stage I fallopian tube cancer, as in ovarian cancer, are not elevated in at least half of the cases studied.<sup>13,14</sup> The largest available review demonstrated that pretreatment serum CA 125 was a prognostic predictor of disease-free and overall survival, regardless of tumor stage. Pretreatment levels correlated with stage, but not lymph node survival or tumor grade. In 90% of patients, an elevated CA 125 preceded clinical or radiographic evidence of recurrence. During post-treatment surveillance, serial CA 125 determinations had a 92% sensitivity in detecting recurrent disease,<sup>14</sup> consistent with other studies, which found that initial elevated levels correlate with stage of disease and prognosis.<sup>12,15</sup> Cervical cytology has not been shown to be predictive (8% to 25%) in diagnosing fallopian tube carcinoma.<sup>9,12</sup> However, positive cervical cytology has identified tubal cancer in patients following hysterectomy.<sup>16</sup> Endometrial aspiration cytology has been found to be positive in 50% of fallopian tube cancer cases, and 85% of cases were found to have either an elevated CA 125 or positive endometrial sampling.<sup>12</sup> In a recent larger series, in 13% of cases, the presumptive pre-operative diagnosis was endometrial cancer based on abnormal uterine curettage.<sup>15</sup>

Retrospective studies of fallopian tube cancer indicate that diagnosis is most often made intraoperatively, often at laparotomy for benign conditions, including torsion, uterine leiomyomata, and/or hematoperitoneum, or as previously mentioned, for presumed ovarian or endometrial cancer.<sup>1</sup> Newer imaging studies (color Doppler ultrasound, positron emission tomography [PET]/CT scanning, and magnetic resonance imaging [MRI]) have also accurately predicted tubal malignancy preoperatively.<sup>17–23</sup> Conventional transvaginal ultrasonography can detect a tubal mass and distinguish tubal from ovarian masses, as illustrated in Figure 47-1, but there is a high degree of overlap in the appearance of benign and malignant tubal pathology. Although not specific, reported features include a sausage-shaped mass, cystic spaces with mural nodules, and a multilocular mass with a “cog and wheel” appearance.<sup>17</sup> Transvaginal color and pulsed Doppler ultrasound with low impedance to blood flow (RI = 0.34 to 0.40) correctly identified eight cases of fallopian tube carcinoma preoperatively, including two patients with no gross evidence of malignancy detected intraoperatively.<sup>18</sup> Three-dimensional static and power Doppler sonography has been shown to depict irregularities of the tubal wall and vascular architecture, consistent with malignant growth.<sup>19</sup> Fallopian tube adenocarcinoma often has a nonspecific appearance on CT scan (Fig. 47-2) and is easily confused with advanced ovarian carcinoma (Figs. 47-3 and 47-4).<sup>20</sup> However, the presence of a hydrosalpinx associated with a soft tissue mass can suggest the diagnosis preoperatively.<sup>21</sup> MRI technology correctly identified a prominent tubal mass (T<sub>2</sub>-weighted) separate from the ovary preoperatively, in a patient with fallopian tube carcinoma with normal serum markers (CA 125, CA 19-9).<sup>22</sup> MRI technology requires further investigation, but shows promise as a potential tool for pre-operative detection of fallopian tube carcinoma. PET scanning fused with CT imaging also warrants further study in this clinical setting. Available data is limited and retrospective; however, PET/CT correctly detected and localized metastatic recurrent disease in 62% of cases, including those with normal CA 125 levels, laparoscopy, and CT scan.<sup>23</sup>

**Figure 47-1** A 62-year-old woman who presented with copious watery vaginal discharge (Latzke sign).

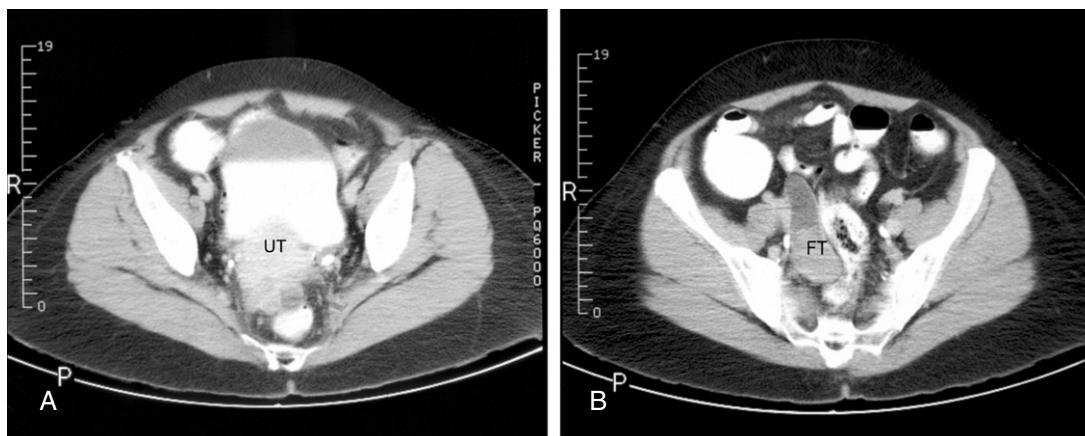

Transvaginal ultrasonography identified a mass in the pouch of Douglas with cystic and solid components (3 cm transverse  $\times$  8 cm AP  $\times$  3 cm superior to inferior) posterior (POST) to the uterus (UT) and compressing the right ovary (RT). Differential diagnosis included a complex adnexal mass or, less likely, an exophytic uterine leiomyomata.

## PATHOLOGY

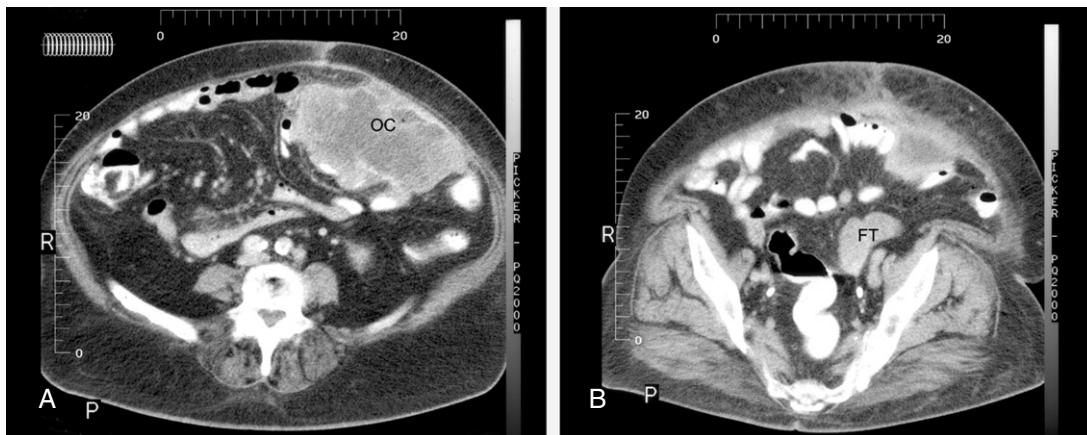

### Patterns of Spread

Fallopian tube carcinoma spreads in the abdominal cavity in a manner similar to ovarian carcinoma, by invasion of adjacent organs, by lymphatic pathways and, less commonly, by hematogeneous spread.<sup>1,8</sup> In most series, at least half of fallopian tube carcinomas were diagnosed in early-stage disease (47% to 61% of fallopian tube cases, Stage I-II).<sup>3,5,24–26</sup> This is quite different from the usual stage distribution of ovarian cancer, in which at best a third have localized disease and two thirds are diagnosed with advanced disease, either within the peritoneal cavity or the retroperitoneal lymphatics. A higher rate of lymph node metastasis for fallopian tube carcinoma relative to that

found for ovarian carcinoma has been reported in some series.<sup>27,28</sup> Lymph node metastases, however, rarely occur in patients with tumor confined to the tube or highly differentiated (grade 1) tumors, even in patients with peritoneal disease.<sup>28–30</sup> Radical lymphadenectomy has been reported to increase the likelihood of accurately detecting nodal involvement (42%), and in a retrospective analysis was shown to significantly increase overall survival (43 months; 95% CI, 20 to 66 vs. 21 months; 95% CI, 10 to 32) as well as disease-free survival.<sup>30</sup> Rarely, tumors involving the proximal tube can metastasize in the lymphatics of the round ligament to the inguinal nodes.<sup>31</sup> Tumors in the ampullary/fimbriated portion of the tube are more likely to spread to pelvic and periaortic lymph nodes.<sup>28</sup>

**Figure 47-2** Pelvic CT scan of patient described in Figure 47-1. Irregular complex mass posterior to the uterus (A) and anterior to the sigmoid colon and a separate fluid attenuation structure extending right superolateral to the uterine bladder of uncertain etiology (B). Laparotomy confirmed this structure to be a dilated, occluded right fallopian tube (FT) with a 2-cm mass at the fimbriated end. A separate solid mass was identified in the cul-de-sac that invaded the sigmoid colon muscularis. Total abdominal hysterectomy, bilateral salpingo-oophorectomy, sigmoid resection with primary anastomosis, infracolic omentectomy, and pelvic and periaortic lymphadenectomy were performed.

**Figure 47-3** A 68-year-old woman who underwent exploratory laparotomy, total abdominal hysterectomy, bilateral salpingo-oophorectomy, omentectomy, small bowel resection, and pelvic/periaortic lymphadenectomy for presumed ovarian cancer. Final pathology revealed high-grade papillary tumor occupying 95% of the tube with transmural penetration. Both ovaries were grossly and microscopically atrophic and without tumor. **A**, The 14 × 9 × 15 cm anterior abdominal mass found on preoperative CT scan was a large omental cake (OC). **B**, At laparotomy, there was a 7 × 3 cm dilated fallopian tube (FT) with a tumor at the fimbriated end; preoperatively this lesion was described as an ill-defined adnexal mass.

### Gross Appearance and Histopathology

Benign and malignant tumors of the fallopian tube are both rare. The typical appearance of localized tubal carcinoma is that of a dilated tube that can resemble a hydrosalpinx or tubo-ovarian abscess. On cut section, the tube may be filled with papillary or solid tumor. In up to 50% of cases, the fimbriated end is

occluded, potentially reducing peritoneal spread. In 26% of cases, tubal involvement is bilateral.<sup>32</sup> Criteria for the histologic diagnosis of fallopian tube carcinoma, first proposed by Hu and colleagues<sup>33</sup> and modified by Sedlis,<sup>32</sup> are depicted in Table 47-2. Although initially papillary features were a required histologic feature,<sup>33</sup> almost any histologic variant consistent with müllerian/epithelial/stromal tumors has been described; tubal neoplasms are classified by the World Health Organization into epithelial, mixed epithelial, and mesenchymal tumors, although the vast majority are serous.<sup>34–36</sup> Histologic features of fallopian tube carcinomas are illustrated in Figures 47-5 through 47-8.

Unlike ovarian carcinoma, fallopian tube carcinoma includes an *in situ* variant. Carcinoma *in situ* of the fallopian tube is characterized by atypical epithelial cells with loss of polarity and mitotic activity, that form papillae, but the basement membrane is intact (see Fig. 47-5).<sup>37</sup> Fallopian tube cancer is rarely found in the *in situ* stage, but in carefully studied sections, *in situ* disease is often found adjacent to invasive tumor.

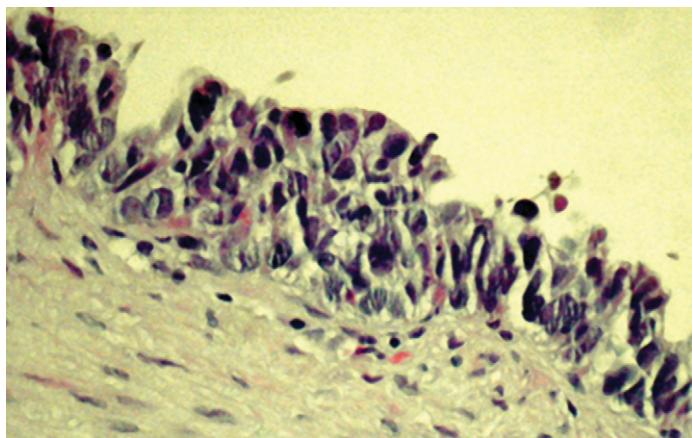

**Figure 47-4** A 68-year-old woman with Stage IIC ovarian carcinoma; this case illustrates the difficulty sometimes encountered in distinguishing ovarian from fallopian tube cancer preoperatively.

This patient presented with elevated CA 125 and a history of serosanguinous vaginal discharge. A preoperative endometrial biopsy was negative for malignancy. At laparotomy, a 4 × 4 cm left ovarian mass was found, but it was unclear grossly if the tumor originated in the dilated fallopian tube (FT) or the ovary. Solid arrows indicate dilated end of fallopian tube; stippled arrows, the ovarian mass.

**Table 47-2**  
Histologic Criteria for the Diagnosis of Primary Fallopian Tube Carcinoma

1. Grossly, the main tumor is within the fallopian tube.
2. Microscopically, the mucosa should be involved, and should show a papillary pattern.
3. If the tubal wall is extensively involved, the transition between benign and malignant tubal epithelium should be demonstrable.
4. The endometrium or ovaries are normal, or at least the volume of tumor in these organs is less extensive than that within the tube.

Adapted from Hu CY, Taymor ML, Hertig AT: Primary carcinoma of the fallopian tube. Am J Obstet Gynecol 1950;59:58–67; Sedlis A: Carcinoma of the fallopian tube. Surg Clin North Am 1978;58:121–129.

**Figure 47-5** **Carcinoma in situ.** Dysplastic cells are disorganized and heaped up, with marked nuclear pleomorphism. Atypical mitotic figures (not shown) may be present.

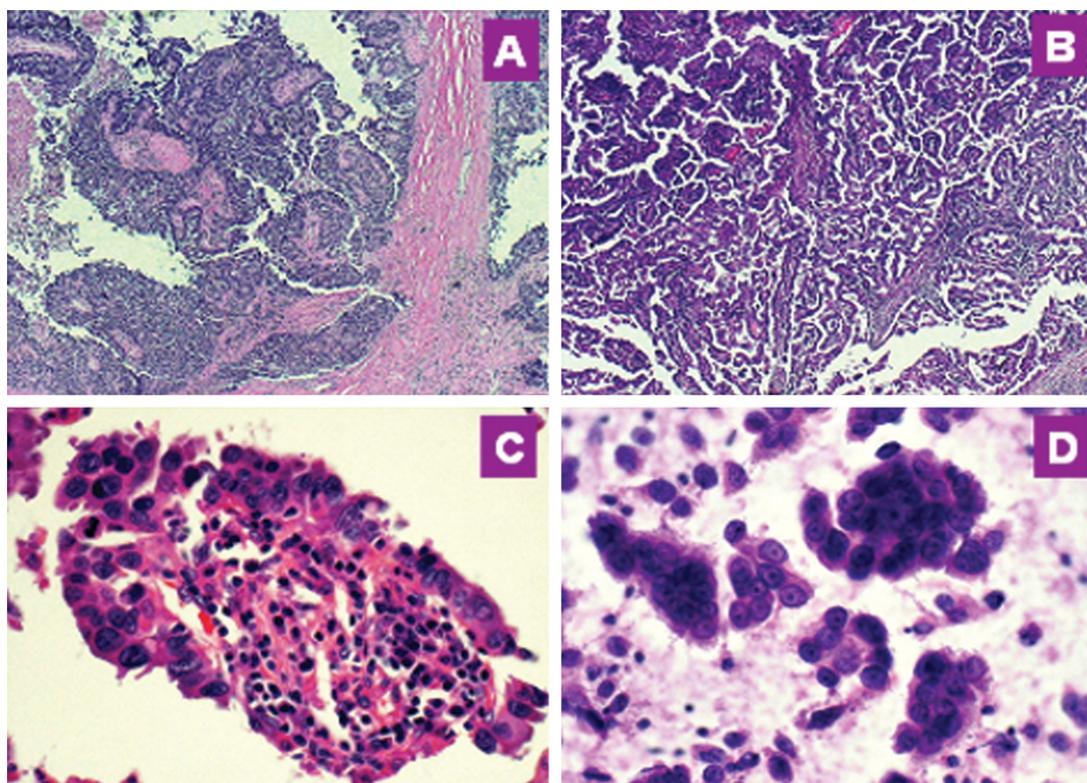

### STAGING AND RISK FACTORS FOR RECURRENCE

As with ovarian and endometrial cancer, surgical staging of fallopian tube carcinoma is considered essential to deliver optimal care and to compare treatment strategies. The current staging schema for fallopian tube carcinoma (FIGO and TNM)

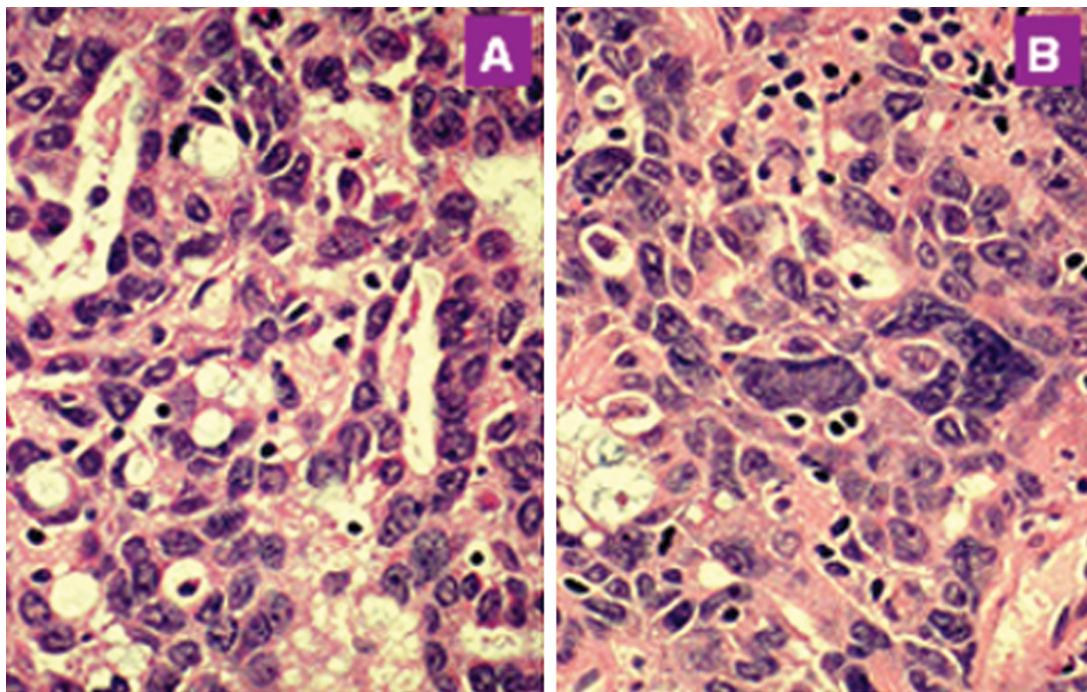

is outlined in Table 47-3.<sup>38</sup> Carcinoma in situ is included in the FIGO staging system as Stage 0. Invasion into the submucosa, muscularis, and extension into and beyond the serosa can be identified histologically and affects survival; this is now incorporated into the staging system. Like ovarian cancer, cases with malignant ascites in the absence of pelvic or extrapelvic extension identified histologically are denoted as Stage IC.

Pathologic factors that influence survival include tumor grade. In one series, patients with grade 1 tumors had a 5-year survival of 58% compared with 47% for grade 2 or 3 lesions.<sup>5</sup> Extent of lymphadenectomy performed may also influence survival.<sup>30</sup> In this clinical setting, initial and serial CA 125 determinations appear to have the same significance as a surrogate marker for response and recurrence as they do in ovarian carcinoma.<sup>14</sup>

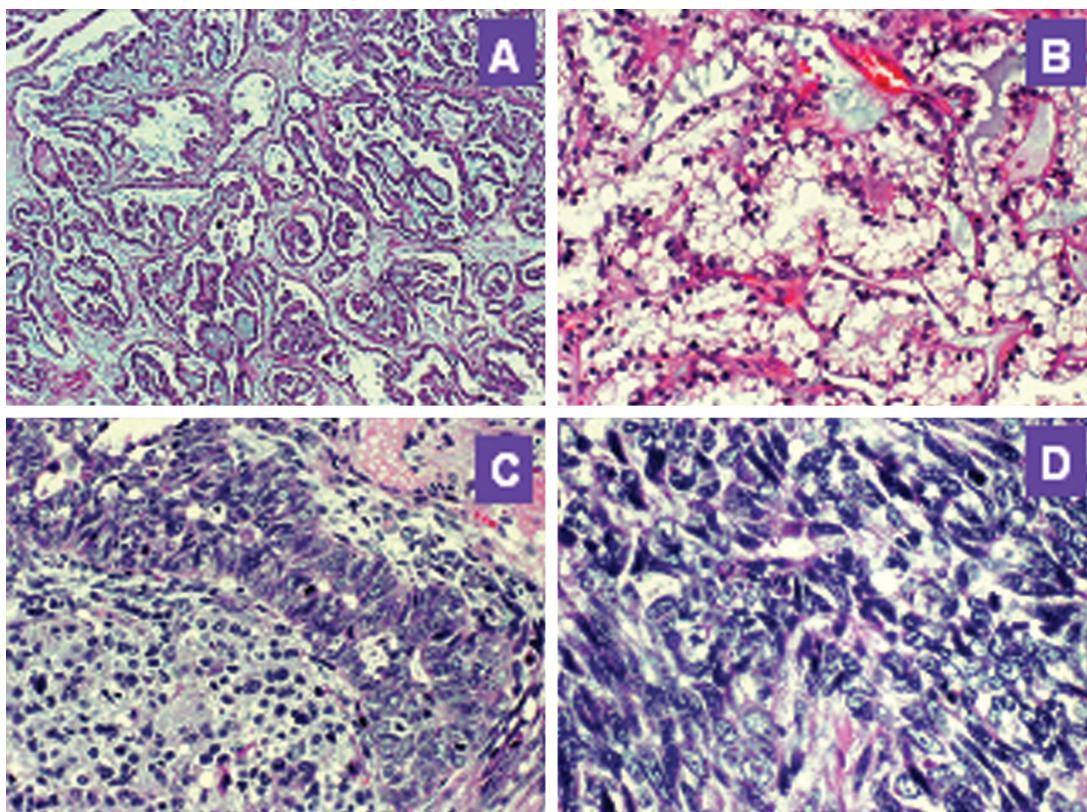

Univariate and multivariate analysis of survival in Stage I and II fallopian tube cancer has identified tumor grade, use of radiation therapy, and chemotherapy as significant factors influencing survival.<sup>8</sup> Cormio and colleagues reported that in addition to stage and grade, the presence of positive peritoneal cytology, node positivity, and residual disease after surgery all significantly reduced survival, whereas age at diagnosis and depth of tubal infiltration were not significant variables.<sup>10</sup> In the series by Alvarado-Cabrero and colleagues, significant prognostic factors included stage and, to a lesser extent, absence of fimbriated-end closure. In Stage I cases, depth of tumor within the tube and location (fimbrial or nonfimbrial) appeared to be prognostically important.<sup>15</sup> Very few studies address the relevance of histologic

**Figure 47-6** **Histologic features of serous carcinoma of the fallopian tube.** *A*, Micropapillary growth pattern (low magnification view of hierarchical layers of papillae). *B*, Complex arborizing papillary growth. *C*, Still higher magnification of tumor papilla with chronic (lymphoplasmacytular) inflammation of the stalk and moderate nuclear atypia. *D*, Fine-needle aspiration specimen showing loose, 3-D clusters of malignant tumor cells with moderate nuclear atypia.

**Figure 47-7 Poorly differentiated (grade 3) serous carcinoma of the fallopian tube.** Histologic sections demonstrate signet ring cells (A) and markedly pleomorphic tumor giant cells (B).

**Figure 47-8 Epithelial papilloma and rare histologic variants.** Epithelial papillomas or polyps are rare, and their malignant potential is uncertain. A, Papillae are formed by a single layer of cells, with no invasion into the submucosa or muscularis of the fallopian tube. B, Clear cell carcinoma. This is an unusual low-grade type of primary fallopian tube carcinoma (the clearing is most likely due to glycogen). C, Malignant mixed mesodermal tumors (MMMT, carcinosarcomas) containing both malignant epithelial and mesenchymal elements. D, Pure sarcomatoid area comprising malignant spindle cells.

**Table 47-3**  
**Surgical Staging of Carcinoma of the Fallopian Tube**

	<b>FIGO Staging Classification*</b>	<b>TNM Classification</b>
Primary tumor cannot be assessed	—	TX
No evidence of primary tumor	—	T0
Carcinoma in situ (preinvasive carcinoma)	0	Tis
Tumor confined to fallopian tube(s)	I	T1
Tumor limited to one tube, without penetrating the serosal surface, no ascites	IA	T1a
Tumor confined to both tubes, without penetrating the serosal surface, no ascites	IB	T1b
Tumor limited to one or both tubes with extension onto or through the tubal serosa, or with malignant cells in ascites or peritoneal washings	IC	T1c
Tumor involves one or both fallopian tubes with pelvic extension	II	T2
Extension and/or metastasis to uterus and/or ovaries	IIA	T2a
Extension to other pelvic structures	IIB	T2b
Pelvic extension (IIA or IIB) and malignant cells in ascites or washings	IIC	T2c
Tumor involves one or both fallopian tubes with peritoneal implants outside the pelvis and/or positive regional lymph nodes	III	T3 and/or N1
Microscopic peritoneal metastasis outside the pelvis	IIIA	T3a
Macroscopic peritoneal metastasis outside the pelvis ≤ 2 cm in maximal size	IIIB	T3b
Peritoneal metastasis over 2 cm in greatest dimension and/or positive regional lymph nodes	IIIC	T3 and/or N1
Distant metastasis (excluding peritoneal metastasis)	IV	M1

\*Stage III classification is based on initial findings, not residual disease at the end of debulking; liver serosal involvement is designated Stage III; inguinal nodal metastases are designated Stage III; pleural effusions must have malignant cells to be designated Stage IV.

Regional lymph nodes (N): Nx—regional lymph nodes cannot be assessed; N0—No regional lymph node metastasis; N1—regional lymph node metastasis

Distant metastasis (M): MX—Distant metastasis cannot be assessed; M0—no distant metastasis; M1—distant metastasis

Histopathologic grade (G): Gx—Grade cannot be assessed; G1—well differentiated; G2—moderately differentiated; G3—poorly or undifferentiated

Adapted from Benedet JL, Bender H, Jones H III et al: FIGO staging classifications and clinical practice guidelines in the management of gynecologic cancers. FIGO Committee on Gynecologic Oncology. Int J Gynaecol Obstet 2000;70:209–262.

subtype, but endometrial histology cases tend to be noninvasive or superficially invasive only and have a generally favorable prognosis.<sup>39,40</sup>

As previously mentioned, even in patients with peritoneal metastases, grade 1 tumors rarely disseminate into the lymphatics.<sup>29,30</sup> Fallopian tube carcinomas biologically are similar to ovarian in the proportion of cases expressing c-erb-b2 and TP53 gene mutations as detected by immunohistochemistry.<sup>41</sup> In some series, the authors could not demonstrate a prognostic relevance for these markers,<sup>41–43</sup> but in other series, altered TP53 expression identified a subset with poorer survival as an independent marker.<sup>44,45</sup> Mutations in the 12th codon of K-ras were found in six of eight patients analyzed, suggesting that mutations in this proto-oncogene may be important in fallopian tube mutagenesis.<sup>46</sup>

Angiogenic tumor vascularity, as measured using the endothelial cell marker CD34, indicates that tumor angiogenesis is a molecular marker for adverse outcome.<sup>47</sup> The similarities in genomic alterations for fallopian tube serous ovarian tumors provides strong support for common molecular etiopathogenesis.<sup>48</sup> One series evaluated hormonal receptor status in fallopian tube carcinoma. Approximately 42% were found to be estrogen-receptor positive and 26% progesterone-receptor positive, but receptor status did not correlate with survival. However, a positive inflammatory reaction correlated with significantly better outcome.<sup>49</sup>

An Italian Cooperative Task Force study reported that the overall 5-year survival was 57%, results similar to most of the other series comparing ovarian and fallopian tube survival.

However, they observed a unique difference in patterns of recurrence; fallopian tube carcinoma was more likely to recur in retroperitoneal nodes and at distant sites.<sup>50</sup>

## TREATMENT

### Surgery

The current management of fallopian tube carcinoma mimics that for ovarian cancer. For cases with disease visibly confined to the fallopian tube, the standard procedure includes exploratory laparotomy, visual inspection of all peritoneal surfaces, total abdominal hysterectomy, bilateral salpingo-oophorectomy, pelvic and periaortic lymphadenectomy, omentectomy, and multiple peritoneal biopsies, including both subdiaphragmatic surfaces, paracolic gutters, and pelvic peritoneum.<sup>38</sup> There is sufficient data to demonstrate that volume of residual disease influences survival.<sup>1,3,5,10,38</sup> There are no comparative trials of optimal cytoreduction in fallopian tube carcinoma. However, when this data was included, most retrospective series indicated that patients with small volume disease had significantly better outcomes.

Because survival is improved in patients with minimum residual tumor,<sup>50</sup> it seems prudent whenever feasible to follow ovarian carcinoma surgical guidelines, that is, tumor debulking if possible to at most 1 cm residual disease. The role of conservative therapy (conservation of the uterus and contralateral fallopian tube) in patients desiring preservation of reproductive function is not well studied, but recurrence following conservative management has been reported.<sup>51</sup> Given recent data that

women with familial breast and ovarian cancer do carry an increased risk for fallopian tube carcinoma and that ovarian carcinogenesis in these women occurs typically a decade younger than for nonfamilial disease, these women should be cautioned even further regarding the potential risk of conservative therapy and should receive genetic counseling.<sup>52</sup>

The role, if any, of second-look surgery in women with fallopian tube cancer is unclear. Most of the series that include cases undergoing second-look surgery do not include a subset analysis of recurrence or survival differences in patients undergoing second-look surgery versus observation.<sup>53</sup> In the series by Cormio and colleagues, four patients (31%) experienced a recurrence after a negative second-look procedure (median follow-up, 49 months).<sup>53</sup> In the series by Gadducci and colleagues, seven (46.7%) undergoing second-look surgery experienced a recurrence (median, 18 months; range, 9 to 41 months).<sup>50</sup> These data are similar to data in ovarian cancer; for ovarian cancer, second-look surgery is considered the best predictor of response to therapy and disease recurrence.

### **Chemotherapy**

Twenty years ago, 5-year survival rates for advanced disease were considered poor (<20%).<sup>54</sup> Again mirroring results from ovarian cancer trials for primary treatment, combination therapy with a platinum compound, Adriamycin (doxorubicin), and cyclophosphamide (PAC regimen) resulted in significantly better responses (complete response rate in various trials of 67%,<sup>54</sup> 64.4%,<sup>50</sup> 80%,<sup>55</sup> and 67%<sup>56</sup>) and 5-year survival rates of 19%,<sup>56</sup> 38%,<sup>55</sup> and 48%.<sup>57</sup> In the series by Gadducci and colleagues, the 5-year survival rate was 57%, and the chemotherapy regimens utilized were all platinum-based (PAC, cisplatin + epirubicin + cyclophosphamide [PEC]).<sup>50</sup> As with ovarian carcinoma, Phase II data indicate that combination therapy that includes paclitaxel improves survival over combination platinum-based therapies developed before the discovery of paclitaxel. Gemignani and colleagues reported a series of 24 patients with all stages of disease that included 8 patients who underwent suboptimum cytoreduction. Patients were treated with paclitaxel in combination with either cisplatin or carboplatin (or paclitaxel alone, one patient). These patients had a median progression-free survival at 3 years of 67%, and overall survival of 90% at 3 years (median follow-up, 24 months; range, 1 to 73 months). There were fewer recurrences in patients undergoing optimal cytoreduction (88% vs. 31%).<sup>58</sup> In another Phase I study, although response was not a primary endpoint, 79% of previously untreated patients were in complete remission after a regimen consisting of paclitaxel (175 mg/m<sup>2</sup> given over 3 hours), carboplatin (AUC = 5), and prolonged oral etoposide, and the progression-free survival was 17 months.<sup>59</sup> In inoperable patients, the combination regimen of carboplatin followed by dose-intense paclitaxel, followed by maintenance paclitaxel resulted in an overall 2-year survival of 48% (95% CI, 34% to 62%).<sup>60</sup> In recent years, cooperative group trials and institutional series have tended to lump advanced ovarian, primary peritoneal, and fallopian tube carcinomas as a single entity, at least for advanced disease trials and in recurrent disease, because response to chemotherapy and tumor biology are similar.<sup>59-65</sup>

As salvage therapy, single-agent liposomal doxorubicin has been shown to have modest activity (4/44 patients, 9%) in

patients with platinum- and paclitaxel-refractory tumors.<sup>61</sup> In a Phase III study of recurrent ovarian, fallopian tube, and primary peritoneal carcinoma, the response rate at 40 mg/m<sup>2</sup> and 50 mg/m<sup>2</sup> as single-agent therapy was 13.5% and 7.7%, respectively.<sup>62</sup> In patients who had previously received at least one platinum- and one paclitaxel-based regimen, liposomal doxorubicin (20 mg/m<sup>2</sup>) in combination with prolonged oral etoposide (50 mg/m<sup>2</sup>/day for 12 days) was associated with a 29% response rate (95% CI, 13% to 53%).<sup>63</sup> Docetaxel has been investigated as second-line therapy in patients with platinum- and paclitaxel-refractory disease, and has a response rate of 10%.<sup>64</sup> Because of this, docetaxel is beginning to be investigated as front-line therapy for ovarian, fallopian tube, and primary peritoneal carcinoma. In one Phase II study, the combination of carboplatin (AUC = 6) and docetaxel (60 mg/m<sup>2</sup>) as front-line therapy had an objective response rate of 81%; the median progression-free interval at the time of publication was unknown.<sup>65</sup> Topotecan has activity for fallopian tube carcinoma; a complete response in a patient with recurrent fallopian tube carcinoma has been reported.<sup>66</sup> Almost no data are available regarding topotecan in the front-line setting for this disease. A Phase II trial (again, combining fallopian tube with other müllerian types) of sequential doublets (carboplatin and paclitaxel, doublet 1; cisplatin and gemcitabine, doublet 2; doxorubicin and topotecan, doublet 3) indicated that sequential doublet therapy is feasible, with a pathologic complete response rate of 38%.<sup>67</sup>

### **Radiation Therapy and Radiation Compared with Chemotherapy**

Chemotherapy and radiation therapy were equally effective in achieving response in early-stage disease and were more effective than observation. In the largest study of its type, survival was higher in patients receiving combination chemotherapy (57 months—95% CI, 33 to 81 months vs. 73 months—95% CI, 68 to 78 months). However, this difference did not reach statistical significance.<sup>68</sup> Wolfson and colleagues, in a multi-institutional retrospective study, argued that relapses outside of typical whole abdominal fields were uncommon (6/40 patients, 15%).<sup>24</sup> Whole abdominal radiation therapy for microscopic and small-volume disease is associated with excellent disease-free survival, but in patients with residual disease, treatment failures are high (5-year survival for Stage I, 76.9%; Stage II, 55.6%; Stage III, 20%; gross residual disease >2 cm in size, 0%).<sup>69</sup> Brown and colleagues advocated whole abdominal radiation therapy in patients with residual disease less than 2 cm, although they found chemotherapy an acceptable alternative in patients with early-stage disease.<sup>70</sup> Together, these data indicate that although whole abdominal radiation therapy may be an effective option,<sup>24,70,71</sup> the best responses and disease-free survival are achieved with platinum-based combination regimens containing paclitaxel.<sup>58,72</sup>

### **GENETIC SUSCEPTIBILITY**

In women with autosomal dominant patterns of genetic susceptibility, the lifetime risk of ovarian cancer approaches 40%, and *BRCA1* and *BRCA2* mutations may account for as much as 90% of hereditary ovarian cancer. Women with *BRCA1* and *BRCA2*

## Fallopian Tube Carcinoma

mutations have also been found to be at increased risk for fallopian tube cancer.<sup>52,73-79</sup> Current epidemiologic evidence indicates that fallopian tube cancer should be considered a clinical component of familial (*BRCA1*, *BRCA2*) cancer. In one study, 11% of fallopian tube carcinoma patients were positive for *BRCA1* and 5% for *BRCA2* mutations. First-degree relatives of these women were found to be at increased risk for ovarian cancer (RR, 2.2; 95% CI, 0.4 to 6.3) and early-onset breast cancer (RR, 2.4; 95% CI, 0.6 to 9.1).<sup>80</sup> In addition to breast and ovarian cancer, carriers of *BRCA2* mutations are also at increased risk for nonmüllerian cancers, including prostate, pancreatic, gallbladder and biliary tract, stomach, and malignant melanoma.<sup>81</sup> Genetic counseling should therefore be offered to women who present with fallopian tube carcinoma.<sup>80-82</sup> The lifetime risk of fallopian tube carcinoma in these families has not yet been fully delineated. However, it has been estimated to be from 1.1% to 3.0%, compared to an estimated 0.025% lifetime risk of fallopian tube carcinoma in the general population.<sup>82</sup> Fallopian tube carcinoma *in situ*<sup>83</sup> and dysplastic changes in prophylactically removed fallopian tubes of women predisposed to developing ovarian carcinoma, have been described.<sup>84</sup> Salpingo-oophorectomy in women with *BRCA1* mutations reduces the risk of subsequent breast cancer development by 50% and also significantly reduces the risk of ovarian cancer.<sup>85</sup> The role of chemoprevention to reduce the risk of ovarian carcinoma in familial cancer is uncertain; at this juncture, the role of chemoprevention in this disease setting is unknown.<sup>86-88</sup>

**SUMMARY**

Survival rates for fallopian tube carcinoma appear to be improving. Compared with early ovarian carcinoma, early-stage fallopian tube carcinoma appears to have a better survival but a higher propensity for retroperitoneal spread and distant metastasis. Treatment requires appropriate surgical staging, debulking where possible, and systemic combination chemotherapy using a platinum-based regimen with paclitaxel. Fallopian tube carcinoma is part of the spectrum of genetically linked müllerian (*BRCA1/BRCA2*) and other tumors (*BRCA2*). Therefore, patients with fallopian tube carcinoma should undergo genetic counseling for familial cancer prevention. When prophylactic surgery is performed, the fallopian tubes must be removed and carefully sectioned.

## KEY POINTS

- Because ovarian cancer is often associated with nonspecific symptoms, a high clinical suspicion and thorough examination, including a pelvic examination, are necessary.
- Ovarian cancer stage is one of the most important prognostic factors for survival; it is especially important that complete staging be performed in early-stage disease.
- The majority of patients present with epithelial ovarian malignancies and advanced-stage disease.
- Advanced-stage ovarian cancer is managed with a combination of surgical cytoreduction and chemotherapy.
- One of the most important advances in ovarian cancer therapy has been the addition of platinum-based chemotherapy.
- Currently there is no cancer screening strategy for ovarian cancer that has demonstrated an impact on mortality in the general population.
- Several controversies remain in the management of patients with ovarian cancer, including the role of neoadjuvant chemotherapy, consolidation chemotherapy, and intraperitoneal chemotherapy.

## EPIDEMIOLOGY AND RISK FACTORS

### Incidence and Mortality

Ovarian cancer has the highest fatality-to-case ratio (63%) and is the most challenging of the gynecologic cancers. The American Cancer Society estimates that approximately 22,220 women will be diagnosed with ovarian cancer in 2005, and nearly 16,210 women will die of this disease.<sup>1</sup> In terms of incidence, it has been estimated that in the United States 1 in 70 women will be diagnosed with ovarian cancer and that 1 in 100 women will die of this disease.<sup>2</sup>

This chapter focuses on epithelial tumors, which comprise the vast majority (85% to 90%) of malignant primary ovarian tumors. Malignant germ cell tumors, stromal tumors, and metastatic tumors almost equally make up the remaining 10% to 15%. These different histologies have dramatically different presentations and prognoses. For epithelial ovarian cancers, approximately 70% of patients are found to have advanced-stage disease at the time of diagnosis, likely due to its direct access to the peritoneal cavity, absence of symptoms, and lack of effective screening.

Over the past 2 decades, however, there have been advances in the management of ovarian cancer. The current median survival after diagnosis has increased from 6 to 12 months to

36 months.<sup>3</sup> The 5-year overall survival increased from 36% (1970s) to 50% in 1996.<sup>4</sup> However, marked differences in survival still exist based on age and stage of disease.

### Patient-Related Risk Factors

Advanced age is the foremost patient-related risk factor for ovarian cancer. The mean age at diagnosis is age 63, women age 70 to 74 represent the peak ages of incidence; up to 57 per 100,000 women in that age group are diagnosed with ovarian cancer.<sup>2</sup>

The second greatest risk factor for the development of ovarian cancer is family history. A female with a single first-degree relative or two or three relatives with ovarian cancer has a lifetime relative risk of 3.6 and 5.5, respectively, for the development of ovarian cancer compared to the general population.<sup>5</sup>

Although 90% to 95% of cases of ovarian cancer are sporadic (unknown etiology), 5% to 10% of cases are linked to identifiable inherited mutations in specific genes. Three familial ovarian cancer syndromes have been identified: site-specific ovarian cancer syndrome, hereditary breast/ovarian cancer syndrome (HBOC), and hereditary nonpolyposis colorectal cancer syndrome (HNPCC), which account for 10% to 15%, 65% to 75%, and 10% to 15% of hereditary ovarian cancers, respectively.<sup>6</sup> Genetic linkage analyses performed in the early 1990s led to the identification of two specific genes, *BRCA1* and *BRCA2*, which are primarily linked to HBOC. Women with mutations of *BRCA1*, *BRCA2* and *MSH2* and *MLH1* (associated with HNPCC) may carry a lifetime risk for developing ovarian cancer of up to 44%, 27%, and 12% by age 70, respectively.<sup>7-9</sup>

Ovarian cancer is most often diagnosed in white women living in industrialized countries. The highest lifetime risk of developing ovarian cancer is noted in Sweden (1.73%), followed by the white population of the United States (1.53%), the United Kingdom (1.25%), Southern Europe (1.11%), South America (0.87%), India (0.75%), and Japan (0.47%).<sup>2</sup> For unexplained reasons, the incidence of ovarian cancer is generally lower for African American women. African American women have a lifetime risk of developing ovarian cancer of 1.08%, compared to 1.86% for white women living in the United States.

It has been noted that the risk of ovarian cancer increases for women who migrate from a country with a low-risk incidence to a country with a higher-risk incidence of ovarian cancer. This leads to the assumption that diet, environmental factors, and behavioral factors play a significant role in the pathogenesis of ovarian cancer.

The western diet has a considerably greater contribution from animal fat than diets of other regions; this has been

suggested as one of the factors supporting the development of ovarian cancer in some industrialized countries. As the diets of countries with lower incidences of ovarian cancer (such as Japan) increase in their consumption of dietary fat, an increase in the incidence of ovarian cancer has been noted. Lending support to this theory are several studies<sup>10,11</sup> that have demonstrated an association between the consumption of whole milk and ovarian cancer risk. The theory hypothesizes that galactose, a metabolite of the milk sugar lactose, may be responsible for affecting the normal development of oocytes. However, follow-up studies have failed to provide substantial evidence definitively establishing the link between lactose consumption and increased cancer risk.<sup>12</sup> No associations have been found between ovarian cancer and coffee, tobacco, or alcohol use.

### Exposure-Related Mechanisms of Carcinogenesis

The incessant ovulation hypothesis forms the basis of a theory by Fathalla,<sup>13</sup> whereby cellular injury and inflammation precipitated by ovulation result in disordered repair and potential neoplastic change. Local inflammation at the level of the epithelium may be associated with oxidant production, which may promote subsequent DNA damage. This theory generated much concern over the intended induction of hyperovulation resulting from the use of infertility drugs. Although conflicting results have been published, results of several case-control studies<sup>5,14</sup> have suggested that women with infertility who had or were taking fertility medications have an increased risk for ovarian cancer. A meta-analysis of eight case-control studies did not find an association between use of fertility drugs and invasive cancer, although some evidence of an increased incidence of borderline ovarian malignancies was noted.<sup>15</sup>

The premise that environmental toxins incite ovarian epithelial injury via retrograde transmission from the vagina has also been posited. Retrograde ovarian exposure to perineal talc has been implicated as a possible ovarian carcinogen, owing to the previous contamination of talc with asbestos, a known carcinogen. Although the carcinogenic potential of talc is unclear, the current literature consensus does not show a significant association between its use and the development of ovarian cancer.

Theoretically, cessation of the retrograde pathway should decrease the risk of ovarian cancer. This premise was demonstrated by prospective cohort data from the Nurses' Health Study (NHS),<sup>16</sup> in which women who had undergone tubal ligation experienced a nearly 70% decrease in the risk of ovarian cancer. This decrease may be attributed to decreased ovarian exposure to toxins, but other possibilities include decreased ovarian blood supply as a result of the ligation and ovulation suppression owing to decreased estradiol and progesterone levels.

The NHS also demonstrated the protective effects of parity. Evidence from this study established that a woman's first full-term pregnancy reduced her ovarian cancer risk by 20% to 40%, and each subsequent pregnancy reduced ovarian cancer risk by an additional 14%. According to cohort studies, this protective effect of pregnancy is also conferred on women with a family history significant for ovarian cancer.<sup>17</sup>

To a lesser degree, lactation has also demonstrated a protective effect against ovarian cancer. Lactation inhibits pituitary

luteinizing hormone, which in turn suppresses ovulation. Longer duration of lactation does not correlate with greater benefit.

The effect of oral contraceptive pills (OCPs) on ovarian cancer risk has also been extensively studied. The Cancer and Steroid Hormone (CASH)<sup>18</sup> study conducted by the Centers for Disease Control and Prevention and the National Institutes of Health, a case-control study, revealed a 40% decrease in the development of ovarian cancer after 3 to 6 months of OCP use. This protective effect increased with increasing duration of use and persisted after discontinuation of OCPs. Narod and colleagues<sup>19</sup> performed a follow-up study combining the CASH and SEER (Surveillance, Epidemiology, and End Results) data and noted that the protective effect of OCP use was also significant for women who had a family history of ovarian cancer. In this case-control study of women with hereditary *BRCA1* or *BRCA2* mutation, a 50% decrease in ovarian cancer risk was associated with any past use of OCPs. Expert consensus agrees that 5 years of OCP use will significantly reduce ovarian cancer risk without an appreciable increase in the risk of breast cancer.<sup>20</sup> However, the exact mechanism by which OCPs decrease ovarian cancer risk is unknown.

## SCREENING AND PREVENTION

### General Population

The World Health Organization has outlined general principles regarding the development of screening programs. Factors considered favorable for the development of a screening program include pathology that poses a significant health problem with a well-defined precursor lesion and known natural history; pathology with a high prevalence in the screened population; demonstrable survival benefit of early diagnosis; accessible, simple testing with high specificity that is able to be performed at designated intervals; and a balanced cost-to-benefit ratio.

Proposed strategies for ovarian cancer screening thus far have had difficulty meeting these criteria. Currently available testing has primarily incorporated the serum CA 125 test and transvaginal ultrasound.

The CA 125 tumor marker is an antigenic determinant derived from coelomic epithelium. It is located on a high molecular weight glycoprotein recognized by the mouse monoclonal antibody (OC 125) developed by using an ovarian cancer cell line as an immunogen.<sup>21</sup> Overexpression of this antigen is noted in 25% of Stage I ovarian cancer patients.<sup>22</sup> Unfortunately, levels are also elevated in several benign and malignant gynecologic and nongynecologic conditions, which limit its utility as a screening test. However, sensitivity is markedly improved with serial determinations.<sup>23</sup> Several large prospective studies have evaluated the utility of the CA 125 as a screening test. One of the largest studies was orchestrated by Jacobs,<sup>24</sup> who performed the first randomized controlled study to assess screening with sequential CA 125 testing. The positive predictive value of screening was 20.7%. Median survival time of women with index cancer in the screened group was 72.9 months compared to 41.8 months for women with index cancers in the control group. However, no difference in overall mortality was demonstrated.

Ultrasonography has been studied as a potential screening modality for several decades. Initially transabdominal ultrasound

was utilized, but specificity has been improved with the use of transvaginal ultrasonography and incorporation of morphologic criteria to categorize pelvic mass characteristics. Characteristics disclosed by ultrasound, such as thick septa, solid components, multicystic patterns, nodularity, or the presence of excrescences are associated with a greater malignant potential. Ultrasonography alone lacks sufficient sensitivity and specificity to be an adequate screening method, however. Doppler flow analysis was incorporated to help differentiate malignant and benign masses; it is valuable because malignant masses tend to have increased blood flow during diastole compared to benign masses, but the interpretation of such studies is subjective.<sup>25</sup>

Sequential multimodality screening can improve specificity and positive predictive value, but the optimal screening strategy and interval are unknown. Current proposed screening measures have not demonstrated an impact on decreased mortality in any clinical trials. High false-positive rates are costly, because they may require an invasive procedure to rule out carcinoma. As a result, cancer screening for the general population is not currently recommended.

### High-Risk Population

Due to the higher lifetime risk of ovarian cancer in women with *BRCA1* and *BRCA2* mutations, screening with serum CA 125 measurements and transvaginal ultrasounds has been recommended in this population,<sup>26</sup> despite the diversity among the data published to date. These recommendations are based on the consensus of expert opinions and have not demonstrated an impact on mortality. Women in this population need extensive counseling on the limitations of current screening recommendations.

Prophylactic oophorectomy has been suggested for over 2 decades as a preventive surgical intervention for women with a family history of ovarian cancer. Primary peritoneal carcinoma, which has an identical embryologic origin, disease presentation, and prognosis as ovarian carcinoma, has been reported in 2% to 11% of patients undergoing prophylactic oophorectomy.<sup>27</sup> Recent prospective studies in women who are carriers of the *BRCA1* or *BRCA2* mutations have demonstrated that prophylactic oophorectomy reduces the risk for both BRCA-associated gynecologic cancer as well as breast cancer.<sup>28</sup>

A recent prospective case cohort study by Rebbeck and colleagues demonstrated a 96% reduction in the risk of ovarian cancer and a 53% reduction in the risk of breast cancer with prophylactic oophorectomy. Mean age at the time of oophorectomy was 42 years. Peritoneal cancer subsequently occurred in only 2 of 259 (0.8%) patients at 3.8 and 8.6 years after oophorectomy.<sup>29</sup>

Several questions remain regarding prophylactic oophorectomy, such as the optimal timing of oophorectomy and whether it should universally include a hysterectomy. Hysterectomy has been advocated by some investigators to ensure the removal of the fallopian tube in its entirety and to reduce the risk of uterine malignancy incurred with prophylactic tamoxifen therapy. Recent evidence also suggests that women with *BRCA* mutations may be at an increased risk of developing fallopian tube carcinoma as well.<sup>30</sup>

The issue of hormone replacement in both high and low risk populations is still the subject of much debate. Epidemiologic

studies have yielded conflicting results regarding the association between hormone use and ovarian cancer. The Cancer Prevention Study II found a positive association only after more than 10 years of use.<sup>31</sup>

### CLINICAL FEATURES

A thorough history and physical examination, including a pelvic and rectovaginal examination, is necessary during evaluation of all women. The suspicion of malignancy must be especially high in a postmenopausal female with a symptomatic and palpable pelvic mass.

Most women with early ovarian cancer are asymptomatic. If a pelvic mass is large enough to produce compression of the bowel or bladder, the patient may complain of urinary frequency or changes in bowel habits. In very advanced disease, patients may have symptoms related to the presence of ascites or metastatic disease, which may include abdominal distension, abdominal pain, bloating, constipation, nausea, emesis, weight loss, anorexia, reflux, or early satiety. If a pleural effusion is present, symptoms may also include cough or shortness of breath. Less commonly, patients may experience abnormal vaginal bleeding, which is more often seen in premenopausal patients with ovarian cancer.

### DIAGNOSIS

Although findings on physical examination may lead one to suspect malignancy, and radiologic studies may confirm these findings, the definitive diagnosis of ovarian cancer is a pathologic one and requires tissue diagnosis. A serum CA 125 may be useful depending on the clinical setting. As opposed to a premenopausal patient, in a postmenopausal patient with a pelvic mass, an elevated serum CA 125 ( $>65$  U/mL) had a sensitivity of 97% and a specificity of 78% for ovarian cancer.<sup>32</sup>

Before a planned exploration, routine blood work is obtained, including a complete blood count and electrolytes, along with additional tests as indicated. Chest x-ray and electrocardiogram may be obtained if indicated. Additional imaging may be useful, such as a computed tomography scan, ultrasound, or magnetic resonance imaging, but these are not strict requisites.

Disease with metastasis to the ovaries should also be on the differential diagnosis in a patient with pelvic masses, an elevated carcinogenic embryonic antigen, and normal CA 125. These patients should undergo endoscopic or radiologic studies to exclude a gastrointestinal or biliary primary neoplasia. If extensive rectosigmoid involvement is suspected on examination, a barium enema may be useful for surgical planning. Abnormal vaginal bleeding should be evaluated with speculum examination, endometrial biopsy, and colposcopy if indicated.

### PATTERNS OF DISEASE SPREAD

Ovarian cancer tends to spread primarily by direct extension to adjacent organs, via transcoelomic routes, as the ovarian cancer cells are shed into the peritoneal cavity, and via lymphatics that provide drainage for the adnexae. A significant number of ovarian cancers have lymphatic involvement which accompanies either the ovarian vessels to the periaortic lymph nodes, the

**Table 48-1**  
**Carcinoma of the Ovary: FIGO Nomenclature**

Stage I	Growth limited to the ovaries
IA	Growth limited to one ovary
IB	Growth limited to both ovaries
IC	Stage IA or IB with tumor on surface of ovaries, with capsule ruptured, or with ascites present containing malignant cells
Stage II	With pelvic extension
IIA	Extension to reproductive organs
IIB	Extension to other pelvic tissues
IIC	Stage IIA or IIB with tumor on surface of ovaries, with capsule(s) ruptured, or with ascites present containing malignant cells
Stage III	Tumor outside the pelvis or positive retroperitoneal or inguinal nodes
IIIA	Microscopic seeding of abdominal peritoneal surfaces
IIIB	Macroscopic disease measuring < 2 cm in diameter
IIIC	Macroscopic disease measuring > 2 cm in diameter or positive retroperitoneal or inguinal nodes
Stage IV	Extra-abdominal extension If a pleural effusion is present, there must be positive cytology; parenchymal liver metastasis

broad ligament to the external and internal iliac lymph nodes, or the round ligament to the inguinal lymph nodes. Hematogeneous spread of ovarian cancer is a less common route of metastasis.

## STAGING AND PROGNOSTIC FACTORS

### Surgical Staging

Ovarian cancer is a surgically staged disease. An international staging system determined by the International Federation of Gynecology and Obstetrics (FIGO) represents the current surgical and pathologic criteria<sup>33</sup> (Table 48-1).

The surgical approach to ovarian cancer involves defining the extent of disease and removing the primary tumor. Defining the extent of disease involves careful exploration and assessment of the entire abdominal and pelvic cavities. If preservation of fertility is not a consideration, the removal of the primary tumor usually involves a total hysterectomy and bilateral salpingo-oophorectomy via an adequate vertical midline incision. In the absence of advanced disease, if the preservation of fertility is a primary concern, a fertility-sparing procedure that incorporates adequate staging may be performed with appropriate patient counseling (Tables 48-2 and 48-3).

**Table 48-3**  
**Surgical Staging for Advanced Ovarian Cancer**

- Laparotomy via vertical midline incision
- Exploration
- Peritoneal washings or ascites for cytology
- Total abdominal hysterectomy, bilateral salpingo-oophorectomy
- Omentectomy
- Pelvic and periaortic lymphadenectomy, except for Stage IIIC and IV, in which case clinically involved lymph nodes are excised
- Excision of any suspicious lesions, including radical tumor resection if indicated

Disease stage is one of the most important prognostic factors for survival (Table 48-4) in epithelial ovarian cancer, yet staging is often inaccurate. Emphasis should be placed on the performance of adequate staging in women with seemingly early disease because approximately one third will be staged higher as the result of histopathologic evaluation<sup>34</sup> (see Table 48-1).

### Optimal and Suboptimal Debulking

The current management of patients with presumed advanced ovarian cancer is surgical exploration and cytoreductive, or debulking, surgery. Although prospective trials are lacking, retrospective data consistently associates low volume of residual disease with prolonged survival.<sup>35</sup>

The definition of maximal cytoreduction has varied, but currently optimal cytoreductive surgery is the removal of all resectable tumors to a residual volume of less than 1 cm.<sup>37</sup> Unlike the approach seen with other solid tumors, aggressive cytoreduction, especially in the cases of advanced disease, has resulted in prolonged disease-free and overall survival in patients with ovarian cancer. Hoskins and colleagues found that patients with residual volume less than 1 cm had a 5-year survival of 30% to 50% compared with patients with bulky residual disease, who had a 5-year survival of 10% to 20%.<sup>38</sup>

Cytoreductive surgery has additional benefits, including alleviation of symptoms from tumor mass effect. In addition, removal of large necrotic tumor masses may improve perfusion to remaining lesions and possibly maximize the cell kill (fractional cell kill hypothesis) of chemotherapy treatments. Small-volume tumors may also be less likely to develop chemotherapy resistance (Goldie-Coldman hypothesis).

**Table 48-2**  
**Complete Surgical Staging for Early Ovarian Cancer**

- Peritoneal washings or ascites for cytology
- Total abdominal hysterectomy with bilateral oophorectomy and intact tumor removal; however, unilateral oophorectomy may be performed in selected patients with Stage I disease who desire fertility and wish to defer definitive surgery
- Omentectomy
- Pelvic and periaortic lymph node sampling
- Peritoneal biopsies: cul de sac, rectal and bladder serosa, right and left pelvic sidewalls, right and left paracolic gutters, right and left diaphragms, and any adhesions
- Excision of any suspicious lesions
- Appendectomy, if indicated

**Table 48-4**  
**Ovarian Cancer Survival by Stage at Diagnosis**

Stage	5-Year Survival Rate (%)
I	85–90
II	80

## Prognostic Factors

Tumor grade and histology play a significant prognostic role in early ovarian cancer. Patients with Stage I disease and poorly differentiated or clear cell histology have a significantly worse prognosis than those with Stage I disease and grade 1 or grade 2 serous histology, with 5-year overall survival rates of 60% and 90%, respectively.<sup>39</sup>

The level of CA 125 at the time of diagnosis may correlate with the volume of disease in some patients; however, it is not thought to be an independent prognostic factor. Conversely, in the setting of postoperative chemotherapy, the rate of decline of the CA 125 marker and normalization of this marker with therapy has been shown to be an independent prognostic factor.<sup>40</sup>

Younger patients have been found to have a slightly more favorable stage distribution and may, therefore, have an improved prognosis. Even when corrected for stage, survival rates are improved for younger women (ages 40 to 50) diagnosed with ovarian cancer versus older women.<sup>41,42</sup> It has also been observed, however, that up to 40% of older patients may not have received definitive treatment. Among 2085 patients who participated in prospective clinical trials evaluating combination therapy with a platinum compound and paclitaxel, age and performance status remained significant prognostic factors for progression-free and overall survival.<sup>42</sup>

DNA ploidy has been studied as a prognostic indicator. Vergote and colleagues conducted a study in Stage I tumors, which concluded that ploidy was more predictive of outcome than other factors, such as adhesions, ascites, rupture, and extracystic growth.<sup>43</sup>

## PATHOLOGY

### Histologic Types of Ovarian Cancer

Approximately 90% of ovarian cancers are epithelial ovarian carcinomas. Epithelial malignancies are adenocarcinomas. In this type of cancer, a malignant tumor originates in the surface epithelium tissue, which is the lining on the outside of the ovary. Epithelial ovarian cancer can be further subdivided into several histologic cell types, including serous, mucinous, endometrioid, clear cell, transitional, and undifferentiated carcinomas. Serous carcinomas are the most common comprising approximately 60%, followed by endometrioid (20%), clear cell (8% to 10%), and mucinous tumors (approximately 3%).<sup>44</sup> Clear cell and mucinous histologies have significantly worse prognoses than other forms of ovarian cancer.

### Tumor Grade

Classically, epithelial ovarian cancers were graded according to their degree of differentiation. Well-differentiated tumors have maintained their glandular appearance and are categorized as grade 1. Poorly differentiated tumors, or grade 3 tumors, no longer have the appearance of glandular features and have instead solid sheets of cells. Intermediate grade tumors (grade 2) have a combination of grade 1 and grade 3 features. All clear cell carcinomas are considered grade 3 tumors.

Although some studies have shown grade to be an independent prognostic factor in early-stage disease, reproducibility has been problematic. A universal grading system has been developed to alleviate the inconsistency by incorporating mitotic score,

nuclear atypia, and cellular architecture.<sup>45</sup> Further revisions of this system are aimed at simplifying the criteria and improving its prognostic ability.

### Tumors of Low Malignant Potential

Noninvasive epithelial ovarian neoplasms account for approximately 15% to 25% of epithelial tumors and are classified as borderline malignancies, tumors of low malignant potential, or more recently as atypical proliferative tumors.<sup>44</sup> These tumors may be serous, mucinous, endometrioid, or, rarely, clear cell type. This heterogeneous subclass of tumors is identified by careful histologic evaluation for the absence of overtly malignant characteristics. Clinically, these tumors are characterized by diagnosis at a lower average age than frankly malignant tumors, early stage at diagnosis, infrequent or late recurrences, and long survival even with residual or recurrent disease. Prognosis of atypical proliferative tumors relies heavily on whether the implants that are often found on or outside of the primary tumor are invasive or noninvasive. Women diagnosed with atypical proliferative tumors have an excellent prognosis, with a 7-year overall survival of 100% in the absence of invasive implants.<sup>44</sup>

## TREATMENT

### Chemotherapy

#### Early-Stage Ovarian Cancer

Early-stage ovarian cancer has an overall excellent prognosis. Women with Stage IA or IB well-differentiated or moderately differentiated tumors are considered to have a very favorable prognosis and have 5-year survival rates nearing 90%.<sup>46</sup> Adjuvant chemotherapy is often given to patients with early-stage disease meeting high-risk criteria (Table 48-5); however, the definition of *high risk* varies and the benefit of such an approach is the subject of controversy.

A systematic review of the literature reveals a total of eight randomized trials of early-stage ovarian cancer that include a comparison of adjuvant chemotherapy with no further treatment. Four of these trials include melphalan or other nonplatinum-based therapy, which is considered of limited relevance to current clinical practice. The four remaining studies incorporating platinum-based therapy versus no further treatment are summarized in Table 48-6. The largest and most recent parallel randomized trials—the International Collaborative Ovarian Neoplasms (ICON)-1 trial<sup>47</sup> and the Adjuvant ChemoTherapy in Ovarian Neoplasm (ACTION)<sup>48</sup> trial in patients with early ovarian cancer—compared platinum-based adjuvant chemotherapy with observation following surgery. Although parallel in

ACTION, 2003 <sup>49</sup>	448	Immediate adjuvant platinum-based chemotherapy vs treatment on progression	85 78

OS, overall survival.

many respects, these trials did differ significantly in their inclusion criteria. Specifically, the ACTION trial required surgical staging, whereas the ICON 1 trial did not. The results of these trials are subject to several interpretations. In summary, adjuvant chemotherapy improved overall and disease-free survival in nonoptimally staged patients but did not show a significant benefit in optimally staged patients. The results of these studies support the importance of complete surgical staging in apparent early-stage ovarian cancer. In the event that complete staging has not been performed and restaging cannot be completed, adjuvant chemotherapy is indicated to treat potential residual tumor, which exists in approximately 25% to 30% of cases.

#### Advanced-Stage Ovarian Cancer

Because most patients are diagnosed with advanced-stage disease, the need for effective chemotherapy after cytoreductive surgery is apparent. In the United States, the standard of therapy for advanced epithelial ovarian cancer has largely been the result of a series of randomized trials orchestrated by the Gynecologic Oncology Group (GOG). One of the most important advancements in ovarian cancer has been the addition of platinum-based chemotherapy for women with ovarian cancer. Adjuvant therapy regimens based on platinum offer overall response rates up to 80%, with complete response rates as high as 50%.<sup>49</sup> Several randomized prospective trials have been conducted, which have culminated in the current standard first-line therapy consisting of carboplatin and paclitaxel. These trials are summarized in Table 48-7.

During the platinum era (since the 1970s), the gold standard of treatment for advanced ovarian cancer had been cyclophosphamide and cisplatin. When paclitaxel was noted to have activity in the second-line setting in patients with platinum-resistant disease, it was deemed appropriate for testing in the first-line setting. The GOG performed a randomized study (GOG 111)<sup>50</sup> in suboptimally debulked Stage III or IV ovarian cancer assigned to either cyclophosphamide (750 mg/m<sup>2</sup>) and cisplatin (75 mg/m<sup>2</sup>) or paclitaxel (135 mg/m<sup>2</sup> in 24-hour infusion) and cisplatin (75 mg/m<sup>2</sup>). Both regimens were given every 3 weeks for six cycles. The objective response rates,

progression-free survival, and overall survival were superior in the paclitaxel/platinum arm (see Table 48-7). A larger confirmatory trial (OV 10)<sup>51</sup> was performed in Europe and Canada. This study used the same doses for the cyclophosphamide/cisplatin arm, but the comparison arm contained paclitaxel (175 mg/m<sup>2</sup> in 3-hour infusion) and cisplatin (75 mg/m<sup>2</sup>). Although protocol differences between the two trials existed, response rates, progression-free survival, and overall survival were superior in the paclitaxel/cisplatin arm. These findings were similar to GOG 111; however, a greater degree of neuropathy was noted, which was attributed to the 3-hour paclitaxel infusion time. The GOG also evaluated the efficacy of single-agent paclitaxel (200 mg/m<sup>2</sup>) therapy versus single-agent cisplatin (100 mg/m<sup>2</sup>) versus a combination paclitaxel (135 mg/m<sup>2</sup>) and cisplatin (75 mg/m<sup>2</sup>) in patients with suboptimal Stage III and IV ovarian cancer in GOG 132. Objective responses were inferior in the single-agent paclitaxel arm compared to the other two arms of the study. Patient tolerance of the combination arm was superior; the authors subsequently concluded that the combination of cisplatin and paclitaxel was the preferred initial treatment for advanced ovarian cancer.

While these studies were being completed, evaluation of cisplatin versus the newer platinum analog carboplatin was also being performed in the ICON 2,<sup>52</sup> ICON 3,<sup>53</sup> and GOG 158<sup>54</sup> studies. The cisplatin and carboplatin compounds were compared in combination therapy; the regimens containing the carboplatin compound were found to be equivalent in efficacy and associated with less nephrotoxicity, less nausea and vomiting, less neurotoxicity, but greater myelosuppression. These studies led to the favoring of carboplatin over cisplatin for first-line therapy.

The current standard of chemotherapy for previously untreated patients with Stage III/IV ovarian cancer who have undergone optimal or suboptimal cytoreductive surgery leaves room for improvement in terms of response rate and both progression-free and overall survival. GOG 182-ICON 5<sup>55</sup> is a five-arm international collaborative study designed to improve on the efficacy of standard platinum/taxane therapy by incorporating newer cytotoxic agents (gemcitabine, topotecan, and pegylated liposomal doxorubicin) in sequential doublet and

triplet combinations. This trial is currently completing accrual, and the benefits of additional cytotoxic agents will need to be evaluated.

### Second-Look Surgery

Second-look laparotomy originally described for colon cancer is a careful laparotomy with extensive cytologic and pathologic sampling to determine if residual disease is present. Second-look laparotomy for ovarian cancer was first introduced in the mid-1960s as a way to determine if the chemotherapy effect had been complete and chemotherapy could be stopped. Until 1999 all trials sponsored by the National Cancer Institute required a second-look procedure to determine the true response rate. However, due to the perception that second-look laparotomy, although identifying good or poor responders, had little effect on the overall prognosis, the NCI stopped mandating this procedure. In the first study without a mandated second-look laparotomy (GOG 158), approximately 400 patients chose to have and 400 not to have a second-look laparotomy. Despite the earlier identification of disease and institution of immediate therapy, there was no significant effect on progression-free or overall survival. As a result second-look laparotomy is not indicated outside of an investigational setting.

### Radiation Therapy

Several studies have been performed evaluating the potential of radiation therapy as consolidation treatment (treatment following initial chemotherapy). Whole abdominal radiation (WAR) therapy in patients with ovarian carcinoma has been evaluated in several prospective, randomized trials. No large studies have demonstrated a statistically significant difference in overall survival between WAR, further chemotherapy, or observation

in patients with complete response to initial chemotherapy. Radiation toxicity (specifically bowel) may be significant in this population owing to prior surgeries and chemotherapy.

### PROGNOSIS

After the completion of initial therapy, patients are placed under careful surveillance. Examinations are performed every 3 months for at least the first 3 years. This includes physical and pelvic examinations and serial CA 125 measurements, if initially elevated. Radiologic evaluation may be performed according to symptoms, examination findings, or at designated intervals.

### Recurrent Ovarian Cancer

The overall response rate to primary platinum-based chemotherapy nears 75%. Ultimately, 25% of patients do not respond to primary therapy and in many other patients the response is short-lived, with relapse occurring within 3 years. Unfortunately, for patients with persistent disease after primary therapy or recurrent disease cure is no longer possible; however, induction of a second remission is still a realistic goal. Management of patients with recurrent disease is a challenge owing to the delicate balance between the maintenance of the patient's quality of life and minimization of treatment-related toxicity.

The role of surgery in patients with recurrent ovarian cancer needs to be individualized. In the event of late recurrent disease that may be chemotherapy-sensitive and focal disease, surgical cytoreduction may be of benefit. This observation, however, has not been conclusively established by large randomized prospective trials. Recurrent disease is often multifocal and associated with bowel obstruction. The decision to surgically manage a bowel obstruction attributed to recurrent disease should be

considered on an individual basis, taking into account response to prior chemotherapy.

The role of chemotherapy for patients with recurrent ovarian cancer is more complex. Patients who have experienced a durable response for longer than 6 months from completion of initial platinum-based therapy are considered potentially “platinum sensitive.”<sup>56</sup> Platinum-sensitive patients may be re-treated with platinum agents (cisplatin or carboplatin). Response rates of 20% to 60% have been demonstrated in this population. Which agent or agents to use is controversial. In a platinum-sensitive population, defined in one study as a platinum-free interval of 12 months, Cantu and colleagues<sup>57</sup> demonstrated an improved progression-free interval with initiating therapy with a platinum-based regimen over nonplatinum-based therapy, in this case paclitaxel. Even with a crossover design, patients who initiated second-line therapy with a platinum regimen had improved survival.

In potentially platinum-sensitive patients, two large randomized trials have evaluated single-agent therapy with carboplatin versus carboplatin in combination. The first trial<sup>58</sup> compared single-agent carboplatin to carboplatin and paclitaxel. An improvement in both progression-free and overall survival was noted. Subgroup analysis suggested the greatest improvement was in patients whose treatment-free interval was 12 months or greater. This study was criticized because not all the patients were treated with paclitaxel primarily and in subgroup analysis only patients not pretreated with paclitaxel had a statistical benefit.

In a second study<sup>59</sup> comparing single-agent carboplatin with carboplatin and gemcitabine, combination therapy was again associated with an improved progression-free survival but the study could not evaluate overall survival differences.

Patients who do not respond to initial therapy or recur in less than 6 months from completion of initial platinum-based therapy are considered “platinum refractory.”<sup>56</sup> Chemotherapy options for patients with platinum-refractory disease have primarily focused on potential agents that are noncross-resistant with platinum therapy. Several options are available for alternative agents (Table 48-8), but there is no clear data to support the choice of one agent over another. Preexisting comorbidities from prior chemotherapy will often dictate the choice of future therapy. The response rates for patients with platinum refractory disease are generally between 10% to 30%.<sup>60</sup> Combination therapy in this setting has not demonstrated improved

progression-free survival; thus, single-agent therapy is employed in an attempt to minimize toxicity. Patient preferences, quality of life, and performance status must be taken into consideration in the setting of recurrent disease.

Radiation therapy may be beneficial as symptom palliation for patients with recurrent ovarian cancer. The duration of palliation varies, but many have reported successful complete palliation of symptoms.

## Controversies

### Cytoreductive Surgery

As noted, multivariate analysis has revealed that residual tumor is a significant prognostic factor for ovarian cancer. Despite its prominent place in the treatment of ovarian cancer, the benefits of cytoreductive surgery remain controversial. The primary criticisms of cytoreductive surgery include the lack of randomized prospective data to confirm its theoretical benefits. The ability to perform maximal cytoreduction may be a function of the biology of the tumor. Remaining tumor volume or distribution may be more important than an absolute measurement of maximum diameter, meaning that the presence of miliary disease may be an indicator of a worse prognosis than a single focus of disease measuring greater than 1 cm. In addition, the morbidity from radical debulking surgery increases the risk of complications, decreases the patient’s quality of life, and possibly delays the initiation of chemotherapy.

### Neoadjuvant Chemotherapy and Interval Debulking Surgery

Many patients are unable to receive maximum cytoreductive surgery owing to several reasons, including coexisting medical morbidities that preclude surgery, the extent of disease, the experience of the surgeon, and possibly the tumor biology itself. A possible advantage of postponing surgical intervention until after chemical cytoreduction is decreased operative morbidity. However, even though neoadjuvant chemotherapy is offered to patients whose disease is considered potentially inoperable, there are no prospective randomized data to demonstrate equivalent results between neoadjuvant chemotherapy and the standard management of surgery followed by chemotherapy.

Two randomized trials have evaluated the role of a secondary interval debulking surgery for patients with suboptimal residual ovarian cancer with a volume greater than 1 cm. A trial performed by the European Organization for Research and Treatment of Cancer (EORTC) Gynecologic Cancer Cooperative Group evaluated interval debulking surgery.<sup>61</sup> In this study, patients who underwent initial suboptimal cytoreduction following three cycles of cisplatin and cyclophosphamide were randomized to either three additional cycles of chemotherapy versus a repeat exploratory laparotomy with a second attempt at cytoreduction followed by three additional cycles of chemotherapy. Among 319 patients those who received interval debulking surgery had a 33% (CI, 95%) reduction in risk of death at 2 years and a significant improvement in progression-free survival ( $p = 0.01$ ).

The GOG performed a similar study,<sup>62</sup> GOG 152, in which 550 patients who had undergone suboptimal cytoreduction were treated with three cycles of paclitaxel/cisplatin after initial surgery. In the absence of progressive disease, patients were then randomly assigned to three additional cycles of chemotherapy

**Table 48-8**

Tamoxifen

versus a second cytoreduction and three cycles of chemotherapy. Results did not demonstrate a difference in median progression-free survival (10.5 vs. 10.8 months) or median overall survival (32 vs. 33 months) for the chemotherapy versus the interval debulking surgery arms, respectively. The European study was primarily criticized for the less aggressive primary surgery, correlating with a greater volume of residual disease bulk before study entry. It appears that interval debulking surgery can only improve outcomes for patients who did not receive maximal cytoreduction at the initial surgical procedure.

### **Intraperitoneal Chemotherapy**

Ovarian cancer usually remains confined to the peritoneal cavity, growing along its surface. The portal circulation, which bypasses the liver, is largely responsible for drug uptake from the peritoneal cavity. For these reasons intraperitoneal (IP) chemotherapy, the administration of cytotoxic agents directly into the peritoneal cavity, provides a potential pharmacokinetic advantage over systemic therapy by enhancing locoregional drug delivery. In theory, IP therapy may allow for greater concentrations administered locally, without a concomitant increase in dose-limiting systemic toxicities. However, it has also been shown in preclinical models that the depth of penetration of IP therapy into tumor nodules is limited, which clinically translates into a limited population (small-volume residual disease) in whom IP therapy may be of therapeutic benefit.

Several drugs have been examined for their potential efficacy when used via the IP route. Cisplatin has been one of the more extensively studied agents due to its pivotal role in the treatment of ovarian cancer. Three large randomized prospective trials have examined the benefits of IP therapy in the treatment of ovarian cancer (Table 48-9).

In the first trial conducted by the Southwest Oncology Group and subsequently joined by the GOG,<sup>63</sup> patients received cyclophosphamide (600 mg/m<sup>2</sup> IV) and cisplatin (100 mg/m<sup>2</sup> IV or IP). A statistical improvement in complete response as determined by second-look laparotomy and survival, was noted in the intraperitoneal arm. The study has been criticized on three bases. First, when analysis after completing the intended accrual demonstrated a lack of statistical benefit, the study was reopened

for further accrual. Second, despite this the intended risk reduction of 33% was never achieved. Last, patients with residual disease measuring between 0.5 and 2 cm had the greatest improvement in outcome when the expected improvement was for those with disease measuring less than 0.5 cm.

The second large randomized trial conducted by the GOG<sup>64</sup> compared intravenous cisplatin and paclitaxel for six cycles to moderately high-dose carboplatin (AUC = 9) for two cycles followed by intraperitoneal cisplatin and intravenous paclitaxel for six cycles. One-tailed statistical analysis demonstrated an improvement in progression-free survival ( $p = 0.01$ ) and a marginal improvement in survival ( $p = 0.05$ ). However, this study had three variables—the use of intraperitoneal therapy, the administration of moderately high-dose carboplatin, and the administration of eight cycles of therapy in the experimental arm—which confounds its interpretation.

The third most recently completed study<sup>65</sup> compared intravenous cisplatin and paclitaxel with a regimen of intraperitoneal cisplatin and intravenous paclitaxel on day 1 and intraperitoneal paclitaxel on day 8. This experimental arm had an improvement in complete response as determined by second-look laparotomy and progression-free survival, but survival data is immature. This regimen was significantly more toxic, which has limited its general acceptance.

Collectively, these studies have failed to convince the medical community to routinely use intraperitoneal therapy as the standard of care. The confusing design of the studies, with multiple variables used simultaneously, left the impact of the IP route uncertain. Yet IP therapy remains an active area of investigation. To further address this issue, the GOG has elected to study IP carboplatin due to its greater tolerability and to develop a study evaluating the IP route as the only variable modified. Current practices await the maturation of the data from this trial.

Observed survival benefits likely cannot be attributed to surgical debulking alone; unrecognized tumor factors play a considerable role as well. It is also interesting to note that, although believed to be a significant prognostic variable, volume of residual disease is not incorporated into the current staging system, largely owing to the fact that a reproducible and accurate measurement for this volume is not available.

**Table 48-9**  
**Randomized Trials of Intraperitoneal versus Intravenous Chemotherapy**

Study	(n)	Residual Disease	Regimen	PFS (mo)	OS (mo)
GOG 104 <sup>63</sup>	546	≤2 cm	IV cisplatin (100 mg/m <sup>2</sup> ) + IV Cytoxan (600 mg/m <sup>2</sup> ) vs IP cisplatin (100 mg/m <sup>2</sup> ) + IV Cytoxan (600 mg/m <sup>2</sup> )	N/A	41 vs 49 ( $p < 0.02$ )
GOG 114 <sup>64</sup>	462	≤1 cm	IV cisplatin (75 mg/m <sup>2</sup> ) + IV paclitaxel (135 mg/m <sup>2</sup> ) vs IV carboplatin (AUC-9) + IP cisplatin (75 mg/m <sup>2</sup> ) + IV paclitaxel (135 mg/m <sup>2</sup> )	22 vs 28 ( $p = 0.01$ )	63 vs 52 ( $p = 0.05$ )

OS, overall survival; PFS, progression-free survival.

### **Consolidation Therapy**

*Consolidation therapy* is defined as chemotherapy given after induction of initial chemotherapy to reduce the number of cancer cells. The role of consolidation therapy for patients with ovarian cancer who have achieved a complete clinical response after initial surgery and platinum-based chemotherapy is controversial. Because so many patients relapse after a seemingly complete response, it is clear that microscopic disease is likely present but cannot be detected by current imaging methods. In an effort to improve the durable responses to therapy and decrease the relapse rate after initial treatment, a study (GOG 178/SWOG 9701) was performed by the GOG and the Southwest Oncology Group (SWOG). This study compared 12 months versus 3 months of paclitaxel consolidation therapy in patients with advanced ovarian cancer who were considered to be in complete clinical response after platinum/paclitaxel chemotherapy.<sup>66</sup> With half of the planned 450 patients accrued, the primary endpoint of progression-free survival advantage was achieved. The study was closed in October 2001 by the Data and Safety Monitoring Committee after an interim analysis. A statistically significant difference in progression-free survival was observed at 28 months in the 12-cycle arm versus 21 months in the 3-cycle arm. However, overall survival benefit cannot be determined because the study was discontinued and patients in the 3-cycle arm were allowed to cross over to the 12-cycle arm.

This has led many to question whether the initiation of therapy immediately after primary treatment (maintenance therapy) is superior to withholding treatment until there is evidence of progression (second-line therapy). The lack of benefit in the two other randomized trials, which utilized topotecan for four cycles versus observation, is also of concern because these agents are equivalent in randomized trials as second-line therapy. Further studies of consolidation therapy evaluating the risks, benefits, optimal agents, and dosing strategies are needed.

## **Nonepithelial Ovarian Tumors**

### **Germ Cell Tumors**

Germ cell tumors account for less than 5% of all ovarian cancers and originate in the egg-producing cells found within the ovary.<sup>67</sup> A variety of pure germ cell histologies have been described. With the exception of dysgerminoma and low grade immature teratoma, the prognosis of the germ cell histologies is similar, with an approximate 50% recurrence rate for Stage I tumors treated with surgery alone. When treated with adjuvant chemotherapy the recurrence rate for these tumors is 22% following chemotherapy with vincristine, actinomycin-D, and cyclophosphamide (VAC), and 3% following chemotherapy with bleomycin, etoposide, and Platinol (cisplatin; BEP). Mixed germ cell tumors should be treated based on the histologic component with the poorest prognosis. This type of ovarian cancer can occur in women of any age, but approximately 80% are diagnosed in women under age 30.

### **Stromal Cell Tumors**

Sex cord stromal tumors, which account for approximately 5% of all ovarian cancers, develop in the connective tissue that holds the ovary together and produces the female hormones—estrogen and progesterone. A variety of pure stromal cell

histologies have been described. Sex cord stromal tumors are usually low-grade malignancies, and observation following initial surgery is the standard practice, with the exception of those with extraovarian metastasis or poorly differentiated Sertoli-Leydig cell tumors. Granulosa cell tumors comprise 70% of the neoplasms in this category.<sup>68</sup> The time to recurrence varies widely, with a median of 8 years, but may be up to 20 years after removal of the original tumor. As with other nonepithelial ovarian tumors, the BEP chemotherapy regimen has been the most commonly used. The GOG studied 38 patients with advanced or recurrent granulosa cell tumor treated with this regimen followed by second-look surgery and noted a 37% response rate.<sup>69</sup> Paclitaxel has been reported to demonstrate activity as well and is currently being evaluated by the GOG.

### **Sarcomas**

Ovarian sarcomas are difficult to diagnose intraoperatively and as a result are only recognized on permanent pathology. For patients with disease spread beyond the ovary the prognosis is poorer than for epithelial tumors. In view of the high grade of most of these tumors, systemic chemotherapy based on other soft tissue sarcomas could be considered.

## **FUTURE DIRECTIONS**

The 20% to 30% 5-year survival rate for advanced disease clearly leaves room for improvement. Most patients present in an advanced stage, and cure rates remain low despite improvements in progression-free and overall survival. The clinical challenges that remain regarding the care of women with ovarian cancer demand further refinement of current screening measures, imaging modalities, serum markers, and control of metastatic disease.

## KEY POINTS

- Gestational trophoblastic disease (GTD) comprises a spectrum of interrelated conditions originating from the placenta.
- Histologically four distinct clinicopathologic forms are recognized: complete and partial hydatidiform moles, invasive mole, choriocarcinoma, and placental site trophoblastic tumor.
- Diagnosis and management can be based solely on history, elevated levels of human chorionic gonadotropins, and metastatic workup.
- Three main systems have been used to categorize patients with gestational trophoblastic disease: the WHO prognostic index score, the anatomic FIGO classification, and the clinical classification system.
- Recently FIGO revised its classification to include both the anatomic stages and a modified WHO prognostic score. The new FIGO risk index also standardized the radiologic studies to be used for determining the number and size of metastases.
- At present with quantitative assays for  $\beta$ -hCG and the use of different protocols of chemotherapy, most women with gestational trophoblastic disease can be cured and their reproductive function preserved even when the disease is widely disseminated.

GTD, or gestational trophoblastic neoplasia (GTN), includes a spectrum of diseases with a wide range of neoplastic potential and is among the rare solid human malignancies that can be cured even when widely disseminated. Reasons for this success include a sensitive marker, beta-human chorionic gonadotropin ( $\beta$ -hCG), and sensitivity to various chemotherapy agents and other modalities such as surgery and radiation. Although four distinct clinicopathologic forms are recognized—complete or partial hydatidiform mole, invasive mole (chorioadenoma destruens), placental site trophoblastic tumor (PSTT), and choriocarcinoma—diagnosis and management can be based solely on history, elevated levels of  $\beta$ -hCG, and metastatic workup. This approach, in which a disease is treated by cytotoxic drugs based on clinical classification without cytologic or pathologic documentation of malignancy, is unique.

## HYDATIDIFORM MOLE

### Epidemiology

The precise incidence of molar pregnancy is difficult to derive, because in most reports neither the total number of pregnancies

nor the total number of hydatidiform moles (HM) in a defined population are known. The most reliable studies suggest that the incidence of HM is slightly less than 1 out of 1000 pregnancies in most of the world and possibly as high as 1 out of 500 pregnancies in the Far East. It is possible that the higher risk in the Far East is the result of bias caused by reporting data from hospital-based studies rather than population based studies. Because many normal deliveries occur at home in these countries, hospital-based studies result in a bias overestimation of the true incidence of hydatidiform mole. The reported incidence of hydatidiform mole varies among ethnic groups; in the United States white women are twice as likely to develop hydatidiform mole as black women. In a study from Hawaii,<sup>1</sup> the incidence was lower in white and native Hawaiian populations (7.7 to 8 of every 1000 pregnancies) and highest in Filipino and Japanese populations (16.5 to 17.5 of every 1000 pregnancies); whether this difference is of genetic or cultural origin is unknown. Familial molar pregnancies were reported as well. The incidence of hydatidiform mole is clearly related to maternal age and is reported to be higher in women younger than age 15 or older than age 40. Women older than age 50 have a 300- to 400-fold increased risk of hydatidiform mole compared to women ages 25 to 29. Patients with a prior history of a molar pregnancy have an increased risk of trophoblastic disease. The risk of hydatidiform mole after one previous molar pregnancy is 1 out of 76; after two previous molar pregnancies, the risk increases to 1 out of 6.5; and after three molar pregnancies the likelihood for a live birth is almost 0.

Unconfirmed risk factors include Rh-positive blood type, artificial insemination, nulliparity, consanguinity, diet (low in protein, folate, vitamin A), history of prior spontaneous abortions, and professional occupation<sup>2</sup> (Table 49-1).

### Classification

Hydatidiform mole (from the Latin *hydatis*—watery vesicle, *moles*—shapeless mass) can be classified as either complete or partial on the basis of gross morphology, histopathology, and karyotype (Table 49-2).

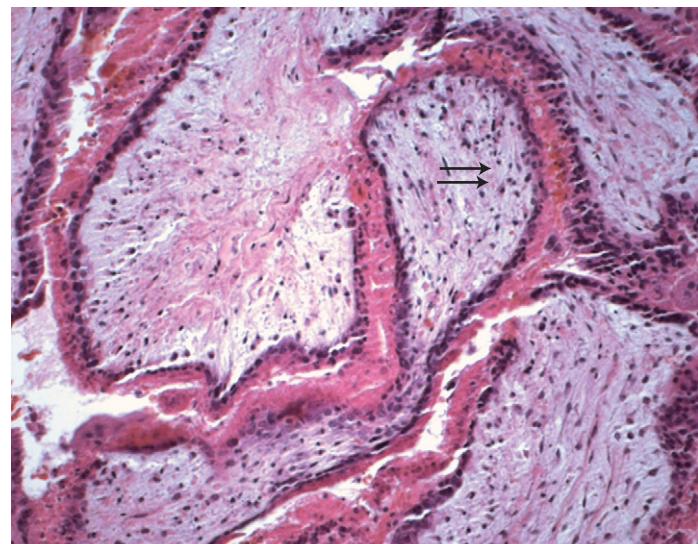

#### Complete Hydatidiform Mole

The complete hydatidiform mole (Figs. 49-1 and 49-2) is characterized by lack of identifiable embryonic or fetal tissues, gross vesicular swelling involving all the placental villi, and diffuse cytotrophoblastic and syncytiotrophoblastic hyperplasia. Cellular anaplasia may also be present.

Complete hydatidiform moles usually have a 46,XX karyotype entirely of paternal origin. Complete mole appears to arise from an empty or inactivated ovum that has been fertilized by a single sperm carrying 23 chromosomes. The haploid set of

Table 49-1 Factors Associated with GTD Occurrence and Corresponding Relative Risks	
Risk Factor	OR Complete Mole (%)
Prior molar gestation	20–40
Maternal Age	
<20 years	1.5
>40 years	5.2
Prior spontaneous abortion	1.9–3.3
Current smoking	2.2
Vitamin A in diet above control median	0.6
Parity >1, abortions 0	0.2–0.6

From Smith HO: Gestational trophoblastic disease epidemiology and trends. Clin Obstet Gynecol 2003;46:541–546.

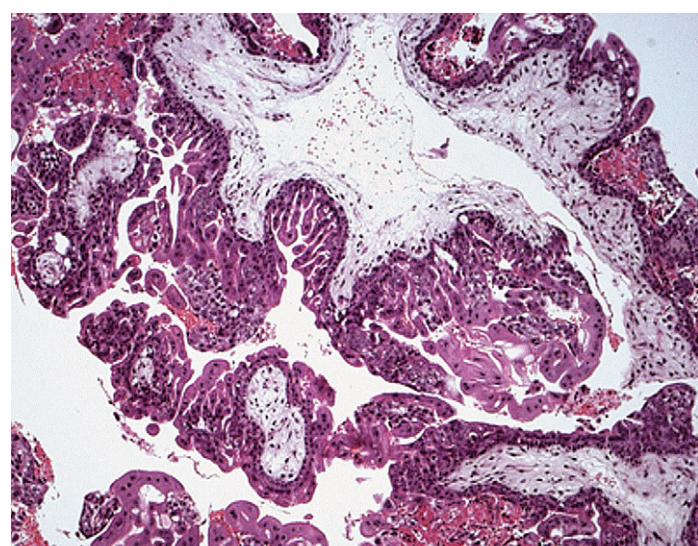

**Figure 49-1** Early complete hydatidiform mole. Note characteristic stromal karyorrhexis (arrows). (Courtesy Dr. Ilana Ariel, Hadassah Medical Center, Jerusalem.)

chromosomes reduplicate to give a 46 karyotype. This process, called *androgenesis*, results in a homozygous conceptus. Although most complete moles have a 46,XX chromosomal pattern, approximately 10% have a 46,XY karyotype. Chromosomes in a 46,XY complete mole also appear to be entirely of paternal origin, but in these circumstances an apparently empty egg is fertilized by two sperm, one carrying the X and the other the Y chromosome. The risk of malignancy is similar in the XX and XY subset. Kovacs and colleagues,<sup>3</sup> using molecular genetic fingerprinting methods in 20 consecutive complete moles, found 12 (60%) to be of homozygous androgenetic origin, 4 (20%) to be of heterozygous androgenetic origin, and 4 (20%) to be of heterozygous biparental origin. The latter heterozygous biparental complete mole appears to be associated with an autosomal recessive condition predisposing to molar pregnancies. Because they are pathologically indistinguishable from androgenetic complete hydatidiform mole, biparental complete hydatidiform moles are likely to result from defects in genomic imprinting.

There is evidence that the gene mutation in this condition, provisionally mapped to 19q13.3–13.4, may be important in setting the maternal imprint in the ovum. Women with biparental complete hydatidiform mole have a much higher risk of recurrent hydatidiform mole than women with androgenetic complete hydatidiform mole; they also have an appreciable risk of persistent trophoblastic disease.<sup>4</sup> Other studies have shown that complete moles were 50% diploid, 43% tetraploid, and 3.6% polyploid.

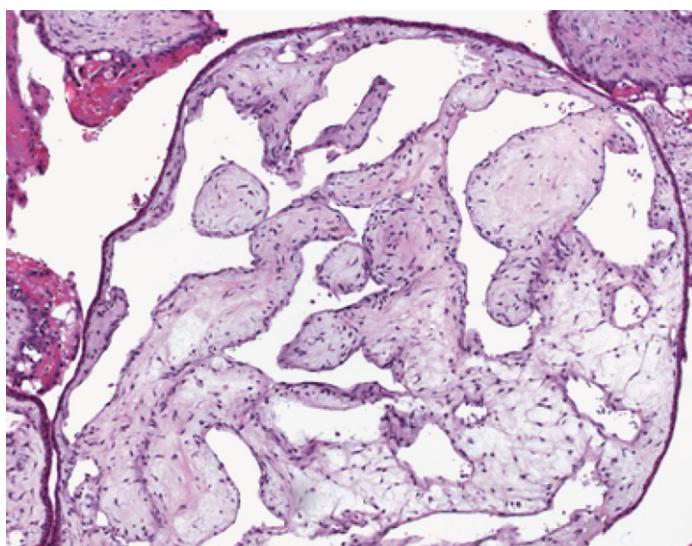

#### Partial Hydatidiform Mole

Partial hydatidiform mole (Figs. 49-3 and 49-4) is invariably associated with an embryo or fetus, cord, or membranes.

**Figure 49-2** Complete hydatidiform mole. Note hydropic degeneration with formation of central cisterns and prominent circumferential trophoblastic hyperplasia. (Courtesy Dr. Ilana Ariel, Hadassah Medical Center, Jerusalem.)

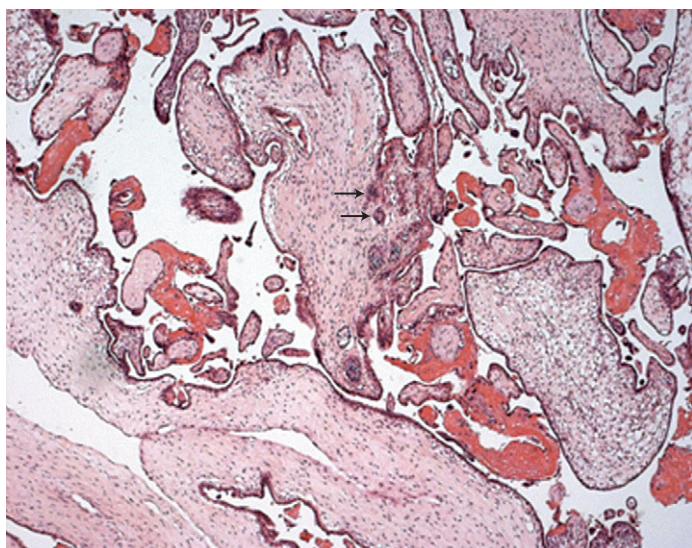

Table 49-2 Features of Complete and Partial Hydatidiform Moles		
Feature	Complete Mole	Partial Mole
Synonyms	Classic, true	Incomplete
Fetal or embryonic tissue or membranes	Absent	Usually present
Villous capillaries	Usually absent; when present, no fetal blood cells	Usually present; may contain fetal blood cells
Hydatidiform swelling of chorionic villi	Diffuse	Focal
Trophoblastic hyperplasia	Usually present	Mild and focal
Malignant potential	15%–25%	5%–10%
Karyotype	46,XX;46,XY	69,XXX;69,XXY

**Figure 49-3 Partial hydatidiform mole.** Labyrinthine vascular pattern. (Courtesy Dr. Ilana Ariel, Hadassah Medical Center, Jerusalem.)

Although the embryo usually dies by 9 weeks' gestation, it may survive to the second and rarely even to the third trimester. The characteristic pathologic features are chorionic villi of varying size with focal hydatidiform swelling and cavitations; marked villous scalloping; focal trophoblastic hyperplasia, usually limited to the syncytial trophoblastic cells; development of functioning capillaries manifested by the presence of erythrocytes; and prominent stromal trophoblastic inclusions.

Partial hydatidiform moles usually have a triploid karyotype (69 chromosomes), containing two sets of paternal and one set of maternal chromosomes. Partial moles may be confused with triploid embryos with a diploid set of maternal DNA and haploid set of paternal DNA.<sup>5</sup> Until these cytologic differences

**Figure 49-4 Partial hydatidiform mole.** Note two populations of villi: small fibrotic and large hydropic villi. The large villi are characterized by scalloped borders and round trophoblastic inclusions (arrows). (Courtesy Dr. Ilana Ariel, Hadassah Medical Center, Jerusalem.)

became recognized, incidence rates were probably falsely elevated, because inclusion of triploid abortus cases resembling partial hydatidiform moles was likely.

### Clinical Features

The presenting symptoms and signs of complete and partial molar pregnancy are provided in Table 49-3.

Essentially all patients with complete hydatidiform mole have delayed menses, and most patients are considered pregnant. Although in the past it was stated that only 50% of hydatidiform moles are diagnosed before expulsion of the typical grape-like vesicles, with the widespread use of sonography to assess early pregnancy and first-trimester bleeding, most molar pregnancies are currently diagnosed before the appearance of symptoms.

According to the Trophoblastic Disease Registration Centre database at Charing Cross Hospital in London, the risk of molar pregnancy is increased in both upper and lower extremes of maternal age ( $\geq 45$  years and  $\leq 15$  years). This association is strongest for complete moles, and the degree of risk is much greater with older rather than younger maternal age.

Because most of cases of complete hydatidiform mole are currently diagnosed in the first or early second trimester, the classic signs and symptoms of excessive uterine size, hyperemesis, anemia, pre-eclampsia, clinical hyperthyroidism, and acute respiratory distress described in Table 49-3 are no longer commonly seen. Soto-Wright and colleagues<sup>6</sup> have described the changing clinical presentation of complete hydatidiform mole. In their series between 1988 and 1993 none of the patients with complete hydatidiform mole had respiratory distress or clinical hyperthyroidism; however, patients continue to present with vaginal bleeding and markedly elevated hCG levels.

As a rule patients with partial hydatidiform mole do not have the clinical features characteristic of patients with complete mole. Most patients with partial molar pregnancy present with vaginal bleeding in the late first trimester, with signs and symptoms suggestive of threatened or spontaneous abortion. The diagnosis of partial mole is generally considered only after histologic review of the curetting specimens. Clinical findings usually include a uterus small or equal to gestational age;

**Table 49-3**  
Presenting Symptoms and Signs in Patients with Complete and Partial Molar Pregnancy

Sign	Complete Mole (%)	Partial Mole (%)
Vaginal bleeding	97	73
Enlarged uterine size	51	4
Hyperthyroidism	7	0
Pre-eclampsia	27	3
Hyperemesis gravidarum	26	0
Theca-lutein cysts	50	0
Acute respiratory distress	2	0

Reproduced from Berkowitz RS, Goldstein DP: Gestational trophoblastic neoplasia. In Berek JS, Hacker NF (eds): Practical Gynecologic Oncology. Philadelphia: Lippincott Williams & Wilkins, 2000; p 617

excessive uterine size or toxemia are the presenting signs in only 6% of patients.

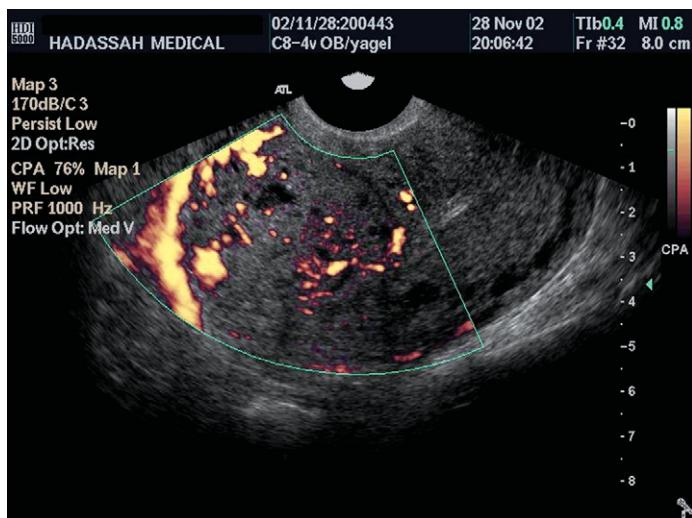

### Clinical Diagnosis

The diagnosis of hydatidiform mole should be suspected in any woman with first- or second-trimester bleeding with any of the clinical features described. Ultrasonography is a simple, sensitive, and reliable approach for the diagnosis of molar pregnancy. The characteristic "snowstorm" pattern, caused by the diffuse hydatidiform swelling of complete moles, is usually easy to identify in a uterus greater than 14 weeks in size. Most complete hydatidiform moles are now diagnosed in the first trimester; the typical sonographic appearance is a complex, echogenic, intrauterine mass containing many small cystic spaces with prominent flow (Fig. 49-5).

The mean serum hCG value for molar pregnancy is about 200,000 mIU/mL compared to a peak value of 50,000 to 100,000 mIU/mL for normal pregnancy. A single hCG determination, however, is not diagnostic because both high hCG titer with normal singleton pregnancy and a normal hCG level in molar pregnancy can be seen. In clinical situations in which sonographic findings are not convincing, serial hCG determinations should be performed. Before ultrasound was available, amniocentesis combined with amniography was the diagnostic test most widely used to confirm the diagnosis of hydatidiform mole. This approach is seldom needed today.

The usual clinical diagnosis of partial mole is similar to missed or incomplete abortion. The ultrasonographic findings may show focal cystic spaces in the placental tissues, but more commonly findings are suggestive of abortion. The pre-evacuation hCG levels in partial mole patients are usually lower than in those with complete mole. Values rarely exceed 100,000 mIU/mL and tend to return to normal promptly.

A partial mole is a pathologic diagnosis, and clinical diagnosis should not be performed without pathologic conformation.

**Figure 49-5 Typical sonographic appearance of complete mole, showing complex, echogenic, intrauterine mass containing many small cystic spaces with prominent flow.** (Courtesy Dr. Simcha Yagel, Hadassah Medical Center, Jerusalem.)

### Natural History

The risk of postmolar trophoblastic disease is reported to range from 5.7% to 36% in complete hydatidiform mole. Both local invasion and distant spread may occur. Risk factors for malignant sequelae include a uterus large for dates, ovarian cysts larger than 6 cm, serum hCG level greater than 100,000 mIU/mL, previous history of molar pregnancy, and age above 40. Goldstein and colleagues<sup>7</sup> noted that patients with symptoms of marked trophoblastic growth (hCG >100,000 mIU/mL, excessive uterine size for dates, and prominent theca-lutein cysts) are at high risk for persistent GTD.

The natural history of twin conceptions consisting of complete hydatidiform mole and a coexisting fetus was studied by the New England Trophoblastic Disease Center (NETDC).<sup>8</sup> Eight cases of twin pregnancy with complete hydatidiform mole and coexisting fetus were compared to 71 patients with singleton complete hydatidiform mole. Five of the eight patients in this series developed persistent gestational trophoblastic neoplasia requiring chemotherapy. Three of these five patients developed metastases and required multiagent chemotherapy to achieve remission. The authors' conclusions were that patients with complete hydatidiform mole and coexisting fetus are at high risk for developing persistent gestational trophoblastic neoplasia.

Partial hydatidiform mole carries a better prognosis than complete mole; invasive disease or metastasis rarely develops. The risk for persistent postmolar trophoblastic disease after partial molar pregnancy is approximately 2% to 4%. Since making a distinction between partial hydatidiform mole and complete hydatidiform mole using histologic criteria alone may be difficult, the reliability of this finding is in question. Cheung and colleagues<sup>9</sup> used fluorescent microsatellite genotyping following laser-capture microdissection and chromosome in situ hybridization to perform genetic analysis of six patients with histologically diagnosed partial hydatidiform mole who subsequently developed metastatic gestational trophoblastic neoplasia. It was found that four of the six patients had a diploid karyotype and no maternal alleles; thus, their neoplasms actually were complete hydatidiform mole. Although this study supports the belief that most aggressive trophoblastic diseases are derived from complete hydatidiform mole, a small number of partial hydatidiform moles do progress to metastatic disease; however, no distinctive clinical or pathologic risk factors have been identified.

### Treatment

As soon as diagnosis is made, evaluation of the associated medical problem should be performed and preparations for termination of the pregnancy should be carried out.

### Suction Curettage

The evacuation method of choice for patients who desire to preserve their fertility is suction curettage, regardless of uterine size. If there is heavy bleeding, plans for immediate evacuation should be made and an oxytocin drip should be started. When bleeding is absent or mild, intravenous oxytocin can be held until surgical intervention has been started.

The suction curettage technique includes dilatation of the cervix to permit insertion of a 10- to 12-mm suction curette just past the internal os. The suction is initiated and uterine contents

are evacuated by gently rotating the curette without inserting it further. The surgeon may also perform a fundal massage to stimulate uterine contractions. This technique reduces the risk of uterine perforation, especially if there is a focus of invasive mole and in cases of a large uterus. After completion of the suction evacuation, sharp curettage should be performed to remove any residual molar tissue. This procedure may be done under sonographic imaging using an abdominal probe to reduce the risk of uterine perforation and remaining trophoblastic tissue in the uterine cavity.

### Hysterectomy

Termination of molar pregnancy by primary hysterectomy (with the mole *in situ*) may be performed in patients who are good surgical candidates and who desire sterilization. Although hysterectomy eliminates the risk of local invasion and the risk of distant metastases is remote, these patients should also be followed with repeated hCG titers.

### Treatment of Non-neoplastic Medical Complications

Hyperthyroidism is present in 2% to 7% of patients with complete mole. Elevated levels of total T<sub>4</sub> or free T<sub>4</sub> compared to normal pregnancy levels can be found in as many as 25% to 50% of patients. If hyperthyroidism is suspected, it is important to administer a beta-adrenergic antagonist before the induction of anesthesia for molar evacuation because of the risk of precipitated thyroid storm.

Acute pulmonary insufficiency is a dramatic, life-threatening complication that develops in approximately 2% of patients. This condition may be related to high output cardiac failure or pulmonary edema. The latter may be caused by excessive fluid administration or, less likely, to trophoblastic tissue embolization to the pulmonary vasculature. The signs and symptoms of respiratory distress usually occurs within 4 hours postevacuation and resolve within 72 hours with cardiopulmonary support. Most cases are reported in patients with a uterus 16 weeks' gestational size or larger.

Because both invasive and noninvasive molar trophoblasts demonstrate the presence of Rh<sub>0</sub>D antigen, Rh-negative patients should receive RhoGam if no anti-Rh<sub>0</sub>D antibodies are detected.

### Prophylactic Chemotherapy

Prophylactic chemotherapy, the administration of single-agent chemotherapy immediately before or after evacuation, is controversial. Several studies suggest that this approach reduces the risk of postmolar trophoblastic disease from 15% to 20% to 1% to 2%. The agents that are mostly used are actinomycin D (dactinomycin) and methotrexate. Goldstein and Berkowitz<sup>10</sup> performed a large case-control study comparing 247 patients with complete molar pregnancy who received a single course of dactinomycin at the time of evacuation and 858 control patients with complete molar pregnancy who did not receive prophylactic chemotherapy. Focal uterine invasion subsequently developed in 4% and 14.6% of the patients, respectively, and distant metastases in 0% and 4%, respectively. No serious toxicity was observed. Kim and colleagues<sup>11</sup> prospectively randomized 71 patients with complete hydatidiform mole into two groups; one group was treated with a single course of methotrexate and

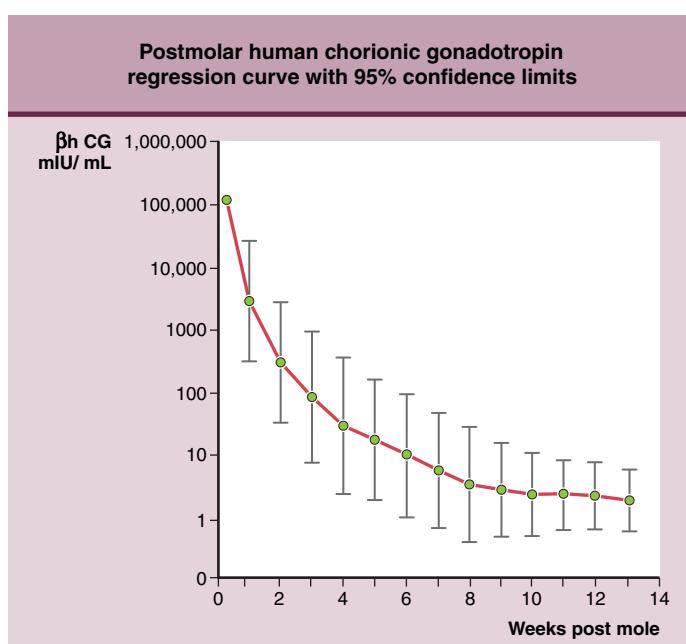

citrovorum factor rescue as chemoprophylaxis and the other group was not treated. After molar evacuation, persistent trophoblastic disease developed in 10% and 31% of the patients in the treated and untreated groups, respectively. All 14 patients with persistent trophoblastic disease achieved complete remission with therapeutic chemotherapy. More courses of chemotherapy were required until complete remission in the treated group than in the untreated group. These findings suggest that even though chemoprophylaxis reduces the incidence of persistent trophoblastic disease in high risk patients, it increases tumor resistance and morbidity. In view of these experiences it seems reasonable to limit prophylactic chemotherapy treatment to patients who have high risk complete molar pregnancies and who may be noncompliant for hCG follow-up surveillance.

### Follow-up

After evacuation of the molar tissue or hysterectomy with the mole *in situ*, patients require weekly determinations of β-hCG levels until these are within normal limits for 3 consecutive weeks. The titers are then observed at monthly intervals for 6 to 12 months. The normal regression curve for β-hCG after molar evacuation is shown in Figure 49-6.

Within the first 8 weeks 65% to 70% of patients should enter into spontaneous regression. From 10% to 15% will continue to show decline in titers, whereas 15% to 20% will show a plateau or rise. The latter group is considered to have postmolar GTD or malignant gestational trophoblastic disease.

Although serial hCG value determinations are the most important part of postmolar pregnancy surveillance, it is important to perform a gynecologic examination postevacuation to evaluate uterine size, adnexal masses, and evidence of metastases to the genital tract (vulva, vagina, cervix, urethra).

**Figure 49-6 Postmolar hCG regression curve, with 95% confidence limit.** (From Morrow CP et al: Clinical and laboratory correlates of molar pregnancy and trophoblastic disease. Am J Obstet Gynecol 1977;128:424.)

### **Human Chorionic Gonadotropin Assay**

Human chorionic gonadotropin, an obligate secretory product of the syncytiotrophoblast, is a glycoprotein composed of two dissimilar subunits,  $\alpha$  and  $\beta$ , held together by charge interaction. The smaller  $\alpha$  subunit is nearly identical to the subunits of luteinizing hormone (LH), follicle-stimulating hormone, and thyrotropin. The  $\beta$  subunit gives these hormones their biologic and immunologic specificities. hCG is an unusual glycoprotein in that as little as 65% of its molecular weight is due to amino acids or protein. The balance is due to large sugar side chains. hCG is not a single molecule but a mixture of regular hCG, large carbohydrate variants of hCG, nicked hCG, hCG missing the  $\beta$  subunit C-terminal peptide, free subunits, and fragments of each of these forms of hCG. This is particularly important in gestational trophoblastic disease, in which one of these hCG variants or its free subunits is commonly the principal molecule in the blood samples. Most tests use the multi-antibody immunoassay method. These tests use multiple antibodies against different sites on hCG and related molecules. A small number of laboratories continue to use the competitive radioimmunoassay (RIA) method. All tests, whether RIA or modern immunometric assays, use at least one antibody against the  $\beta$  subunit to differentiate hCG and LH, which share indistinguishable  $\alpha$  chains. Considering the heterogeneity of hCG, especially with regard to trophoblastic disease, it is essential to use an hCG test that measures all forms of hCG and its free subunits.

### **Phantom hCG**

Rarely patients present with persistently elevated hCG levels but are subsequently found to have a false-positive hCG assay result, sometimes after receiving unnecessary chemotherapy or surgery for presumed malignant GTD. Most of these patients have a mild elevation of their hCG serum levels, but occasionally values higher than 200 to 300 mIU/mL are seen. The false-positive hCG values result from interference with the hCG immunometric sandwich assay caused by nonspecific heterophil antibodies in the patient's sera. Most of these patients have undefined previous pregnancy events and do not have radiographic evidence of metastatic disease. Serial hCG levels usually do not vary and are unresponsive to surgery or chemotherapy. Phantom hCG may also present after evacuation of a hydatidiform mole or clearly defined pregnancy. The diagnosis of phantom hCG relies on the absence of hCG immunoreactivity in the urine and the lack of parallel dilution of hCG levels with serial dilution of the patient's serum.<sup>12</sup> Persistent low levels of hCG following a pregnancy or hydatidiform mole are related to a noninvasive condition, quiescent GTD, or remain unexplained. Two recommended strategies to differentiate between malignant GTD and the benign conditions are: (1) Follow the pattern of hCG rise; if hCG levels rise consistently or sharply, this will indicate a higher risk for persistent or invasive disease. A shallow rise and plateau pattern are more likely to represent quiescent trophoblastic disease, a condition that most probably should not be treated by chemotherapy.<sup>13</sup> (2) Use the hyperglycosylated hCG test. Hyperglycosylated hCG is produced only by invasive cytotrophoblast cells and therefore can be an invaluable second marker to differentiate malignant GTD from benign conditions.

### **Contraception**

Because hCG produced by the neoplastic trophoblast is indistinguishable from the hCG produced during normal pregnancy, it is important to avoid pregnancy in the entire interval of hCG follow-up. Pregnancy may also limit treatment options should malignant sequelae develop. In the absence of contraindications, oral contraceptives are the method of choice. Because ovulation may occur soon after evacuation (4 weeks or less), the patient should be encouraged to start oral contraception as soon as possible. Other methods of contraception are possible but intrauterine devices should be avoided before normal hCG levels are obtained because of the risk for perforation. Data from both the NETDC<sup>14</sup> and the Gynecologic Oncology Group (GOG)<sup>15</sup> revealed no association between the use of oral contraceptives and risk of requiring chemotherapy. In addition, the contraceptive method did not influence the mean hCG regression time.

### **Reproductive Sequelae**

Patients who have been diagnosed with molar pregnancy can anticipate normal reproductive function in subsequent pregnancies. Sebire and colleagues<sup>16</sup> recently published a retrospective review of a large supraregional database of registrations for gestational trophoblastic disease. Of 2578 complete moles, further pregnancy was observed in 1417 patients and the subsequent pregnancy was affected by hydatidiform mole in 27 (1.9%) cases, including 22 (81%) complete moles and 5 (19%) partial moles. Of 2627 partial moles, further pregnancy was observed in 1512 patients and the subsequent pregnancy was also molar in 25 (1.7%) cases, including 17 (68%) partial moles and 8 (32%) complete moles. Overall recurrence risk for molar pregnancy was 1.8% (1 in 55), or a 20-fold increase over the background risk. Of 27 cases with repeat complete moles, 3 had further complete moles, suggesting the recurrence risk following two previous complete moles is approximately 10%. No other significant differences in pregnancy outcome were observed between patients with previous complete or partial hydatidiform mole and an unselected obstetric population. The authors concluded that women having a pregnancy affected by a histologically confirmed complete or partial hydatidiform mole may be counseled that the risk of repeat mole in a subsequent pregnancy is about 1 in 60; in addition, if this were to occur, the majority of cases would be of the same type of mole as the preceding pregnancy. However, more than 98% of women who become pregnant following a molar conception will not have a further hydatidiform mole, and these pregnancies are at no increased risk of other obstetric complications. Current recommendations for patients with a history of molar pregnancy who plan another pregnancy include the following: (1) an early ultrasound to confirm normal gestational development and dates, (2) a chest x-ray to screen for occult metastasis masked by the hCG rise of pregnancy, (3) histologic examination of the placenta or products of conception at the time of delivery or evacuation for evidence of occult GTD, and (4) hCG levels 6 weeks after evacuation or delivery to confirm normalization.

### **Diagnostic Criteria for Postmolar Gestational Trophoblastic Disease**

The risk of post molar GTD ranges from 3% to 25%, including both partial and complete hydatidiform moles, and as noted

**Table 49-4****FIGO Criteria for the Diagnosis of Postmolar Gestational Trophoblastic Disease**

- Four values or more of hCG documenting a plateau ( $\pm 10\%$  of hCG values) over at least 3 weeks: days 1, 7, 14, 21
- A rise of hCG of 10% or greater for three values or longer over at least 2 weeks: days 1, 7, 14
- The presence of histologic choriocarcinoma
- Persistence of hCG 6 months after mole evacuation

previously the risk for postmolar GTD is higher among patients with complete compared to partial hydatidiform moles (20% vs. 5%, respectively). The risk of metastatic disease at the time of postmolar GTD diagnosis is 6% to 25%. Because criteria for the diagnosis of postmolar GTD varied between North America and Europe, an attempt was recently made by the Society of Gynecologic Oncologists, the International Society for the Study of Trophoblastic Diseases, the International Gynecologic Cancer Society, and the International Federation for Gynecology and Obstetrics (FIGO) to standardize these criteria.<sup>17</sup> The current FIGO criteria for the diagnosis of postmolar GTD are summarized in Table 49-4.

Although the revised FIGO criteria did not address the issue of metastatic disease, in most centers the diagnosis of metastasis is sufficient for the diagnosis of postmolar GTD and a cause for initiating chemotherapy.

**Repeated Uterine Curettage**

Patients with postmolar GTD may present with vaginal bleeding, signifying persistent or recurrent trophoblastic disease in the uterine cavity. The bleeding is very often attended by an enlarged uterus and abnormal hCG regression. The issue of secondary curettage is controversial; it is not recommended on a routine basis. Although some investigators report that secondary curettage obviates the need for chemotherapy in 10% to 20% of cases,<sup>18</sup> this approach is not without risks; uterine perforation (8% of repeated curettage), intra-abdominal hemorrhage, and the occasional need for transfusion and hysterectomy have been reported. In view of this information, secondary D&Cs are recommended only in patients with life-threatening hemorrhage, and most other patients with bleeding can be managed with chemotherapy. An algorithm for molar pregnancy management after evacuation or hysterectomy is illustrated in Figure 49-7.

**OTHER FORMS OF GESTATIONAL TROPHOBlastic DISEASE****Invasive Mole (Chorioadenoma Destruens)**

Complete and partial moles can invade the myometrium or blood vessels and produce a condition designated *invasive mole*. Based on hysterectomy specimens it is estimated that between 5% and 10% of all molar pregnancies contain myometrial invasion, but because this process is clinically occult, and usually does not necessitate hysterectomy it is difficult to accurately assess the frequency of this clinical entity. Invasive mole is the most common form of persistent GTD following a molar pregnancy and is probably 6 to 10 times more common than choriocarcinoma.

**Pathology**

Grossly, invasive mole appears as hemorrhagic, erosive masses, and perforation is possible when the full thickness of the uterine wall is penetrated. Histologically, invasive mole is characterized by hydrophilic villi and proliferating trophoblastic epithelium invading the uterine muscle and blood vessels, with associated hemorrhage and necrosis. In extrauterine sites, the distinction from choriocarcinoma is based on the presence of villi, which can be sparse in number, and the presence of masses within blood vessels without significant invasion into the surrounding tissue.

**Clinical Features**

Clinically the hallmark of the disease is hemorrhage; both severe vaginal and intraperitoneal bleeding may occur. The most common sites for metastases are the vagina and lung, although rare instances of secondary lesions in the brain and spinal cord have been documented. Invasive mole is a self-limited disease; if no bleeding or serious complications occur, the tumor may regress spontaneously, including in patients with metastatic disease.

**Treatment**

In the absence of metastatic disease, patients require post-surgical surveillance and treatment similar to patients with complete or partial moles. Additional therapy in the form of chemotherapy is indicated when metastases are present or abnormal regression of serum hCG levels is observed.

**Choriocarcinoma**

Gestational choriocarcinoma is a highly malignant tumor, developing in relation to a gestational event, and must be distinguished from a nongestational choriocarcinoma, which typically arises in extrauterine sites. Choriocarcinoma is preceded by molar pregnancy in 50% of cases, by spontaneous abortion in 25%, by normal pregnancy in 22.5%, and by ectopic pregnancy in 2.5% of patients.

Metastases are common with a predisposition to hematogenous spread, and the organs that are most frequently involved (in decreasing order of frequency) are the lung, lower genital tract (cervix, vagina, vulva), brain, liver, kidney, and gastrointestinal tract.

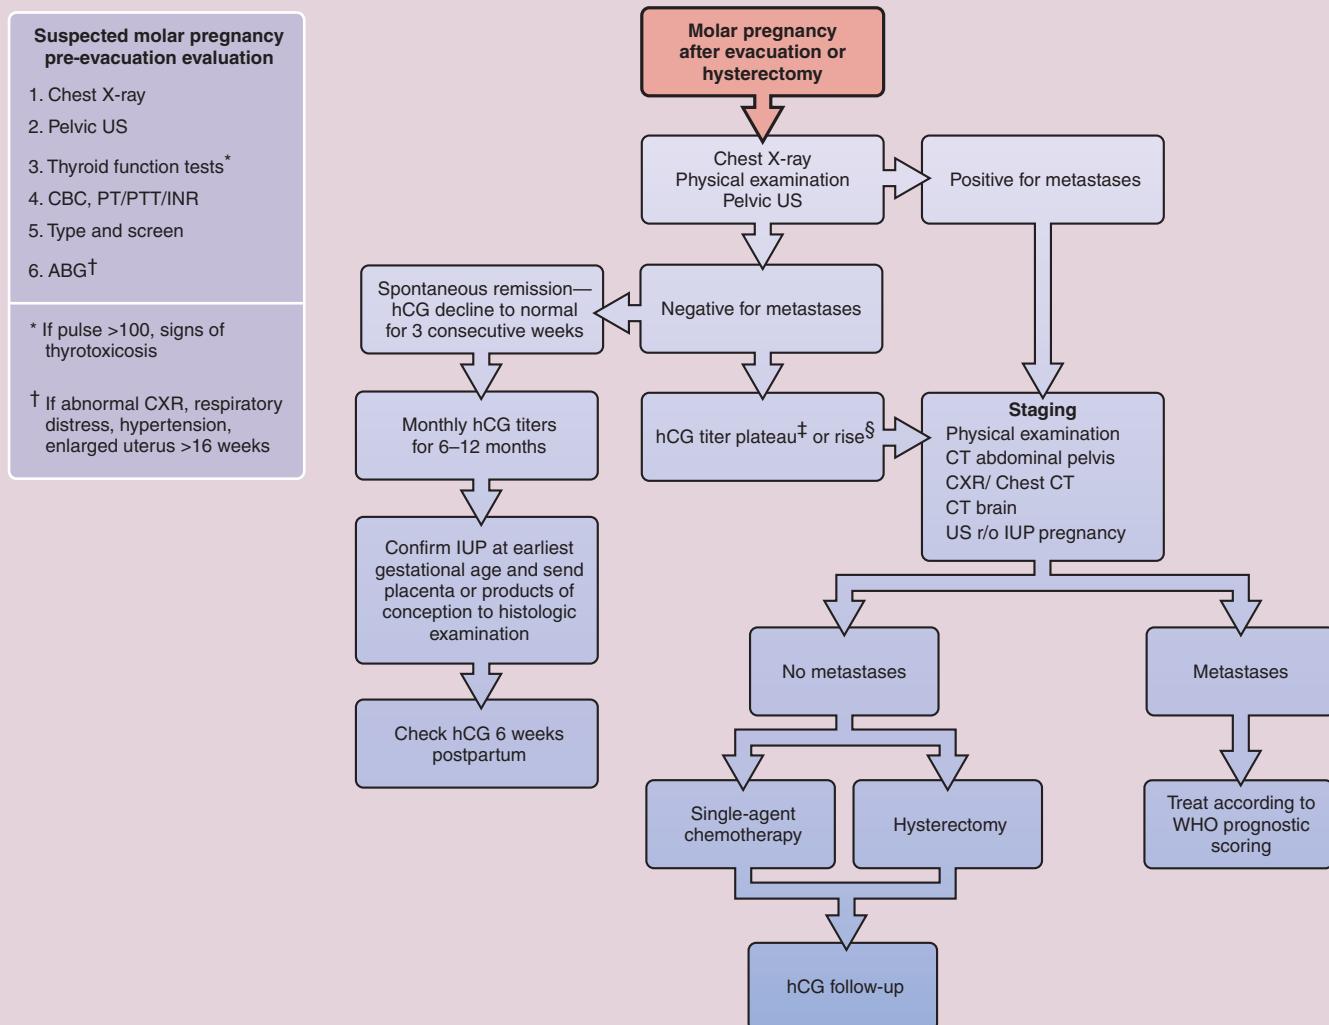

**Pathology**

Grossly choriocarcinoma are extremely hemorrhagic neoplasms, often resembling a friable segment of placenta. Microscopically, the tumor is characterized by hemorrhage and necrosis, clusters and sheets of poorly differentiated cytotrophoblastic cells, surrounded and encased by multinucleated syncytiotrophoblast cells, and by the absence of villi.

**Clinical Features**

The clinical presentation of patients with choriocarcinoma is related to disease spread. The strong propensity of trophoblastic cells to disrupt normal vascular integrity, leading to focal hemorrhage, usually leads to the symptoms of the disease. Local disease may resemble threatened abortion or ectopic pregnancy, with amenorrhea followed by vaginal bleeding. Some cases are manifested by intraperitoneal bleeding secondary to uterine perforation, liver or spleen rupture, bleeding from ovarian tissue,

or ruptured theca-lutein cyst. Other manifestations may be cough, hemoptysis, pleuritic pain, and dyspnea in cases of pulmonary involvement; anemia, melena, or massive gastrointestinal bleeding in patients with gastrointestinal involvement; and focal neurologic signs caused by spinal or intracranial metastases.

### **Diagnosis**

The diagnosis of metastatic choriocarcinoma may be considered in any woman of reproductive age who presents with metastatic

disease from an unknown primary tumor. Diagnosis is often based on history, imaging, and serum hCG determinations. Histologic confirmation is not mandatory for diagnosis and treatment. The two main risks associated with an attempt to obtain histologic confirmation are bleeding from the biopsy site and failure to achieve satisfactory tissue for diagnosis because of tissue necrosis and hemorrhage obscuring the disease, possibly contributing to a delay in treatment. A diagnosis based predominantly on hCG alone should raise the question of phantom hCG.

Choriocarcinoma in situ is a rare finding and is diagnosed when a focus of choriocarcinoma is discovered on a routine microscopic examination of placenta. In these cases both the mother and the fetus need hCG monitoring.

### **Placental Site Trophoblastic Tumor**

Placental site trophoblastic tumor (PSTT) is a malignant tumor derived from intermediate trophoblast. Intermediate trophoblast is mostly extravillous and is a biologically unique cell type that performs an important function in placentation. Initially the disease was thought to be a nonneoplastic syncytial endometritis, but subsequent reports identified the malignant potential of this tumor. Over the past two decades, approximately 100 cases of PSTT have been reported, in numerous case reports and small case series.<sup>19</sup>

#### **Pathology**

Grossly, PSTT are generally well-circumscribed, solid masses within the myometrium, although polypoid components projecting into the uterine cavity are frequently observed. In contrast to choriocarcinoma, hemorrhage and necrosis are focal or absent. Microscopically the cells of PSTT are mononuclear with abundant cytoplasm and strongly resemble intermediate trophoblast of the implantation site. A characteristic feature of the tumor is a nondestructive pattern of infiltration into the myometrium. Immunohistochemical staining demonstrates strong expression of human placental lactogen (hPL) and little or no expression of hCG. Distinction of PSTT from normal implantation site is based on the presence of a grossly or radiographically detectable tumor and the presence of mitotic activity, both of which are more common in PSTT. PSTT should also be distinguished from placental site nodule, usually an incidental finding in a hysterectomy specimen performed for uterine fibroids.

#### **Clinical Features**

Women of reproductive age are at risk, although diagnosis is occasionally made in the sixth decade of life. Patients usually present with vaginal bleeding after amenorrhea of variable duration. Most patients present following normal pregnancy, but antecedent hydatidiform molar pregnancy or spontaneous abortion have been reported. hCG values are usually less than 1000 mIU/mL; serum hPL has not proven to be a reliable serum marker, despite the reliability of hPL tissue staining.<sup>20</sup> Nephrotic syndrome, with its distinctive renal lesion, and virilization have also been reported to be associated with the disease. Most patients are diagnosed in Stage I when disease is confined to the uterus and metastases usually occur late. More common sites of metastases are the lung, vagina, and lymph nodes.

#### **Diagnosis**

Diagnosis is usually based on uterine curettage or hysterectomy specimen showing diffuse immunohistochemical positive staining for hPL and focally positive for hCG.

#### **Treatment**

Because this disease tends to metastasize late and is fairly resistant to chemotherapy, surgical excision (hysterectomy) is the primary treatment for patients with PSTT. Management of

patients who wish to preserve fertility is more difficult and includes systemic chemotherapy, regional infusion chemotherapy, hysteroscopic tumor resection, and uterine curettage. In patients with metastatic disease, hysterectomy may offer little or nothing in terms of improved survival.

Only 5% of early-stage PSTT patients will have recurrence of disease, whereas 70% to 90% of Stage IV disease will be diagnosed with recurrence. Because recurrence has been reported after an interval of 5 years, longer follow-up is indicated in these patients. However, the diagnosis of PSTT more than 2 years after the suspected gestational source carries a poor prognosis.

### **Malignant Gestational Trophoblastic Disease**

#### **Diagnosis**

It is crucial to diagnose malignant GTD with no delay because such a delay may increase the patient's risk and adversely affect response to treatment. Patients with GTD should undergo a metastatic workup, and clinically prognostic factors should be identified.

One half to two thirds of cases of malignant GTD occur following evacuation of complete or partial hydatidiform moles.<sup>21</sup> Because most patients are treated based on hCG levels with no tissue diagnosis, the exact histologic distribution of the lesions is not precisely known. Approximately 50% to 70% of patients with malignant GTD have persistent or invasive mole; 30% to 50% have postmolar gestational choriocarcinoma.<sup>21</sup> Women diagnosed with GTD after evacuation of molar pregnancy are usually identified earlier in the course of the disease because they are followed with serial hCG blood tests. In contrast, patients with malignant GTD diagnosed after non-molar pregnancies are usually diagnosed secondary to a variety of gynecologic or nongynecologic symptoms. Therefore, the possibility of malignant GTD should be suspected in any women of reproductive age who presents with metastatic disease of unknown primary site or unexplained cerebral hemorrhage.<sup>22</sup>

Diagnosis of malignant GTD is based on the following<sup>17</sup>:

- Abnormal pattern of hCG regression after evacuation of hydatidiform mole
- Histologic result showing choriocarcinoma on curettage or hysterectomy specimens
- Presence of metastasis with unknown primary site in the presence of positive serum hCG after excluding pregnancy.

Identification of metastases on examination or imaging is an indication for chemotherapy treatment in most centers, although some centers in the United Kingdom would follow pulmonary metastases conservatively as long as serum hCG levels regress properly.

#### **Clinical Features**

Pretherapy evaluation (Table 49-5) of patients with malignant GTD includes history assessment for clinical risk factors, thorough physical examination, laboratory evaluation, and imaging survey for possible sites of metastases. Clinical risk factors include the duration of disease as determined by the interval from the antecedent pregnancy, the type of antecedent pregnancy, and previous treatment.

Physical examination may identify vaginal lesions. The lesions are most often dark blue, soft nodules. Ulceration and active

**Table 49-5**  
**Staging Workup for Malignant Gestational Trophoblastic Disease**

- History, physical and neurologic examination
- Pelvic ultrasound to exclude pregnancy
- Chest CT/Chest x-ray
- CT/MRI of brain, abdomen, and pelvis
- Liver, renal, and thyroid function tests
- Complete blood count
- Serum hCG levels

bleeding may necessitate vaginal packing or selective embolization; because of the vascular nature of the lesions, it is suggested not to biopsy these lesions, especially not in the outpatient clinic.

Laboratory evaluation should include serum hCG level, blood counts, and renal and liver function tests to determine baseline functions before chemotherapy initiation.

Imaging should include computed tomography (CT) scan of the brain, chest, abdomen, and pelvis. Although some studies recommend performing chest x-ray and more advanced evaluation in the case of an abnormal x-ray finding, other studies showed a 29% to 41% false-negative rate with chest x-ray. In patients in whom the use of contrast material is contraindicated, magnetic resonance imaging (MRI) may be used. Ultrasound of the pelvis should be used to exclude pregnancy and to identify intrauterine tumors and foci of myometrial invasion (Fig. 49-8).

Although operative procedures may be used in the course of treatment of patients with malignant GTD, surgery is rarely required for diagnosis or staging. Routine endometrial curettage is therefore not indicated before chemotherapy.

**Figure 49-8** Computed tomography scan of pelvis, showing heterogeneous mass in enlarged uterus with vascular enhancement. The mass extends into the uterine wall (invasive GTD). The uterus, the mass, and the surrounding tissues are commonly very vascular. (Courtesy Dr. Tamar Sella, Hadassah Medical Center, Jerusalem.)

**Table 49-6**  
**Anatomic FIGO Staging of Malignant Gestational Trophoblastic Disease, 1992**

Stage I	Disease confined to uterus
Stage II	Metastases to pelvis and vagina
Stage III	Metastases to the lung
Stage IV	Distant metastases
A, No risk factors; B, One risk factor; C, Two risk factors	
Risk factors For any stage	hCG levels >100,000 mIU/mL Antecedent pregnancy >6 months

### Staging and Classification

The staging and classification of malignant GTD have changed significantly over the past 40 years. The three main systems used are the anatomic staging system, the clinical classification system, and the prognostic scoring system; the latter system includes variables that predict the likelihood of drug resistance. The more recent staging systems combine these systems. An anatomic staging system for malignant GTD was adopted by FIGO in the early 1980s. This staging system was revised in 1992 (Table 49-6) to include additional risk factors: hCG levels greater than 100,000 mIU/mL and time from antecedent pregnancy greater than 6 months.

The clinical classification system (Table 49-7) is frequently used in United States.<sup>23</sup> In this classification patients with nonmetastatic disease are not assigned into prognostic groups because of the good outcome that can be achieved with single-agent chemotherapy in nonmetastatic disease. The risk factors used in this system were originally identified by retrospective analysis to predict resistance to single-agent chemotherapy among women with metastatic GTD at the National Institutes of Health.

Another prognostic scoring system was developed by the World Health Organization (WHO) in the early 1980s. This system was based on the experience from Charing Cross Hospital in London published by Bagshawe<sup>24</sup> and included nine

**Table 49-7**  
**Clinical Classification System for Patients with Malignant Gestational Trophoblastic Disease**

Category	Criteria
Nonmetastatic GTD	Not assigned to prognostic category
Metastatic GTD	Any extrauterine metastases
Good prognosis metastatic GTD	No risk factors Short duration (<4 months) Pretherapy hCG <40,000 mIU/mL No brain or liver metastases No antecedent term pregnancy No prior chemotherapy
Poor prognosis metastatic GTD	Any risk factors Long duration (>4 months) Pretherapy hCG >40,000 mIU/mL Brain or liver metastases Antecedent term pregnancy Prior chemotherapy
GTD, Gestational trophoblastic disease.	

prognostic factors identified among patients treated with simple chemotherapy regimens. The WHO prognostic index applies a weighted score to each of these factors, and the sum of component scores is then used to determine the individual patient's risk category.

In 2000, FIGO revised their staging<sup>25</sup> with the addition of a risk factor score that modified from the original WHO prognostic index score (Table 49-8). Patients are categorized as either low or high risk. Although some patients assigned to the low risk category will need additional and occasionally intensive therapy, the ultimate outcome is not compromised. Importantly, mortalities rarely occur in the low-risk group, thus validating this system of classification.

It is hoped that this updated scoring system will encourage objective comparison of data among various centers and will be the basis for standardization of treatment protocols for GTD patients in the future.

#### Low-Risk Malignant Gestational Trophoblastic Disease

The following groups of patients are considered to have low-risk malignant GTD:

- Nonmetastatic GTD
- Metastatic malignant GTD with good prognosis (other than brain or liver metastases)
- FIGO stage I, II, or III
- FIGO 2000 scoring system = 6

**Role of Hysterectomy.** Patients categorized with malignant GTD and found to have a nonmetastatic form may be offered a hysterectomy if the patient no longer wishes to preserve fertility. It is acceptable to preserve the ovaries in these cases because ovarian metastases are extremely rare in the absence of other

Table 49-8 FIGO 2000 Scoring System <sup>*†</sup>				
FIGO Score	0	1	2	4
Age	<39	>39		
Antecedent pregnancy	HM	Abortion	Term pregnancy

Total score: 0–6, low risk; ≥7, high risk				
HM, hydatidiform mole; GI, gastrointestinal.				
*Under the new FIGO system, reporting of patients will include both anatomic stage (see Table 49-6) and FIGO risk score.				
†Number of lung metastases should be assessed by chest x-ray and not CT; intra-abdominal metastases should be assessed by CT; brain MRI is superior to CT scanning.				
‡Histologically diagnosed PSTT patients should be reported separately.				

metastatic disease. Because the remote risk of hCG-producing germ cell tumor of the ovary presenting as GTD cannot be ruled out, it is important for the clinician to evaluate any suspicious mass on the ovary at the time of hysterectomy.

Adjuvant single-agent chemotherapy at the time of hysterectomy is recommended by the NETDC for three reasons: (1) to reduce the likelihood of disseminating viable tumor cells at the time of surgery, (2) to maintain a toxic level of chemotherapy during surgery in the event of hematogenous spread of viable tumor cells, and (3) to treat any occult metastases that may already be present at the time of surgery. Because no survival benefit has been demonstrated with this approach, it is not widely used.

After hysterectomy, patients are followed over time for normalization of their hCG levels. If the hCG levels do not resolve, the patient should be assigned to low-risk chemotherapy treatment protocols.

Hysterectomy for low-risk metastatic disease has been advocated by some authors to reduce the amount of cytotoxic chemotherapy and the likelihood of recurrence; however, because these patients will always need some amount of chemotherapy this approach is not uniformly accepted. Hysterectomy is also performed in all patients with placental site trophoblastic tumor. Because these tumors are resistant to chemotherapy, hysterectomy for presumed nonmetastatic disease is the only curative method.

**Chemotherapy for Low-Risk Gestational Trophoblastic Disease.** Patients diagnosed with malignant GTD and categorized as low risk are almost always cured using modern chemotherapy regimens. Patients with nonmetastatic disease will have cure rates of virtually 100% with single-agent therapy. Patients with low-risk metastatic disease have a higher failure rate with initial single-agent chemotherapy, but their overall cure rate approaches 100%. Methotrexate, dactinomycin, and etoposide, used singly, have demonstrated clearcut superiority to all other cytotoxic drugs in the treatment of malignant GTD. The more common treatment protocols are summarized in Table 49-9.

Methotrexate is the most commonly used single agent. The decreased toxicity associated with alternate-day folinic acid treatments may be attributed to both the scheduling interval of methotrexate and to the rescue effect of the folinic acid.

Patients with nonmetastatic and low risk metastatic disease are treated with single-agent therapy at 10- to 14-day intervals, waiting for the major toxicities (usually granulocytopenia and stomatitis) to clear. Chemotherapy is continued until hCG serum levels are down to normal. Usually at least one additional treatment cycle is then given before discontinuing treatment; patients are followed with close observation of their hCG values. Table 49-10 summarizes the management and follow-up of patients with low risk malignant GTD.

From 10% to 30% of patients with low-risk malignant GTD will demonstrate resistance to single-agent therapy. If the disease is confined to the uterus, the resistant focus is usually located deep in the myometrium. These patients are more likely to have high hCG levels at initiation of treatment and a longer interval since the antecedent pregnancy compared to those who do not demonstrate drug resistance. When hCG levels fail to drop significantly during two consecutive treatment courses, or if

Table 49-9 Chemotherapy Options for Low-Risk Malignant Gestational Trophoblastic Disease		
Agent(s)	Dosage and Route of Administration	Toxicities
Methotrexate (MTX)	<ul style="list-style-type: none"> <li>20–25 mg (0.4 mg/kg) or 16 mg/m<sup>2</sup> IM/IV q day × 5 days (repeat in 7–14 days)</li> <li>30–50 mg/m<sup>2</sup> IM (repeat weekly)</li> </ul>	More common: myelosuppression, gastrointestinal effects (mucositis, nausea), alopecia, rashes Less common: hepatotoxicity, nephrotoxicity, pleuritis, pulmonary fibrosis
MTX and folinic acid (FA)	<ul style="list-style-type: none"> <li>MTX 1 mg/kg IM/PO days 1, 3, 5, 7 alternating with FA 0.1 mg/kg days 2, 4, 6, 8 (repeat q 14 days)</li> <li>MTX 300–500 mg/m<sup>2</sup> IV followed by FA 15 mg q6h × 4 doses (repeat q 14 days)</li> </ul>	As described for MTX, but usually milder and last for <5 days
Dactinomycin	<ul style="list-style-type: none"> <li>9–13 µg/kg IV qod × 5 days (repeat q 14 days)</li> <li>1.25 mg/m<sup>2</sup> IV bolus (repeat q 14 days)</li> </ul>	Myelosuppression, gastrointestinal effects (nausea, vomiting, stomatitis), alopecia Less systemic toxicity compared to MTX
MTX and dactinomycin	<ul style="list-style-type: none"> <li>MTX 20–25 mg (0.4 mg/kg) IM qod × 5 days in week 1 alternating with dactinomycin 9–13 µg/kg IV qod × 5 days in week 2 (repeat q 14 days)</li> </ul>	Cumulative toxicity is reduced compared to MTX or dactinomycin alone
5-fluorouracil	<ul style="list-style-type: none"> <li>28–30 mg/kg/day (continuous 10-day infusion)</li> </ul>	More common: gastrointestinal effects (nausea, vomiting, stomatitis, diarrhea, pseudomembranous colitis), hepatotoxicity Less common: cerebellar ataxia
Etoposide	<ul style="list-style-type: none"> <li>100–200 mg/m<sup>2</sup> PO for 5 days (repeat q 2 weeks)</li> </ul>	More common: myelosuppression, gastrointestinal effects (nausea, vomiting), alopecia Less common: acute myelogenous leukemia (0.6%; chromosomal damage: 11q23)

Modified from Carney ME: Treatment of low risk gestational trophoblastic disease. Clin Obstet Gynecol 2003;46:579–592.

more than 8 weeks are required to induce titer remission, a change to dactinomycin or methotrexate, depending on which drug was initially used, is usually successful in eradicating the disease. If the tumor fails to respond to this change, use of oral etoposide or one of the combination chemotherapy regimens for high-risk malignant GTD is recommended.<sup>26</sup>

#### High-Risk Malignant Gestational Trophoblastic Disease

The following groups of patients are considered to have high-risk malignant GTD:

- Metastatic malignant GTD with poor prognosis (i.e., long duration [>4 months], pretherapy hCG > 40000 mIU/mL, brain or liver metastases, antecedent term pregnancy, or prior chemotherapy)
- FIGO stage IV
- FIGO 2000 scoring system = 7

Patients with high-risk malignant GTD preferably should be treated by physicians who are experienced in the management of this disease. Although chemotherapy with multidrug regimens is the cornerstone of treatment, both surgery and irradiation have been used to achieve a curative outcome.

**Chemotherapy for High-Risk Gestational Trophoblastic Disease.** Women with high-risk gestational trophoblastic disease should be treated initially with multidrug combination chemotherapy. The superiority of combination chemotherapy protocols over single-drug regimens was demonstrated in the early 1970s.<sup>27</sup>

The first multidrug regimen for high-risk GTD to be extensively evaluated was MAC: methotrexate (15 mg IV/IM), actinomycin D (dactinomycin; 8 to 10 µg/kg IV) and chlorambucil (8 to 10 mg PO), all given daily for 5 days with an interval of 10 to 14 days between courses. Cyclophosphamide (3 mg/kg/day IV) is often substituted for chlorambucil in the MAC regimen because the latter cannot be given parenterally. The reported remission rates for primary treatment with these triple regimens range from 50% to 73%. The variation in the reported results most probably reflects patient tumor factors rather than

Table 49-10  
Management and Follow-up of Single-Agent Chemotherapy

- Chemotherapy regimen as described in Table 49-8.  
Check CBC, liver and renal functions before chemotherapy administration.  
Repeat chemotherapy according to protocol and toxicity.  
Start oral contraception (if not contraindicated).
- Chemotherapy continued until hCG titer is normal, usually, 1–3 courses are additionally given.
- Chemotherapy should be switched if:  
hCG titers rise  
hCG titers plateau  
New metastases
- Chemotherapy is held if:  
WBC <3000/µL  
ANC <1500/µL  
Platelets <100,000/µL  
Abnormal liver or kidney functions  
Toxicity develops (e.g., oral or gastrointestinal ulceration, neutropenic fever)
- Remission defined as three consecutive normal weekly hCG
- Follow-up includes:  
hCG titers every 2 weeks for 3 months, then monthly for 3 months, then every 2 months for 6 months, then every 6 months  
Frequent pelvic examination
- Contraception should be continued for at least 6 months.

differences in the treatment protocols. Because of the relatively high failure rates, Bagshawe and coworkers from the Charing Cross Hospital proposed the seven-drug CHAMOCA regimen, consisting of cyclophosphamide, hydroxyurea, actinomycin D (dactinomycin), methotrexate, Oncovin (vincristine), citrovorum factor, and Adriamycin (doxorubicin).<sup>28</sup> When the CHAMOCA and MAC regimens were compared by the GOG in a prospective, randomized trial, the cure rates were 70% and 96%, respectively. The MAC regimen was also found to be significantly less toxic; the authors concluded that this regimen has a more favorable therapeutic index.<sup>29</sup> Newlands and colleagues<sup>30</sup> were the first to introduce the EMA-CO protocol and reported a complete response rate of 80% and overall survival of 82% to 89% in high-risk GTD patients. The new protocol consisted of etoposide, methotrexate, actinomycin D (dactinomycin), cyclophosphamide, and Oncovin (vincristine). Since its introduction it has generally replaced MAC as the treatment of choice for high-risk disease because of greater efficacy and lower risk of serious toxicity (Table 49-11).

Whatever combination regimen is used to treat high-risk malignant GTD patients, chemotherapy should be continued three courses past the first normal hCG titer to minimize the risk of relapse. The risk of recurrence after 12 months of normal hCG levels is less than 1% but pregnancy should be postponed for 2 years after remission.

**Salvage Chemotherapy.** Salvage therapy for recurrent disease has improved significantly since the late 1970s. The reported salvage rate after 1978 is reported to be 83%.

Regimens containing cisplatin and etoposide are commonly employed for the treatment of persistent or relapsed trophoblastic tumor. Newlands and colleagues<sup>31</sup> reported their experience with the EMA-EP regimen, consisting of etoposide, methotrexate, actinomycin D (dactinomycin), and cisplatin. The overall survival rate for their series was 88%; myelosuppression was significant, causing treatment delay and dosage adjustment in 88% and 38% of the patients, respectively. Other regimens used include the PVB (Platinol [cisplatin], vinblastine, and bleomycin) regimen, BEP (bleomycin, etoposide, and Platinol

[cisplatin]) regimen, and the combination of high dose chemotherapy with autologous bone marrow transplantation.

**Management of Metastatic Sites.** Brain metastases occur in about 10% of women with metastatic GTD. The most common presenting clinical symptoms are headaches, paresis, vomiting, and seizures. Unfortunately many women with brain metastases from choriocarcinoma die without receiving therapy because of late diagnosis. The presence of brain or spinal metastases can be evaluated by either CT or MRI; measurements of hCG levels in the cerebrospinal fluid are rarely needed. The most common management strategy for CNS lesions in the United States is the addition of whole brain irradiation (total dose, 3000 cGy) to the EMA-CO chemotherapy protocol. This approach doubles the survival rate (50% vs. 24% without irradiation). Protocols for the management of CNS lesions in the United Kingdom include administration of intrathecal methotrexate (12.5 mg every 2 weeks). Craniotomy is performed in a select group of patients with drug-resistant lesions, when intracranial hemorrhage occurs, or when edema decompression is needed.

Liver metastases are reported to occur in 5% to 20% of poor prognosis patients; poor prognosis is related to hemorrhagic sequelae. The survival rate for these patients is 26% to 33%. Several authors advocate whole liver irradiation (2000 cGy over 10 days) to reduce the risk of bleeding. Liver metastases can also be managed with hepatic artery embolization and partial hepatectomy.

Lung metastases are relatively common ( $\approx$ 50%) in malignant high-risk GTD patients. Most of these patients can be cured by chemotherapy. Thoracotomy with wedge resection or partial lobectomy may be considered in patients with focal resistant disease. Patients who present with extensive pulmonary disease are at risk for an early respiratory death after the initiation of chemotherapy. Progressive hypoxia may be related to interstitial bleeding or edema. In patients who develop early respiratory failure from diffuse metastatic GTD, mechanical ventilation with low tidal volumes and a pressure-targeted approach should be considered in combination with chemotherapy.<sup>32</sup> Correction of anemia and extracorporeal perfusion are important aspects of management; unfortunately, extracorporeal perfusion requires complete therapeutic anticoagulation and therefore is dangerous in this setting (Fig. 49-9).

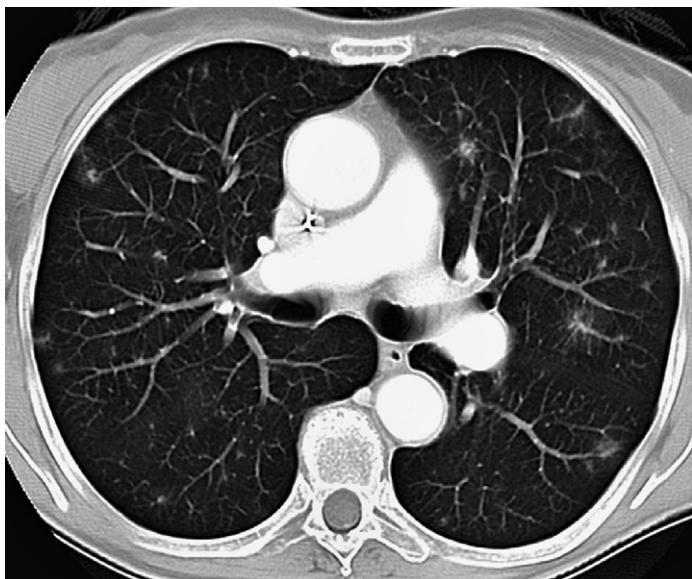

Although the placenta is the site of origin of gestational choriocarcinoma, even when complicating term pregnancy, the primary intraplacental choriocarcinoma is rarely detected and metastases to the fetus are seldom seen. When transplacental metastasis occurs, the prognosis is poor. Consideration should be given to hCG testing of the infant when maternal diagnosis is made.

**Follow-up and Outcome.** Follow-up recommendation is similar to that for low-risk malignant GTD patients; long-term follow-up indicates a 5-year survival rate of 86% for this group of women. The most common causes of death are hemorrhage and pulmonary insufficiency.

#### Pregnancy after Chemotherapy for Malignant Gestational Trophoblastic Disease

Because malignant GTD can be cured with chemotherapy, preserving an intact reproductive system, the issue of the effects

Table 49-11 EMA-CO Regimen for High-Risk Malignant Gestational Trophoblastic Disease		
Day	Agent	Dose and Route
1	Etoposide	100 mg/m <sup>2</sup> , IV infusion over 30 minutes
	Methotrexate	100 mg/m <sup>2</sup> , IV bolus
	D actinomycin	200 mg/m <sup>2</sup> , IV infusion over 12h 350 µg/m <sup>2</sup> , IV bolus
2	Etoposide	100 mg/m <sup>2</sup> , IV infusion over 30 minutes
	D actinomycin	350 µg/m <sup>2</sup> , IV bolus
	Folinic acid	15 mg, PO/IM q12h $\times$ 4 doses, 24h after MTX bolus
8	Cyclophosphamide	600 mg/m <sup>2</sup> , IV infusion over 30 minutes
	Vincristine	1 mg/m <sup>2</sup> , IV bolus
15	Begin next cycle	
Toxicities: Neutropenia and thrombocytopenia are the most common toxicity (27%). Stem cell support may be required. Post-therapy AML: 0.4%–2.4%		

**Figure 49-9 Computed tomography of the chest, demonstrating hematogenous spread of malignant trophoblastic neoplasia.** The most common site of spread is the lungs. These pulmonary metastases tend to be hemorrhagic; therefore, they may have a fuzzy border. (Courtesy Dr. Tamar Sella, Hadassah Medical Center, Jerusalem.)

of cytotoxic drugs on fertility and the genetic well-being of the oocytes is important. Several researchers have examined fertility as well as fetal health following chemotherapy for malignant GTD. The majority of these series conclude that there is no detrimental effect in either outcome after chemotherapy. Rustin and colleagues<sup>33</sup> reported that only 3% of patients who tried to conceive after chemotherapy for GTD failed to do so and that 86% had at least one live birth. The ability to conceive was not worse for patients older than age 30, but was slightly lower in patients receiving multiagent chemotherapy. Both the use of gonadotropin-releasing hormone analogs and oral contraception during chemotherapy to protect the ovaries from premature ovarian failure and the rule of 1-year pregnancy delay from treatment to permit clearance of damaged oocytes are speculative. Pregnancies should not be attempted until 12 months after conclusion of treatment, because although pregnancies occurring before completion of hCG follow-up tend to do well, the patient is at risk for delayed diagnosis of a relapse.<sup>34</sup>

## KEY POINTS

- Effective analgesic therapies are available for cancer patients.
- Large numbers of patients are dissatisfied with pain control.
- Morphine plus multidimensional therapy is encouraged for relief of cancer pain.
- Interventional therapy should be considered sooner rather than later.
- Accurate pain assessment is essential for effective management of cancer pain.
- Identification of barriers to implementation of effective therapies is the key to success.

Perhaps more is known today about the mechanisms of pain and its exacerbation than during any other period in medical history. This is combined with the availability of more evidence-based analgesic medications and procedures than ever before. However, the most palpable improvement in cancer pain management has been the willingness of physicians to routinely prescribe potent opioid medications for extended periods of time and their recognition that inducing opioid addiction in this population is the exception rather than the rule. Titration of potent opioid medications has become the standard of care for managing moderate to severe cancer pain in North America and many other developed regions of the world. Despite widespread use of morphine and other opioids and the development of new methods to administer these drugs, it has become apparent that many patients still do not achieve satisfactory pain relief.<sup>1</sup> This is occurring even in environments where opioids are prescribed readily to control pain. Now that the barrier of limited access to opioid medications is falling, other obstructions that block the path toward consistent relief of symptoms must be identified and dismantled.

One clinical variable that makes achieving adequate analgesia for patients difficult is the presence of comorbid symptoms. Multiple symptom incidents are typical in cancer patients, particularly in late stages of the disease. Distressing nonpainful symptoms tend to cluster and potentially exacerbate the intensity and impact of painful symptoms (e.g., depression, anxiety, insomnia, fatigue) on life quality.<sup>2,3</sup> Rather than an isolated experience, pain must be viewed globally in the context of multiple undesirable symptoms in a single patient; as such, multiple therapies should be prescribed simultaneously when appropriate. The mechanism for the “pain” itself typically is multifactorial as well. Hence, a multidimensional approach to controlling symptoms is warranted for most patients. This is

particularly important and relevant when pain intensity is perceived to be moderate or greater.

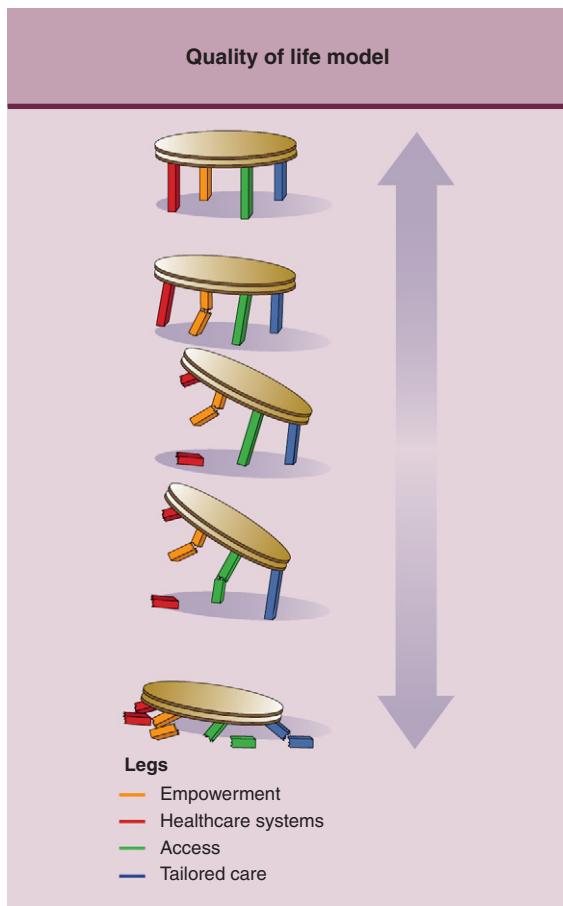

Another affront to effective symptom management is limited assessment of symptom complaints. For a variety of reasons, many cancer patients will not complain or reveal the gravity of their symptom intensity until after they are incapacitated.<sup>4,5</sup> Cancer patients in particular need to be queried systematically about symptoms so that appropriate treatment actions can be triggered early. Symptom complaints should be evaluated and managed aggressively, preferably long before the intensity of the symptom becomes severe. This chapter discusses specific therapies for cancer pain management. Options that clinicians should consider in their clinical decision making to improve cancer pain management are discussed.

## A MODEL FOR QUALITY OF LIFE ENHANCEMENT

Many components go into developing and maintaining a high quality of living for cancer patients. The ingredients necessary to experience high-quality living include intimacy, creativity, productivity, and independence. Health care providers can be key participants in achieving these goals by eliminating or controlling undesirable symptoms. During the patient’s illness, there are at least four legs of support that the patient stands on in order to maintain a high-quality life experience. The first is the health care system. Ideally, cancer patients have access to health care providers who bring a broad knowledge base and experience to symptom management and are able to respond to specific needs rapidly and compassionately. Second, patients have access to effective symptom control measures (analgesics and techniques in the case of pain). Third, patients are greatly advantaged if they are given a sense of empowerment through understanding of the mechanisms of their disease and the therapies used to treat symptoms. Fourth, a symptom management regimen works best when it can be tailored to the patient’s particular circumstances and needs. In the Quality of Life model presented in Figure 50-1, the tabletop represents quality of life. Quality of life is supported on the strength of the four legs described here. Quality of life falls along a continuum. As the supporting legs fail, quality of life diminishes. Strengthening of these key supports will improve the impact of services rendered for all patients in need of care.

## EPIDEMIOLOGY

In 2002 the nation’s leading cancer organizations reported that Americans’ risk of getting and dying from cancer continued to decline and that survival rates for many cancers continue to

**Figure 50-1 Quality of life model.**

improve. The Annual Report to the Nation on the Status of Cancer, 1975–2001, found that overall observed cancer incidence rates dropped 0.5% per year from 1991 to 2001, whereas death rates from all cancers combined dropped 1.1% per year from 1993 to 2001.<sup>6</sup> According to the report's authors, the new data reflect progress in prevention, early detection, and treatment; however, not all segments of the U.S. population have benefited equally from the advances.<sup>7–10</sup> Disparities in this arena are a blight on our medical system and must be addressed and eliminated. Disparities notwithstanding, there is good news to report overall. For the first time, lung cancer incidence rates among women are on the decline. Incidence rates decreased for 5 additional cancers out of the top 15 in women (colon, cervix, pancreas, ovary, and oral cavity). Only breast, thyroid, bladder, and kidney cancer and melanoma rates are rising among women.<sup>6</sup>

Increased survival from cancer can be a double-edged sword for many patients. Residual effects from the disease or toxicities from the treatment can sometimes lead to chronic pain. The prevalence of pain in cancer patients is extremely high, occurring in more than three fourths of patients with advanced disease. Despite optimism generated from clinical trial data, uncontrolled pain in cancer patients remains unacceptably high.<sup>4,6</sup> This leads to the conclusion that available effective therapies are not being utilized to the fullest extent. The solution to this problem is not necessarily to increase the units of morphine administered per cancer patient in pain, but first to make an assessment of

systemic and individual barriers to good analgesia that attenuate the efficacy of treatment.

## ANATOMY OF PELVIC CANCER PAIN

A variety of anatomic sites, including viscera, nerves, muscles, ligaments, and skeletal structures, give rise to painful sensations in the pelvis during progression of cancer. Seldom is the disease confined to only one type, and commonly the most troublesome tissue can be identified based on imaging studies and clinical presentation. This is important to consider because some analgesic approaches have specific indications. Pelvic and perineal cancer pain broadly are classified as visceral, neuropathic, and somatic. *Visceral pain* is the result of but not limited to spasms of the smooth muscle of a hollow viscus, distortions of the capsule of a solid organ, inflammation, ischemic conditions, and visceral encroachment by tumor growth.<sup>11,12</sup>

*Neuropathic pain* may occur from tumor invasion of the nearby lumbosacral plexus and peripheral nerves. Irritation and destruction of nerves result from extension of tumor or from secondary complications of radiation and chemotherapy. Neuropathic pain is particularly difficult to treat and too often slow to reverse, even if the disease is eradicated. *Somatic pain* occurs with stimulation of pain fibers (*nociceptors*) in the peripheral structures, such as striated muscles, bones, and joints.

Sympathetic and parasympathetic nerves supply the viscera of the pelvis. Both contain afferent and efferent fibers. The aortic plexus contributes fibers for the formation of the superior and inferior hypogastric plexus, which in turn supply all of the pelvic viscera. Neurolysis of these structures can be an effective means to analgesia and opioid reduction. The somatic structures of the perineum are predominately innervated by branches of the pudendal nerve, which originates from sacral nerve roots. Figure 50-2 illustrates the anatomy of this neural network, as well as anatomic sites for injection of neurolytic agents to locally disrupt painful transmissions related to advancing tumor involving the pelvis and lower abdominal structures.

## CONDITIONS RELEVANT TO CANCER PAIN MANAGEMENT

### Breakthrough Pain and Incident Pain

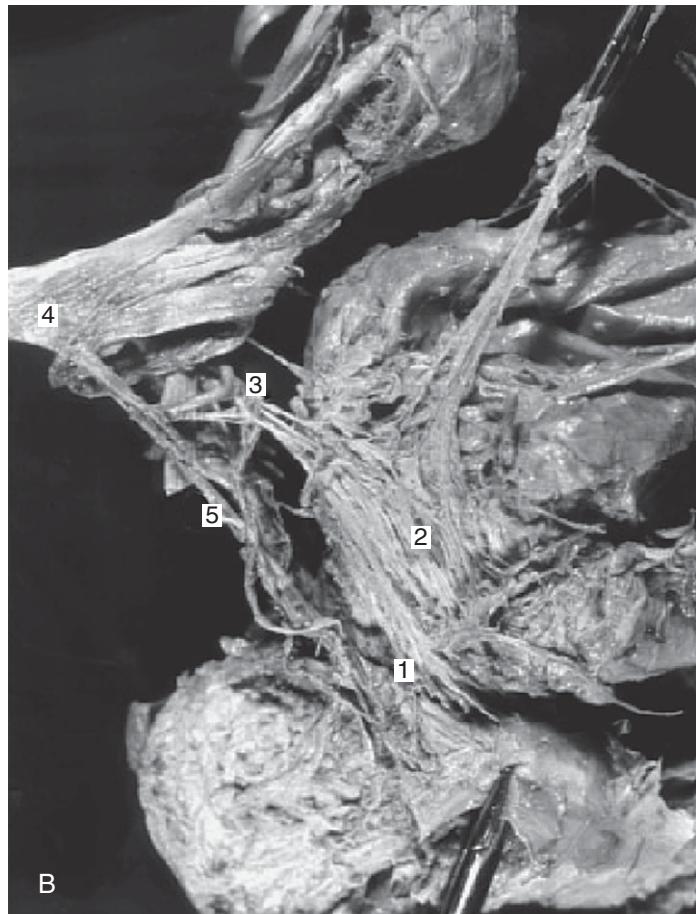

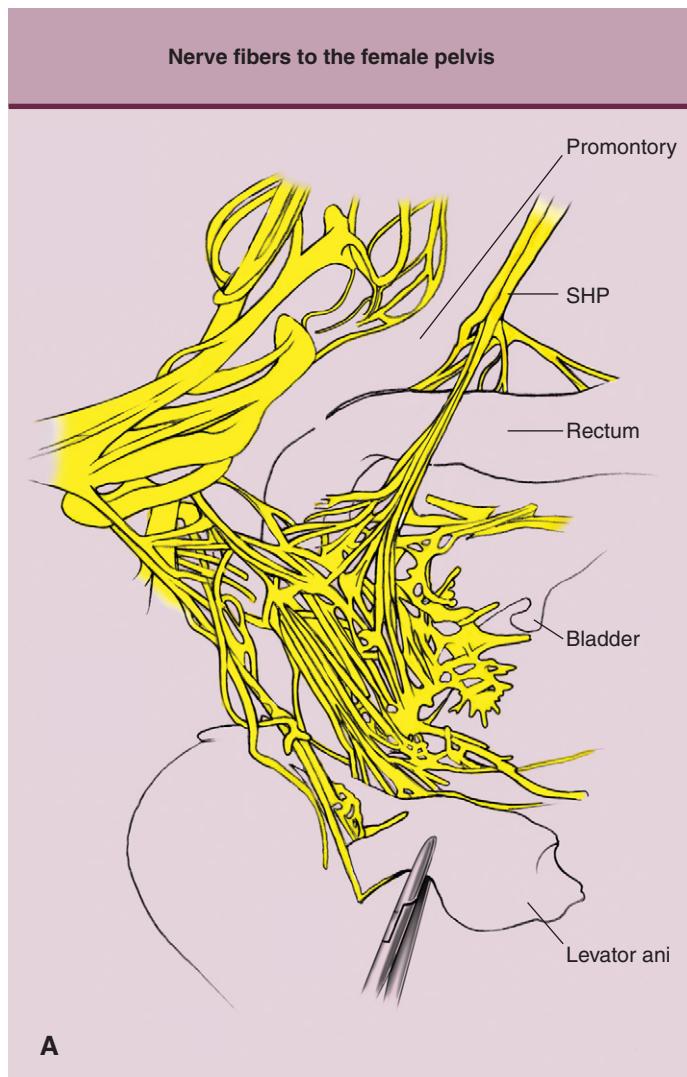

*Breakthrough pain* is a transitory flare of pain that occurs on a background of well-controlled baseline pain. Breakthrough pain is highly prevalent among patients with cancer and predicts more severe pain, pain-related distress and functional impairment, and relatively poor quality of life.

*Incident pain* also is a transitory flare of pain but is associated or initiated by a specific activity, such as activation of visceral functions and movement of the offended body part. Lack of control of incident pain can be particularly debilitating, especially when avoidance of the activity further reduces quality of life.

Rescue medications are rapid-onset, short-acting medications (typically opioids) used concurrently with controlled-release or long-acting opioids to control breakthrough and incident pain.

### Physical Dependence and Addiction

*Physical dependence* is the physiological adaptation of the body to the presence of an opioid. It is defined by the development of

**Figure 50-2** A, Nerve fibers to the female pelvis. B, Female adult, right side; shows the sacral plexus reflected posteriorly (4), giving rise to the pudendal nerve (5) and pelvic splanchnic nerves (3). Both connect to the inferior hypogastric plexus (2). Furthermore, the most inferior parts of the inferior hypogastric plexus contribute to a neurovascular bundle (1). The hemostat shown in the right upper corner holds the superior hypogastric plexus. (From Baader M, Herrmann B: Clinical Anatomy 2003;16:119–130.)

withdrawal symptoms when opioids are discontinued, when the dose is reduced abruptly, or when an antagonist (e.g., naloxone) or an agonist-antagonist (e.g., pentazocine) is administered. It is not synonymous with addiction.

*Addiction* is compulsive use of drugs for nonmedical reasons despite potential harm; it is characterized by a craving for the mood-altering drug effects. Tolerance and physical dependence are physical changes in the body, but addiction is defined by aberrant changes in behavior. Addiction means dysfunctional behavior, in sharp contrast to the improved function and quality of life that result from pain relief. Aberrant behaviors that indicate addiction may include denial of drug use, lying, forgery of prescriptions, theft of drugs from other patients or family members, selling and buying drugs on the street, and using prescribed drugs to get “high.”

It should not be assumed that cancer patients are exempt from the reinforcing properties of opioid medications, and drug diversion does occur in this population. However, a true drug addiction rarely develops after prescription of opioids to treat cancer-related pain unless prior risk factors for addiction exist.<sup>13</sup>

*Pseudoaddiction* describes what happens when health care workers inappropriately perceive as addictive behavior a pain patient’s requests for more or stronger pain medications. In fact, the patient’s behavior may be a response to inadequate pain management.

#### Incomplete Cross-tolerance

Although all morphine receptor agonists are associated with tolerance following repeated usage and exhibit cross-tolerance to other opioids acting at the receptor, the degree of cross-tolerance

varies widely. Indeed, clinicians use incomplete cross-tolerance to restore analgesic sensitivity in highly tolerant patients.<sup>14</sup>

Opioid rotation takes advantage of the concept of incomplete cross-tolerance. It is the process of switching a patient who is highly tolerant to one opioid-selective drug to another to restore analgesia. It has been reported that analgesia may be restored by the second drug at doses 50% below the predicted equivalent dose determined by relative potency studies in naive subjects.<sup>14</sup>

## MAJOR RISK FACTORS FOR CHRONIC SEVERE CANCER PAIN

### Bone Metastasis

Metastatic bone disease is a major risk factor for severe pain and is a common cause of deterioration in quality of life in cancer patients. Breast cancers more commonly metastasize to bone, but malignancies involving the pelvis may also cause bone pain via vascular spread to distant sites and via direct tumor spread into surrounding bony structures. Bone metastases to the vertebral column can be particularly troubling because of the possibility of structural collapse, bone fracture, and nerve compression.

The painful bone lesions are the result of a complex pathophysiological process between host and tumor cells leading to cellular invasion, migration, and adhesion and stimulation of osteoclastic and osteoblastic activity. External beam radiation therapy remains the mainstay of pain palliation of solitary lesions, and bone-seeking radiopharmaceuticals have entered the therapeutic armamentarium for the treatment of multiple painful osseous lesions. Bisphosphonates act by inhibiting osteoclast-mediated resorption and have been increasingly used in treatment of painful bone metastases. Deformation of the periosteum is thought to generate an intense, sharp, stabbing pain. Bisphosphonates reduce the destruction, and should significantly reduce movement-evolved pain.<sup>15</sup>

Several sequelae occur as a result of osseous metastases, and resulting bone pain can lead to significant debilitation. Pain associated with osseous metastasis is thought to be distinct from neuropathic or inflammatory pain. Several mechanisms—such as invasion of tumor cells, spinal cord gliosis, and sensitization of the nervous system—have been postulated to cause pain. A significant reorganization of the spinal cord that received sensory input from the cancerous bone occurs, and this reorganization generates a neurochemical signature of bone cancer pain, which is both dramatic and significantly different from that observed in mouse and rat models of chronic neuropathic or inflammatory pain.

Bone scan is the most effective screening procedure to determine vertebral involvement, and magnetic resonance imaging (MRI) effectively shows epidural involvement. Front-line therapy for this problem is control of tumor activity when possible. Treatments include hormonal therapy, chemotherapy, bisphosphonates, and radiation therapy. Analgesic approaches are applied simultaneously, but too often are ineffective when given alone.

### Neuropathic Pain

Neuropathic pain is a chronic pain syndrome with characteristic clinical symptoms including the feeling of pins and needles; burning, shooting, and/or stabbing pain with or without throbbing;

and numbness. Neuropathic pain is caused directly by cancer-related pathology (compression/infiltration of nerve tissue, combination of compression/infiltration) or by diagnostic and therapeutic procedures (surgical procedures, chemotherapy, radiotherapy). Neuropathy is infrequently associated with major pelvic surgery. The usual etiology is direct surgical trauma, stretch injury, suture entrapment, or retractor injury.

Neuronal hyperexcitability represents the hallmark cellular mechanism involved in the underlying pathophysiology of neuropathic pain. Pathophysiological mechanisms are very complex and are still not completely understood. Neuropathic pain is generated by electrical hyperactivity of neurons along the pain pathways. Peripheral mechanisms (primary sensitization of nerve endings, ectopically generated action potentials within damaged nerves, abnormal electogenesis within sensory ganglia) and central mechanisms (loss of input from peripheral nociceptors into dorsal horn, aberrant sprouting within dorsal horn, central sensitization, loss of inhibitory interneurons, mechanisms at higher centers) are involved. The most frequent sites of neurologic injury for pelvic cancer are nerve roots, the spinal cord and cauda equina, lumbosacral plexus, and peripheral nerves. Typically, painful neuropathic lesions are difficult to treat and resistant to opioid therapy. Breakthrough and incident pain are commonly present.

## PAIN ASSESSMENT

In addition to determining the location of pain, intensity of pain, and its response to current analgesic medications, an assessment of the patient's medical experiences, social background, and current mental state should be undertaken. An evaluation of the patient's mood and cognitive ability, daily activity, nutritional status, family/social support system, and spiritual beliefs can be useful in designing a treatment plan. Mood disorders, such as depression and anxiety, can greatly affect the intensity of pain and other troublesome symptoms.<sup>3</sup> In the author's opinion, patients who have significant depression or major anxiety occurring in conjunction with severely painful symptoms, rarely find satisfactory relief of the pain for extended periods. Patients who are paranoid and disoriented are very difficult to manage and assess going forward. Subtle disorientation may not be appreciated at first. Family can help decipher normal and abnormal behavior and cognitive ability for the patient. The nutritional status and daily activity assessment reveals a great deal about the general physical condition of the patient. Patients who are unable to tolerate food by mouth, have very poor appetites and spend most of their time in bed are generally in poor mental and physical health. This leads ultimately to overwhelming fatigue and malaise and difficulty in controlling painful symptoms. It is always desirable to have good family support systems in place. Patients who are concerned with spiritual matters should be encouraged to practice their beliefs. A psychosocial assessment upfront will help shape and tailor the treatment regimen for a given patient.

The patient's pain history is an important determinant in the assessment (Table 50-1). It is important to note if the patient has visceral versus peripheral/somatic pain symptoms. Visceral symptoms may be treatable with sympathetic ganglion modulation. Neuropathic pain involving peripheral regions of the body

Table 50-1 Pain History Considerations
Visceral pain vs. peripheral/somatic pain
Somatic pain vs. neuropathic pain
Acute pain vs. chronic pain
Intermittent pain vs. unrelenting pain
Incident pain vs. nonincident pain

can often be controlled with adjuvant therapies such as anti-convulsants and neurotransmitter-modulating medications. Acute exacerbations, because they may be short-lived, are amenable to short-term aggressive analgesic approaches, such as epidural analgesia or high-dose, high-potency opioid therapy for several days. During this rest period, radiation therapy and other palliative approaches can be implemented to provide a longer-term solution. Chronic pain should set in motion formulation of a long-term analgesic regimen. Intermittent pain might be best treated with potent medications administered in varying dosages on an as-needed basis. Incident pain can be particularly problematic if the source of the insult cannot be stabilized. When incident pain does not improve spontaneously, interventional approaches should be considered.

Current medications, duration of therapy, and effect on pain are critical components of pain assessment. Patients with an acute pain syndrome on top of a chronic pain disorder usually necessitate variation in the treatment approach.

## TREATMENT CONSIDERATIONS

Because opioid analgesics are generally effective in controlling cancer pain, it is important to evaluate opioid effectiveness, dosage, duration of use, and side effect profile in every patient before launching a new regimen. A history that evaluates use of adjuvant drugs and interventional therapies also help develop the analgesic plan. Table 50-2 outlines a potential course of action as these data are analyzed.

### Psychiatric Therapy

The psychological dimensions of pain control should not be underestimated in cancer patients. The diagnosis of cancer places a great burden on one's psyche, and the strain of it will exacerbate the impact of unrelenting symptoms, particularly pain. Symptom clustering (e.g., pain, depression, and fatigue) is a common occurrence in cancer patients, and each should be rigorously treated simultaneously to maximize improvement in quality of life.<sup>16</sup>

### Sympathetic Ganglionic Neurolytic Blockade

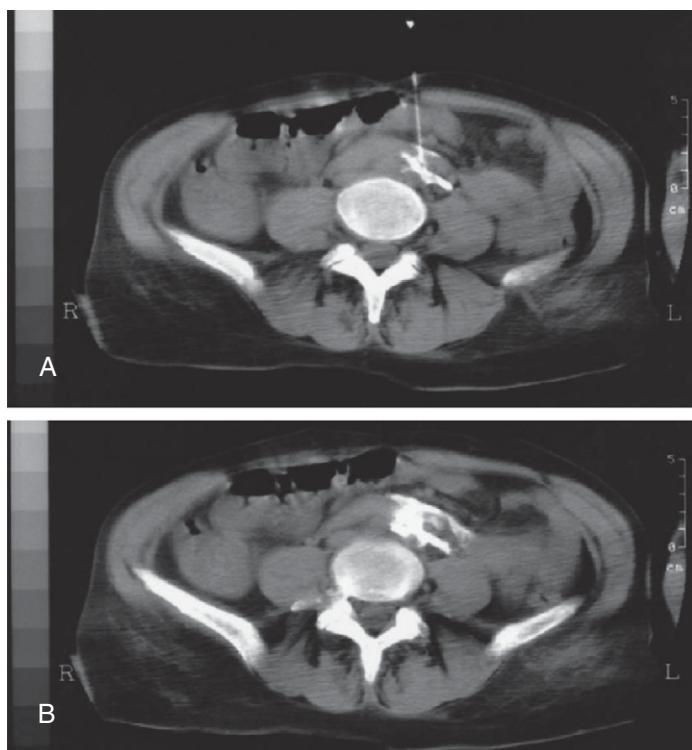

Sympathetic ganglionic blockade has been shown to significantly reduce the intensity of cancer pain, decrease opioid consumption, improve quality of life, and significantly reduce the incidence of drug-induced undesirable side effects when compared to a control group of patients treated with opioids only.<sup>17</sup> The majority of reports related to sympatholysis for cancer pain relate to the effectiveness of this technique against pain due to pancreatic adenocarcinoma. Positive results have also been

demonstrated for pelvic malignant diseases.<sup>18,19</sup> A more recently published controlled study showed difficulty in reducing the intensity of pain in the control group in spite of the weekly increase in opioid dosage.<sup>20</sup> Sympathetic procedures for pain conditions due to pancreatic and pelvic cancers should be intended as adjuvant techniques to reduce analgesic consumption and not as a panacea, given that multiple pain mechanisms are often involved because progression of disease can change underlying pain mechanisms. Pancreatic pain seems to maintain visceral characteristics amenable to sympathetic block more than pain due to pelvic cancer.

### Technique (Superior Hypogastric Plexus Neurolysis)

A number of different specialists are capable of performing this procedure, including trained anesthesiologists, surgeons, and physiatrists. The hypogastric plexus is the target of sympathetic neurolysis for painful lesions involving the pelvic viscera. The preganglionic fibers of the hypogastric plexus originate primarily in the lower thoracic and upper lumbar region of the spinal cord. These fibers interface with the lumbar sympathetic chain via the white communicantes. Postganglionic fibers exit the lumbar sympathetic chain and, together with fibers from the parasympathetic sacral ganglion, make up the superior hypogastric plexus. The plexus lies in front of L4 as a coalescence of fibers and passes downward in front of the L5–S1 interspace. This location marks the site of needle placement for neurolytic injection. The needle is guided to position via computed tomography (CT), fluoroscopy, or under direct vision at surgery. Incremental

Table 50-2 Development of an Analgesic Treatment Plan		
Analgesic Therapeutic History	Potential Consideration When Analgesia Inadequate	
Opioid-responsive pain?	Yes No	Alter timing, route of administration, or dosing of medication. Opioid-resistant symptom (e.g., neuropathic pain), inadequate dosing (too little or too much opioid medication)
High-dose opioid required?	Yes No	Opioid-resistant symptom (e.g., neuropathic pain), inadequate dosing (too little or too much opioid medication); Switch opioid medication. Add adjuvant or intervention approach if not done. Increase dose or potency of medication.
Long-term opioid history?	Yes No	Analgesic tolerance; depression; anxiety Adjust dosing schedule.
Adjuvant therapy responsive	Yes No	Assess patient compliance; is dosing adequate? Add adjuvant therapy.
Severe side effects to therapy?	Yes No	Add adjuvant therapy; reduce dosage; counter side effect. Make notation in patient record.
Interventional approach considered?	Yes No	Evaluate if performed optimally. Add intervention.
Concomitant symptom control therapy on board?	Yes No	Evaluate and treat. Make notation in patient record.

doses of absolute alcohol or 6.5% aqueous phenol are injected to achieve neurolysis (Fig. 50-3).

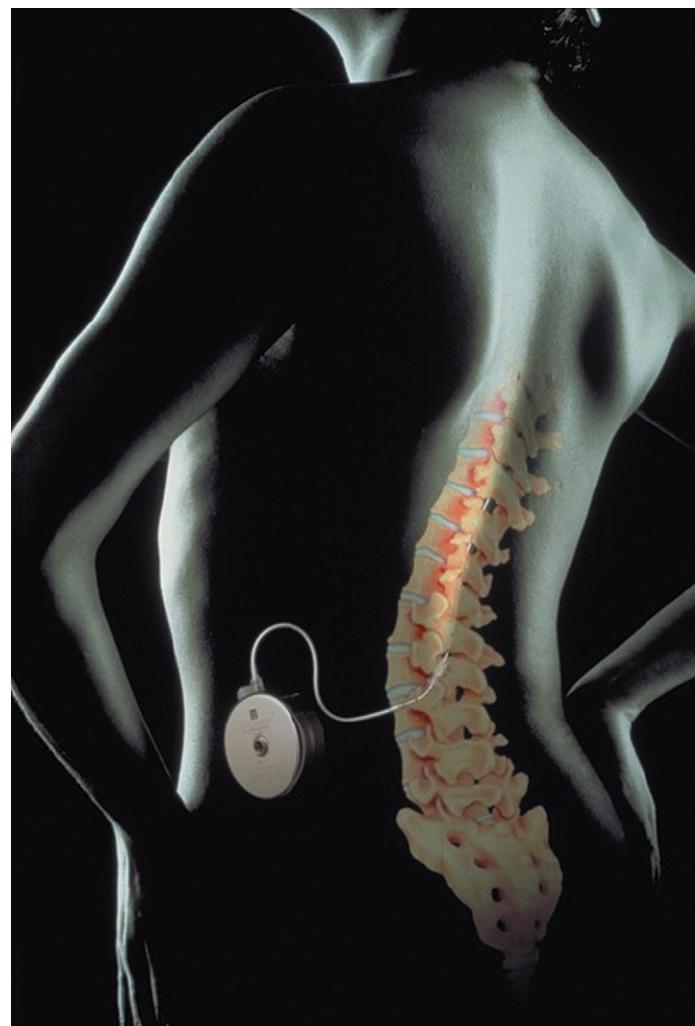

Hypogastric neurolysis performed either with radiologic guidance or under direct visualization has the potential of producing undesirable nerve damage leading to loss of lower extremity mobility as well as bladder and bowel control. Also, given the proximity of vital viscera, including the ureters, unwanted destruction of vital organs is possible. The incidence of major complications is very low, however. Case reports for a variety of complications are assessable. Interestingly, no such complications have been reported in the few controlled clinical trials that have been performed. The potential benefit from this procedure greatly overshadows the potential side effects. Unfortunately, these procedures are considered very late in the course of the patient's disease. It is the authors' opinion that these procedures should be performed earlier. There is no apparent downside to early neurolysis,<sup>17</sup> and complications from advancement of tumor frequently complicate or prevent the use of these techniques late in the disease.

#### Intraspinal Analgesic Therapy

Soon after it was shown that opioid analgesia could be activated in the spinal cord independent of cerebral site activation, techniques were developed to administer intraspinal opioids (monotherapy) for acute pain and chronic pain therapy. Intraspinal implantable drug delivery systems deliver small doses of drug directly to the spinal fluid, achieving pain relief with much smaller doses than are possible with oral or parenteral routes. The

technology used to deliver the medication has received most of the attention, as compared to drug discovery and development. Clonidine has been developed for intraspinal use in humans and is Food and Drug Administration (FDA) approved for epidural administration.<sup>21</sup> Ziconotide (Prialt), a snail conotoxin peptide derivative, has been shown to effectively control cancer pain and is currently under review by the FDA.<sup>22</sup> Many different drugs and drug combinations are used for intrathecal analgesia. Morphine continues to be the standard by which other drugs are compared. To date morphine is the only FDA-approved agent for long-term intrathecal administration to control pain.

The analgesic drug solution is placed in the reservoir of a battery-powered programmable or a bladder-driven non-programmable pump, both of which can be refilled percutaneously as needed (Fig. 50-4). The pump is implanted under the skin of the abdomen and connected to a small catheter tunneled to the site of spinal entry. The cost-effectiveness of this intervention has not yet been formally studied in cancer patients but it could work to reduce cost by cutting significantly the total number of hospital visits and the need for other medications, while providing better pain relief than conventional therapies.

**Figure 50-4** An implanted pump and catheter system for intraspinal analgesic administration. (From Medtronic Inc., Minneapolis, MN.)

Emerging data provided by randomized controlled studies offer evidence that this approach can be highly efficacious,<sup>23,24</sup> although more study is necessary as direction in patient selection is lacking and methods to assure sustained relief after implantation continue to be elusive. Before implantation of the system, a trial is performed, and patients are asked if they experienced 50% or greater relief of their symptoms. No standard approach has been used to conduct this trial; the ideal method is intrathecal infusion of the analgesic drug through a temporary intrathecal catheter and pump system for at least several days. Long-term therapy should be considered if the pain relief is sustained. Single-shot trials are commonly used, but these may be prone to more false-positive and false-negative test results. Another challenge to the use of intrathecal analgesic therapy is the high likelihood that tolerance to the analgesic drug will occur and that disease progression in the cancer patient will limit the effectiveness of the analgesic over time. When the correct patient has been matched with the appropriate drug and dosage, excellent analgesia can be achieved.<sup>21</sup> The reversibility of the technique and its efficacy at multiple body sites and for different types of pain are important advantages.

### Systemic Opioid Therapy

Opioid medications such as morphine are age-old therapies for treating severe pain. These molecules work via activation of opioid receptors located throughout the body. The locations associated with analgesia are found deep in the brain and in the dorsal horn of the spinal cord. The varieties of opioid products differ in pharmacokinetics and affinity/potency at the opioid receptor-binding site. The side effect profiles for the different agents are similar, but the incidence and severity of a particular effect may differ between agents (Table 50-3). It has been demonstrated that patients started on strong opioids required

significantly fewer changes in therapy, had greater reduction in pain when a change was initiated, and reported greater satisfaction with treatment than the comparison group. Strong opioids were safe and well-tolerated, with no development of tolerance or serious adverse events. These data suggest the utility of strong opioids for first-line treatment of pain in patients with terminal cancer.<sup>4</sup>

Opioids remain the cornerstone of pharmacotherapy for cancer pain. We are currently benefiting from a proverbial explosion of products that increase the range of opioid agents and formulations available for the treatment of cancer pain. Analgesic regimens involving opioids can be tailored to suit the individual circumstances for each patient. Short half-life drugs, such as morphine, hydromorphone, fentanyl, oxycodone, and oxymorphone, are common front-line agents because they are easier to titrate than long half-life agents and have a record for being effective. Long-acting opioid and controlled-release preparations can provide convenience and reduce around-the-clock administration of drugs with a short duration of action. In recent years several new formulations have been developed, including controlled-release morphine suppositories and suspensions; controlled-release tablets of oxycodone, hydromorphone, and codeine; and transdermal fentanyl, a patch that allows 3-day dosing and avoids the first-pass effect of the liver. The efficacy of opioid medications for the control of cancer pain is well established both from experience and clinical trials, particularly for treating mild to moderately intense pain. The difficulty occurs when the pain is very severe and extremely high doses are required. Appropriate strategies must be tailored to suit the patient's requirements and a series of trials are required. This can be complicated further when the mechanism of the pain is neuropathic in nature, when higher than typical dosing regimens are required. Of course, the risk of severe side effects is increased

**Table 50-3**  
**Opioid Medications**

<b>Drug</b>	<b>Recommended Starting Dose (Adults)</b>		
	<b>Oral</b>	<b>Parenteral</b>	<b>Comments</b>
Morphine			
Immediate release	15–30 mg q 3–4 hr	4–10 mg q 3–4 hr	Prototype opioid analgesic. Available in a variety of preparations.
Extended release	15–30 mg q 12 hr		
Hydromorphone	2–6 mg q 3–4 hr	1–2 mg q 3–4 hr	Extended-release preparation under review by FDA.
Oxycodone			
Immediate release	5–10 mg q 3–4 hr	—	No parenteral formulation is available. Oral formulation available plain or in combination with aspirin or acetaminophen.
Extended release	10–20 mg q 12 hr	—	
Levorphanol	2–4 mg q 6–8 hr	1–2 mg q 6–8 hr	Long half-life may lead to drug accumulation.
Meperidine	—	50–100 mg q 3–4 hr	Oral preparation generally not effective. First-order metabolite, normeperidine, can accumulate if renal function compromised, leading to CNS toxicity, including seizures.
Oxymorphone			
Immediate release	—		
Extended release	10–20 mg q 12 hr	0.5–1 mg q 3–4 hr	Under review by FDA.
Fentanyl			
Patch	25–50 µg/hr q 3 day		Patch designed for transdermal administration. 25, 50, 75, 100 µg/hr dose units available.
Oral dispenser	200 µg q 3–4 hr		Oral dispenser designed for severe breakthrough pain in opioid tolerant cancer patients. 200, 400, 600, 800, 1200, and 1600 µg dose units available

## Gynecologic Oncology

as the dosage of medications is increased. Effects are not confined to analgesia. Other effects include euphoria, respiratory depression, sedation, slowing of bowel motility, sphincter contraction (glands), dysphoria, and hyperalgesia (exaggerated pain responses).

Potent agonist opioid analgesics are in focus here. Mixed agonist–antagonist opioids (e.g., butorphanol) are sometimes prescribed for chronic pain. These drugs are not typically prescribed for treatment of cancer pain because of their antagonistic effects at the mu receptor. Likewise, partial agonists (e.g., buprenorphine) have a ceiling effect of analgesia and should not be used to treat moderate to severe cancer pain or mild pain that could escalate in intensity.

### **Commonly Prescribed Opioid Agents**

#### Morphine

Morphine is a relatively selective mu receptor agonist with which other opioid and nonopioid analgesics are compared. Morphine is a moderately lipid-soluble molecule and is available in a variety of preparations, including immediate- and extended-release tablets, elixir, suppository, and intravenous and intrathecal (preservative-free) solutions. The extended-release preparation provides even plasma concentrations of drug to control ongoing background chronic pain and minimizes the need for frequent analgesic dosing. The bioavailability of orally administered morphine is 25% to 30%. There is significant first-pass metabolism in the liver. The minor metabolite is active, but accumulation is slow if normal renal function is preserved. Morphine is considered to have strong potency, but other commercially available agents have much greater potency. The side effect profile is very similar to other opioids. Morphine can cause greater histamine release, resulting in significant pruritus.

#### Hydromorphone

Hydromorphone is a synthetic opioid agonist that was originally synthesized and promoted as a safe, nonaddicting substitute for morphine. It is structurally related to morphine but is approximately 5 to 10 times as potent. It is currently available as an immediate-release tablet, oral elixir, rectal suppository, and injectable solution. When taken orally, the onset of analgesia occurs within 15 minutes and lasts 3 to 5 hours. An application has been submitted to the FDA for an extended-release tablet. Orally administered drug has a bioavailability of 50%. Hydromorphone is primarily used to control breakthrough pain and is commonly used in combination with long half-life or extended-release opioid preparations.

#### Oxycodone

Oxycodone is a synthetic opioid agonist with equianalgesic potency to morphine when given parenterally. Oxycodone has twice the potency of morphine because of a significantly greater bioavailability in comparison to morphine (less first-pass metabolism). Oxycodone is produced as an oral solution, and in immediate- and extended-release tablets. Parenteral preparations are not commercially available. OxyContin, an extended-release preparation, has been associated with a disturbing number of drug diversion cases across the United States, prompting investigations from the FDA and other agencies. Some suggest that oxycodone may have greater abuse potential relative to other

legally prescribed opioids, but the evidence is lacking to this point.

#### Fentanyl

Fentanyl (and congeners) is a synthetic opioid mu receptor agonist and is about 100 times more potent than morphine as an analgesic. Fentanyl has been a popular drug in anesthesia as an intravenous agent, but is now commonly administered to manage cancer pain via a transdermal patch device (Duragesic). The available patches come in four dose formulations, 25, 50, 75, and 100 µg/hr. Used patches are replaced every 3 days. Interruptions in steady-state analgesia can be avoided by changing patches every other day in some patients. Fentanyl is also formulated for oral transmucosal administration (Actiq). Six different available dosages are available: 200, 400, 600, 800, 1200, and 1600 µg. Actiq is used only to control severe breakthrough pain and should not be used as the primary analgesic for persistent symptoms. Careful titration of this formulation is needed to avoid severe, potentially lethal, side effects. The time to peak analgesic effect after intravenous administration of fentanyl is minutes. Likewise, the duration of action (offset of analgesia) is fast (1 to 2 hours).

#### Methadone

Methadone is a long-lasting mu receptor agonist with pharmacologic properties similar to morphine. In addition to the mu opioid receptor agonist effects, methadone has an antagonist at the N-methyl-D-aspartate (NMDA) receptor. NMDA blockade effectively prevents and reverses opioid analgesic tolerance in animal preparations. This effect has not been clearly shown to occur in humans,<sup>25</sup> but clinical experience suggests benefit from adding methadone to opioid-tolerant patients.<sup>26</sup> This benefit could be explained by incomplete cross-tolerance. The main clinical consideration in using this drug is its long half-life. Miotic and respiratory depressant effects can be detected for more than 24 hours after a single dose. The long half-life of this drug can be an advantage, however, for cancer patients who require constant plasma concentrations of a potent opioid to control pain. The onset of analgesia occurs 10 to 20 minutes after parenteral administration and 30 to 60 minutes after oral medication. Accumulation of the drug can occur because of the prolonged half-life. Despite a long terminal plasma half-life, methadone, when used to control cancer pain, is frequently administered in divided doses, two to three times per day, although theoretically once-daily doses should be adequate. Care must be taken when escalating the dosage. A number of sudden death cases have been associated with the use of methadone. Hypoventilation is a possible cause of these deaths, but methadone has also been shown to lengthen the QT interval and therefore may be arrhythmogenic in high doses (>150 mg/day).

Opioid agents can induce severe side effects, including death. The primary means of death is respiratory depression. Fortunately, death from opioid medications is rare for cancer patients. The dosing regimen typically is titrated to levels that provide an acceptable balance between side effects and analgesia. Fairly soon after initiation of daily usage of opioid medications (1 week), patients develop tolerance to the respiratory effects of the drug at the prescribed level. If the regimen is increased, the body must adjust to the higher dosage; respiratory depression

and oversedation is a possibility but the risk is reduced. Constipation, reduced libido, and reduced ability to concentrate are common side effects. Altered sleeping patterns and muscle jerking are also major concerns to patients.

Use of these drugs may be limited by inappropriate fears of addiction, drug abuse, and misuse. Unpublished data suggest that at least 10% of cancer survivors are concerned about developing addiction to morphine. This is in addition to physician bias concerning addiction potential and legal liabilities. All patients taking opioids will develop tolerance to the drug to some degree. The significance of analgesic tolerance without evidence of advancing disease is an area of controversy. More recent data suggest that we can reach a level of opioid administration at which the patient becomes hyperalgesic and that additional opioid administration would paradoxically exacerbate the painful symptom. No specific guidelines are available, but for many patients who are treated with extremely high doses of opioid may improve with respect to their pain complaints if the daily dosage is reduced.

### Dosing Strategies

There are no rigid dosing strategies that practitioners must adhere to in order to be within the standard of practice in the community, but there are a few principles that might enhance analgesic performance. Typically, a long-acting drug or a sustained-release preparation is administered with a fast-acting, shorter-duration drug to treat “breakthrough” pain. This is commonly necessary because pain intensity is rarely static but rather waxes and wanes over time. Activity is a common reason for increased pain, but pain may increase or decrease without apparent cause.

### Opioid Switching

Anecdotal observations suggest that opioid switching is a useful practice that will improve pain relief and drug tolerability. Some practitioners schedule switching of opioid medications after 2 to 3 months of therapy. It is also acceptable to switch after effectiveness begins to wane or when unacceptable side effects manifest. Constipation seems to be the only side effect that is equivalent across the board.

Morphine is typically the first-line strong opioid of choice for treating severe pain. Although most patients achieve adequate analgesia with morphine, a significant number suffer either intolerable side effects, inadequate pain relief, or both. Switching these patients to an alternative opioid is becoming established clinical practice. For patients with inadequate pain relief and intolerable opioid-related toxicity/adverse effects, a switch to an alternative opioid may be the only option for symptomatic relief. However, the evidence to support this practice is largely anecdotal or based on observational and uncontrolled studies. Randomized trials, including “N of 1” studies, where a patient acts as their own control, are needed: first, to establish the true effectiveness of this clinical practice; second, to determine which opioid should be used first-line or second-line; and third, to standardize conversion ratios when switching from one opioid to another.<sup>27</sup>

Opioid-containing medications are age-old remedies for controlling cancer-related pain. Among the important advances in the past decade in the treatment of cancer pain is the

realization that the goals of care and the best means of achieving them differ not only among individuals, but also for a single patient throughout a long course of care. Physicians must not only be knowledgeable, but also flexible in their approach to managing cancer pain. An understanding of the range of opioid agents and the formulations available can allow physicians to maintain the best possible quality of life for their patients with chronic pain.

### Adjuvant Therapies

#### **Nonsteroidal Anti-inflammatory Drugs**

On the basis of limited data, nonsteroidal anti-inflammatory drugs (NSAIDs) appear to be more effective than placebo for cancer pain. Clear evidence to support superior safety or efficacy of one NSAID compared with another is lacking. Trials of combinations of an NSAID with an opioid have disclosed either no significant difference or at most a slight but statistically significant advantage compared with either single entity.<sup>28</sup> The cyclooxygenase-2 (COX-2) selective inhibitors are not expected to be any more efficacious than the standard NSAIDs, but have less gastrointestinal irritation. Rofecoxib (Vioxx) was pulled from the market because evidence indicated that this agent increased the risk of cardiac ischemia and cerebrovascular incidents. It remains to be seen what impact, if any, this will have on the remaining COX-2 inhibitors under study.

#### **Steroids**

Spinal cord and nerve root compression following epidural metastasis is a dreaded complication of metastatic cancer. Severe pain is the most common presentation. Steroids can provide significant relief of pain and improve the patient’s quality of life. Glucocorticosteroids are believed to exert their influence on brain tumors mainly by reducing the tumor-associated vasogenic edema, probably by decreasing the increased capillary permeability of the blood-brain barrier. Although some prefer methylprednisolone, dexamethasone is the glucocorticosteroid given to most neuro-oncology patients, at an empirically chosen dosage of 4 mg four times a day; lower doses in a twice-daily regimen may be sufficient. Side effects may be divided into three groups: those originating from the mineralocorticoid activity, from withdrawal of the drug, and from chronic excess glucocorticosteroid administration. Steroid myopathy is the most frequent occurring serious side effect in neuro-oncology patients. Others include gastrointestinal perforation and hemorrhage, opportunistic infections, steroid diabetes, and skin and facial changes. The most important interaction is that with phenytoin. Phenytoin uniformly decreases the levels of dexamethasone, accelerating its metabolism through induction of hepatic microsomal enzymes.<sup>29</sup>

#### **Anticonvulsants**

Anticonvulsant adjuvant medications are used primarily to treat pain secondary to neural damage or irritation. Nerve injury pain and sympathetically maintained pain are treated more frequently with adjuvant analgesics, especially antidepressants and anticonvulsants. For many years this anticonvulsant was used off label for control of neuropathic pain syndromes. Gabapentin has stood the test of time and continues to be the medication of choice when neuropathic pain is suspected because of its

favorable side effect profile. Efficacy has been demonstrated in control trials for use in small-fiber neuropathy and other neuropathic pain related to cancer invasion and treatment.<sup>30</sup>

### Bisphosphonates

Bisphosphonates are potent inhibitors of osteoclast-mediated bone resorption. It is well accepted that tumor cells in bone can stimulate osteoclast formation and activity, leading to the release of growth factors or cytokines, which will further stimulate cancer cell growth and secretion of osteolytic factors. Bisphosphonates are now the standard treatment for cancer hypercalcemia. Clodronate is the most potent drug available in this class and has a longer lasting effect. It has been reported that pamidronate infusions exert clinically relevant analgesic effects in more than half of patients with metastatic bone pain, but randomized, controlled trials have yet to definitively show efficacy of these agents as analgesics for bone pain.<sup>31,32</sup> Perhaps nonresponding patients should be treated with higher doses.

### Psychostimulants

A variety of psychostimulants have been studied and are used clinically as adjuvant therapy for uncontrolled pain. Typically these drugs are used with opioid medications to counter sedative effects and fatigue complaints. Methylphenidate and dextroamphetamine have been the primary agents used in this regard. A number of studies have been conducted to estimate expected benefits and side effects of these adjuncts. In a recent publication, Bruera and colleagues showed that not only were fatigue complaints improved with methylphenidate (5 mg q 2 hours p.r.n.), but that anxiety, appetite, pain, nausea, depression, and drowsiness also all improved significantly.<sup>33</sup> This is in keeping with the concept that a multidimensional approach is essential to good analgesia in cancer patients.

## CONCLUSION

The cancer patient with chronic painful symptoms that resist initial efforts at symptom control presents a complex conundrum, requiring a multidimensional approach to seize control and relieve the pain. Patients with severe pain often have multiple mechanisms that produce the painful symptoms, each requiring a different approach for relief. Many patients expect complete relief of their pain or other symptoms, and many doctors believe that increasing the dose of the opioid can relieve all pain. The reality is that not all pain complaints can be completely purged in all circumstances, but if barriers to good analgesic techniques can be reduced and a multidimensional approach can be the rule, most patients can enjoy a reduction in their pain and an improvement in their quality of life. It is recommended that an aggressive approach on all fronts as early as possible in the course of a patient's management. The evidence suggests that attention to psychosocial issues, aggressive opioid and adjuvant regimens, and application of interventional therapy early in the course of the patient's complaints offer the best opportunity for relief and satisfaction for both the patient and the health care provider.

## KEY POINTS

- Cancer is a genetic disease that results from a series of mutations in various cancer genes.
- Cancer gene mutations affect genes that are responsible for control of normal cell proliferation and cell death (gatekeeper genes), and genes that control genomic stability (caretaker genes).
- Cancer predisposing genes are categorized into oncogenes, tumor suppressor genes, and stability genes.
- The majority of gynecologic malignancies are a result of sporadic mutations.
- Hereditary syndromes in gynecologic cancers include genomic mutations in *BRCA1* and *BRCA2* genes (ovarian cancer), and mismatch repair gene alterations (endometrial cancer).

Cancer is caused by the accumulation of various genetic mutations that lead to the transformed phenotype. A tumor may arise through the accumulation of somatic mutations or the inheritance of one or more mutations through the germline followed by additional somatic mutations. Mutations in genes that are directly involved in normal cellular growth and proliferation can lead to the development of uncontrolled cell growth, invasion, and metastasis.

All cells in a tumor arise from a single cell in which the regulatory mechanisms of proliferation have been disrupted. Based on the Knudson hypothesis, first described in children with hereditary retinoblastoma, two hits or mutations are required within the genome of a cell to develop into the malignant phenotype.<sup>1</sup> In hereditary cancer, the first hit is present in the genome of every cell, therefore requiring only one additional hit to disrupt the correct function of the second cancer gene allele. In contrast, sporadic cancers develop in cells that don't harbor mutations in the cancer-predisposing alleles. In this case, both hits must occur in a single somatic cell that disrupts both cancer gene alleles<sup>2</sup> (Fig. 51-1).

Cancer-causing mutations include gain of function mutations that convert proto-oncogenes into oncogenes, loss of function mutations that inactivate tumor suppressor genes, and disruption of cellular mechanisms that preserve genomic integrity. Epigenetic changes such as DNA methylation of, for example, "promoter" sequences of tumor suppressor genes might also contribute to malignant transformation. Promoter methylation can impair the transcription of the following open reading frame of a gene and therefore cause reduced or absent expression of that particular gene. These genetic and epigenetic changes are

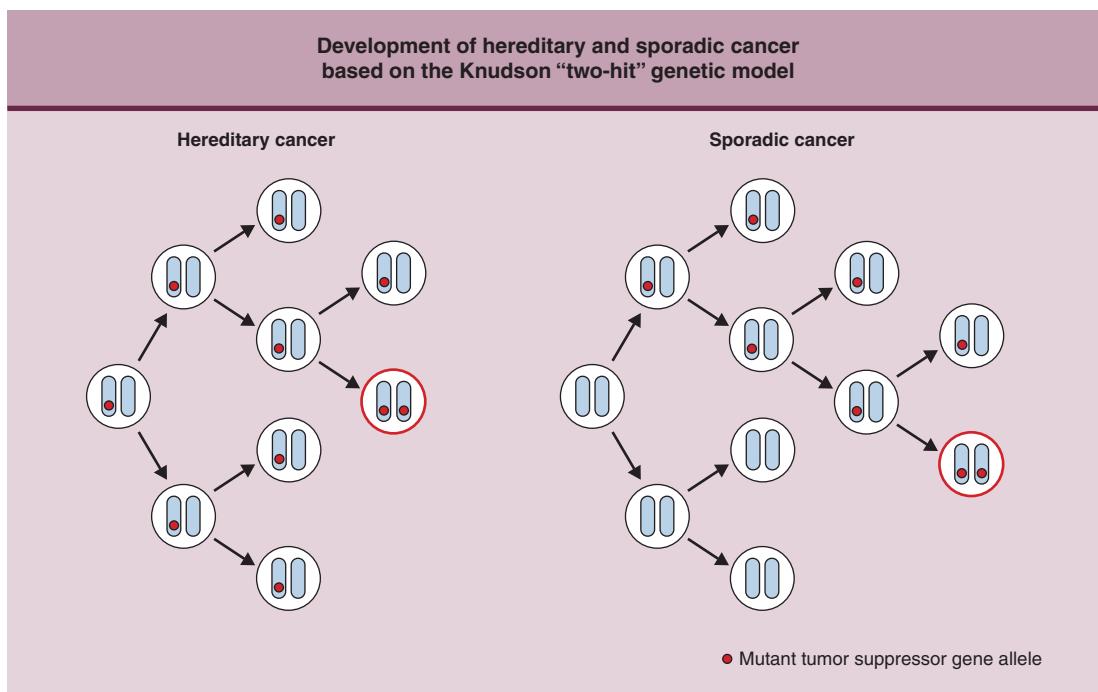

collectively responsible for the development of cancer characterized by growth factor independence, diminished susceptibility to *apoptosis* (programmed cell death), the ability to invade and metastasize, induction of angiogenesis, and escape from immunity and senescence.

Mathematical models based on age-specific cancer incidence and spontaneous mutation rates have shown that most adult solid tumors require 5 to 10 rate-limiting mutations to acquire the malignant phenotype. The most compelling evidence for the mutagenic tumor development process is that the age-specific incidence rates for most human epithelial tumors increase at roughly the fourth to eighth power of elapsed time. Although the precise number of mutations in solid tumors is unknown, it is important to distinguish between mutations that cause the cancer phenotype and other mutations, which might be considered bystander mutations (e.g., the amplification of genes that are adjacent to an oncogene).

## CANCER GENES

About 300 human genes are implicated in tumorigenesis, accounting for more than 1% of genes from the human genome.<sup>3</sup> The molecular effects of cancer genes are mediated by proteins. Overall, approximately 90% of cancer genes show somatic mutations and up to 20% show germline mutations. In general, the spectrum of neoplasms associated with germline mutations in a particular gene is similar to that reported with somatic mutations. Exceptions include the neoplasms related to the tumor suppressor gene *TP53* and *BRCA1/BRCA2*. *TP53* mutations are found in about 50% of colorectal cancers, yet germline mutations, as observed in the Li-Fraumeni syndrome, do not cause a predisposition to colorectal cancer. In contrast, germline mutations of the *BRCA1* and *BRCA2* genes confer a high incidence of breast and ovarian cancer, but somatic mutations are found very infrequently in sporadic cancers of the same type.

Most somatic mutations involve chromosomal translocations that result in chimeric transcripts, with juxtaposition of one gene to the regulatory region of another gene. This mutation type is most commonly reported in leukemias, lymphomas, and mesenchymal tumors. The Philadelphia chromosome in chronic myeloid leukemia, for example, is the result of a reciprocal translocation between one chromosome 9 and one chromosome 22. This translocation results in one chromosome 9 that is longer than normal and one chromosome 22 that is shorter than normal. The DNA sequence removed from chromosome 9 contains the proto-oncogene *ABL* and inserts into the *BCR* gene sequence on chromosome 22 (*Philadelphia chromosome*). The resulting chimeric *bcr-abl* gene product functions as a constitutively active tyrosine kinase and stimulates cellular proliferation, for example,

**Figure 51-1 Development of hereditary and sporadic cancer based on the Knudson “two-hit” genetic model.** In hereditary cancers, all cells harbor one mutant tumor suppressor gene allele. The loss of the second allele will result in the malignant phenotype. In contrast, sporadic cancers develop in cells with normal genomes, therefore requiring both alleles to be inactivated (two hits).

via an increase of growth factors. Epithelial neoplasms such as thyroid papillary carcinoma and breast secretory carcinomas have been reported to harbor chromosomal translocations that are likely responsible for the development of the malignant phenotype. Other cancer gene mutations involve base substitutions that can result in missense amino acid changes, non-sense changes, and alterations in splice sites. Insertions or deletions in coding sequences or splice sites can cause in-frame or frame-shifting mutations, resulting in loss of protein function. Increased gene copy numbers can lead to overexpression of proteins like proto-oncogenes. In contrast, decreased gene copy numbers result in loss of sufficient protein function (Table 51-1).

### Gatekeepers and Caretakers

Cancer susceptibility genes are divided into gatekeepers and caretakers. Gatekeeper genes act directly to control cellular proliferation. They are divided into oncogenes, which elicit a stimulatory effect on growth and proliferation, and tumor suppressor genes, which suppress cell growth.<sup>4</sup> Gatekeepers directly prevent the development of tumors by inhibiting growth

or promoting cell death. Mutations of a gatekeeper gene result in a risk of developing cancer at least 100 times greater than in the general population. Examples of gatekeeper genes include the tumor suppressor genes *TP53* and the *RBI* (retinoblastoma) gene (Table 51-2).

Caretaker genes (stability genes) preserve the integrity of the genome and are involved in DNA repair and maintenance of genomic integrity. The inactivation of caretakers facilitates the development of mutations in gatekeeper genes and other cancer-related genes. Caretakers, like gatekeepers, may be tissue specific, but mutation in the caretaker is neither necessary nor sufficient for the development of cancer. The DNA mismatch repair genes *MLH1*, *MSH2*, and *MSH6* are examples of caretaker genes.

### Oncogenes

Oncogenes comprise a family of genes that result from gain of function mutations of their normal counterparts, proto-oncogenes. The normal function of proto-oncogenes is to drive cell proliferation in the appropriate context. Activated oncogenes act in a dominant fashion to stimulate cell proliferation or

- Stability genes**

development of the malignant phenotype. It is important to note that this requires the mutation of only one allele.

Oncogenes were initially discovered via the mechanism of retroviral tumorigenesis. Viral transduction of mammalian cells can lead to integration of the viral sequences into the proto-oncogene sequence of the host cell. The integrated viral promoter activates transcription from the surrounding DNA sequences, including the proto-oncogene. Subsequent overexpression of the proto-oncogene sequences results in the expression of growth factors, growth factor receptors, signal transduction proteins, nuclear proto-oncogenes, and transcription factors. The resulting cellular effect is stimulation of cell proliferation. One of the most important group of viral oncogenes is the family of *RAS* genes, which include c-H(Harvey)-*ras*, c-K(Kirsten)-*ras*, and N(neuroblastoma)-*ras*. Human homologs of c-H-*ras* and c-K-*ras* murine sarcoma virus oncogenes were identified using in vitro assays to screen for active transformation of mouse fibroblasts. The third, N-*ras*, was found in human neuroblastoma and fibrosarcoma cell lines.

Proto-oncogene growth factors include platelet-derived growth factor (PDGF), epidermal growth factor (EGF), insulin-like growth factors I and II (IGF-I and IGF-II), and transforming growth factor  $\alpha$  and  $\beta$  (TGF- $\alpha$  and TGF- $\beta$ ). Growth factor receptors mediate the stimulatory effect of growth factors and the intracellular signaling pathways. Examples include the two transmembrane receptor protein tyrosine kinases RET and MET, which are mutated in multiple endocrine neoplasia type II and familial papillary renal cancer. Proto-oncogene signaling includes membrane-associated guanine nucleotide proteins such as *RAS* and membrane-associated cytoplasmic protein tyrosine kinases (e.g., *ABL* and *SRC*). The *MYC* genes are examples of nuclear proto-oncogenes. Amplification of the *MYC* genes has been found in a variety of tumor types, including ovarian cancer.

### Tumor Suppressor Genes

Tumor suppressor genes are involved in the development of most cancers and are usually inactivated in a two-step process in which both copies of the tumor suppressor gene are mutated or inactivated by epigenetic mechanisms such as methylation.<sup>5</sup> The most commonly mutated tumor suppressor gene in human cancers is *TP53*. The p53 protein regulates transcription of other genes involved in cell-cycle arrest such as *P21*. Up-regulation of *TP53* expression is induced by DNA damage and contributes to cell-cycle arrest, allowing DNA repair to occur. *TP53* also plays an important role in the initiation of apoptosis. Interestingly, the most common mechanism of inactivation of *TP53* differs from the classic two-hit model. In most cases, missense mutations that change a single amino acid in the DNA-binding domain of *TP53* results in overexpression of nonfunctional p53 protein in the nucleus of the cell.

The identification of tumor suppressor genes has been facilitated by positional cloning strategies. The main approaches are cytogenetic studies to identify chromosomal alterations in tumor specimens, DNA linkage techniques to localize genes involved in inherited predisposition to cancer, and examination for loss of heterozygosity or allele among studies in sporadic tumors. Comparative genomic in situ hybridization allows fluorescence identification of chromosome gain and loss in human cancers within a similar experiment.

### Stability Genes

The third class of cancer genes, called stability genes, promote tumorigenesis in a way that differs from tumor suppressor genes or amplified oncogenes. Stability genes function mainly to preserve the correct DNA sequence during DNA replication (caretaker function). Mistakes made during normal DNA replication or induced by exposure to mutagens can be repaired by a variety of mechanisms that involve mismatch repair genes, nuclear-type excision repair, and base excision repair genes. Inactivation of stability genes leads to a higher mutation rate in potentially all genes. However, only mutations in oncogenes and tumor suppressor genes influence cell proliferation and confer a selective growth advantage to the mutant cell. As with tumor suppressor genes, both alleles of stability genes must be activated to cause loss of function.

### HEREDITARY CANCER

A small number of cancers arise on a heritable genomic background. Germline mutations require additional mutations at one or more loci for tumorigenesis. These mutations can be acquired via either environmental factors such as ionizing radiation or mutations of stability genes, further increasing the chance of spontaneous mutations. Hereditary cancers are characterized by a relatively early age of onset compared with similar sporadic tumors. The germline mutations in hereditary cancer might confirm a phenotype in multiple tissues. The production of multiple phenotypic effects by a single mutant gene is called *pleiotropy*. Different manifestations among members of a family with the same genetic defect is also called *variable expressivity*. Because the development of cancer is a multistep process involving more than the germline mutation, genetically cancer-prone individuals might not develop a phenotype because of insufficient somatic hits. The event of a gene carrier escaping all manifestations of disease is called a *nonpenetrant carrier*. This concept might explain why some women with *BRCA1* or *BRCA2* mutations do not develop breast or ovarian cancer during their lifetime yet are at high risk for development of these diseases.

Several multisystem genetic syndromes with a high risk of cancer have been described. The Li-Fraumeni syndrome with germline mutations in *TP53* and the *CHEK2* gene is associated with early-onset breast cancer, childhood soft tissue sarcoma, osteosarcoma, brain tumors, adrenocortical carcinoma, and acute leukemia. The hereditary nonpolyposis colorectal cancer syndrome (HNPCC) is an autosomal dominant disorder that confers a high lifetime risk of colon, endometrial, stomach, ureteral, and ovarian cancer. The genes responsible for the phenotype of the HNPCC syndrome involve mutations in mismatch repair genes such as *MLH1*, *MSH2*, and *MSH6*. Table 51-3 summarizes hereditary cancer syndromes that are associated with gynecologic tumors.

### CANCER GENETICS IN GYNECOLOGIC CANCERS

#### Genetics of Breast and Ovarian Cancer

Ovarian carcinoma is generally a monoclonal disease that originates in the ovaries. Both familial and sporadic cases of ovarian cancer require the accumulation of genetic mutations.

**Table 51-3**  
**Hereditary Tumor Syndromes Associated with Gynecologic Tumors**

Hereditary Syndrome	Associated Tumors
<b>Tumor suppressor genes</b>	
TP53, CHEK2	Li-Fraumeni syndrome
PTEN	Cowden syndrome Bannayan-Zonana syndrome
Menin	Multiple endocrine neoplasia type I
PRKARIA	Carney complex
STK11	Peutz-Jeghers syndrome
<b>Stability genes</b>	
BRCA1, BRCA1	Hereditary breast and ovarian cancer
MLH1, MSH2, MSH3, MSH6, PMS2	Hereditary nonpolyposis colorectal cancer (HNPCC)
<b>Oncogenes</b>	
RET	Multiple endocrine neoplasia type II
	Cancer of thyroid and parathyroid; pheochromocytoma, ovarian carcinoid

The mechanism of these mutations is unclear. However, the frequency of ovulation has been correlated with the incidence of epithelial ovarian cancer. In general the inhibition of ovulation (e.g., during pregnancy or contraceptive use) protects against the development of ovarian cancer. It is unclear how ovulation leads to mutations in the ovarian surface epithelial cells. Mutations in the ovarian surface epithelium might result in errors in DNA synthesis during the repair of ovulatory defects because spontaneous mutations are more likely to occur in cells that are proliferating compared to cells at rest. Although DNA repair mechanisms usually maintain high-grade fidelity of DNA synthesis, the efficiency of DNA repair systems may vary among individuals and therefore result in persistent mutagenic changes.

#### **Family History of Breast and Ovarian Cancer**

Approximately 5% to 10% of women in the general population have a first-degree relative with breast cancer, and about twice as many have either a first-degree or a second-degree relative with breast cancer. The relative risk of breast cancer conferred by a first-degree relative with breast cancer is about 2.1.<sup>6</sup> The relative risk is dependent on the age of diagnosis: the younger the affected relative, the greater the risk to the related individual. Other important factors that influence the relative risk are the number of affected relatives and the closeness of their biologic relationship. The larger the number of affected relatives and the closer the biologic relationship, the greater the risk.

The lifetime risk for developing ovarian cancer in the United States is approximately 1 in 70, or 1.4%. The single greatest ovarian cancer risk factor is a family history of the disease. Several studies have evaluated the risk of developing ovarian cancer in relatives of ovarian cancer cases compared with controls. In a meta-analysis that included the Cancer and Steroid Hormone (CASH) study, the relative risk for ovarian cancer was 3.1 for a woman with a single first-degree relative with ovarian cancer and 4.6 for a woman with two or three

relatives with ovarian cancer. This translates into lifetime probabilities for ovarian cancer of 5.0% and 7.2%, respectively.<sup>7</sup> About 12% of invasive ovarian cancer results from a hereditary predisposition. The family characteristics that suggest hereditary breast and ovarian cancer predisposition include the occurrence of cancer at an earlier age than in sporadic cases, two or more primary cancers in a single individual, and cases of male breast cancer (Table 51-4).

#### **BRCA1 and BRCA2**

No single gene conferring increased susceptibility to ovarian cancer alone has been isolated. The majority of germline mutations that control the risk for ovarian and breast cancer occur in the *BRCA1* and *BRCA2* genes. Genetic linkage initially identified a susceptibility gene for breast cancer on the long arm of chromosome 17. Subsequent positional cloning identified the *BRCA1* gene. The second breast cancer susceptibility gene, *BRCA2*, was localized to the long arm of chromosome 13 through linkage studies of 15 families with multiple cases of breast cancer that were not linked to *BRCA1*. Mutations in *BRCA2* are not only associated with breast and ovarian cancer, but are also linked to male breast cancer, prostate cancer, and pancreatic cancer.

The risk estimates of developing breast and ovarian cancer in patients with mutations in *BRCA1* and *BRCA2* vary. The range of risk estimates is caused by a number of different factors,

**Table 51-4**  
**Family Characteristics Suggestive of Hereditary Breast and Ovarian Cancer**

Early age of onset
Two or more primary breast and/or ovarian cancers in a single individual
Cases of male breast cancer

including the variable penetrance of different mutations. For example, *BRCA2* mutations that occur in families with a high risk of ovarian cancer are clustered in the central portion of the gene, which has been termed the ovarian cancer cluster region (OCCR), between nucleotides 3059 to 4075 and 6503 to 6629. Mutations in this region are associated with a significantly lower risk of breast cancer and a significantly higher risk of ovarian cancer. Based on recent studies, the lifetime risk of breast cancer among female *BRCA1/BRCA2* mutation carriers is up to 87%, which is similar to risks in families with many cases. For ovarian cancer, lifetime risk estimates range between 44% and 68% by age 70. In a recent study, the risk to develop ovarian cancer was found to be 54% for *BRCA1* and 23% for *BRCA2* mutation carriers, respectively.<sup>8</sup>

In the general population, *BRCA1/BRCA2* mutations occur at a frequency of about 1 in 250 women, with probably 250,000 carriers in the United States. Most *BRCA1/BRCA2* mutation carriers are identified in ovarian cancer patients with a family history significant for early age of diagnosis, dual primary cancers of the breast and ovaries, or relatives affected by breast and ovarian cancer. The occurrence of at least two cases of ovarian cancer and at least two cases of breast cancer relates to an estimated likelihood of 56% to 63% for *BRCA1* mutations. Among cases identified from the Cancer Surveillance System of Western Washington, the frequency of *BRCA1* mutations was highest in cases diagnosed before age 30 (23%) and in those with more than three relatives with breast cancer (20%). A family history of ovarian cancer in a first-degree relative was also associated with an increased prevalence of *BRCA1* mutations (25%). In another study of 263 women with familial breast cancer, *BRCA1* mutations were found in 7% of families with site-specific breast cancer, 18% of families with bilateral breast cancer, and 40% of families with both breast and ovarian cancer. In a population-based series of incident cases of ovarian cancer in Canada, the overall prevalence of *BRCA1/BRCA2* mutations was 11.7%.

The occurrence of specific *BRCA1/BRCA2* mutations in multiple apparently unrelated families is consistent with a “founder effect.” These mutations can be traced back from a contemporary population to an early small group of founders. For example, two *BRCA1* mutations (185delAG and 5382insC) and one *BRCA2* mutation (6174delT) have been reported to be common in Ashkenazi Jews of Central and Eastern European descent. The overall frequency of these three mutations is about 2.5% among Ashkenazi Jews; they account for up to 90% of both breast and ovarian cancer in families with multiple cases. In contrast, in the general Jewish population, carrier frequencies for these mutations are lower: 0.9% for the 185delAG mutation, 0.3% for the 5382insC mutation, and 1.3% for the *BRCA2* 6174delT mutation. Additional founder mutations have been described in other ethnic groups, including from the Netherlands (*BRCA1* 2804delAA and several large deletion mutations), Iceland (*BRCA2*, 995del5), and Sweden (*BRCA1*, 3171ins5).<sup>9</sup>

#### **Biologic Functions of *BRCA1* and *BRCA2* Proteins**

The *BRCA1* gene contains 24 exons that encode a protein of 1863 amino acids. The *BRCA2* protein is even larger, with 3418 amino acids. The *BRCA* genes were initially classified as tumor suppressor genes based on several observations. First, the hered-

itary breast and ovarian cancer syndrome is an autosomal dominant condition with one normal and one mutated *BRCA1* or *BRCA2* allele. In most breast and ovarian cancers that develop in mutation carriers, deletion of the normal allele with subsequent loss of *BRCA1/BRCA2* function is observed. The loss of the second allele in the process of carcinogenesis is a classic characteristic of tumor suppressor genes, suggesting a recessive function. Second, overexpression of the *BRCA1* protein leads to tumor growth suppression in vitro and in mouse models, another feature commonly associated with tumor suppressor genes.

However, based on recent biochemical evidence and data from knockout models, both *BRCA1* and *BRCA2* proteins play a much more complex role and are implicated in various cellular pathways that regulate DNA repair, cell-cycle progression, ubiquitination, and transcriptional regulation.<sup>10</sup> Cells deficient in *BRCA1/BRCA2* sustain spontaneous aberrations of chromosome structures as seen, for example, in murine cells in culture. Similar structural aberrations occur in *BRCA1/BRCA2*-deficient human cancer cells. Gross chromosomal rearrangements might include triradial or quadriradial structures, markers of defective mitotic recombination. Collectively, these findings suggest that *BRCA* genes are essential for preserving chromosome structure and suppressing genome instability (caretaker function).

One of the common functions of both proteins is their role in homologous recombination as an important DNA repair mechanism. On DNA damage by ionizing radiation or chemotherapy, for example, the *BRCA2* protein binds to the RAD51 protein, which is central for the repair of double-stranded breaks via homologous recombination. *BRCA2* regulates the availability and activity of RAD51 in this key reaction. Phosphorylation of the *BRCA2*–RAD51 complex allows RAD51 to bind to the site of DNA damage and in conjunction with several other proteins to mediate repair of DNA by homologous recombination. In contrast, *BRCA1* is involved more proximally in the cellular response to a double-stranded break. *BRCA1* has a complex network of protein–protein interactions mediating DNA repair by homologous recombination and regulating transcription via the *BRCA1*-associated surveyant complex.

It is still unclear how cells deprived of *BRCA1* and *BRCA2* physiological functions develop into the malignant phenotype. Mice deprived of either protein by transgenic deletion of gene expression are embryonically lethal, suggesting that *BRCA1* is critical for normal development. Most mutant strains exhibit an embryonic lethal phenotype due to cellular proliferation defects, genomic instability, and developmental retardation. Generally, mutations are found in every cell of the body, yet *BRCA1/BRCA2* mutations confer a malignant phenotype mainly for breast and ovarian cancer. The specificity of malignant transformation on a *BRCA1*-deficient background is still unclear. It is possible that the *BRCA* proteins play a much more important role in tumor suppression in breast and ovarian tissue compared to other tissues in the body that use alternative mechanisms for tumor suppression, even in the absence of *BRCA* protein function.

#### **Genetic Testing for Breast and Ovarian Cancer Syndrome**

Genetic screening of high risk families provides useful prognostic information. Genetic testing to identify patients with germline

## Gynecologic Oncology

mutations should always be preceded by genetic counseling. The careful evaluation of an individual's medical and family history is crucial to estimate the likelihood for the presence of a cancer-predisposing mutation. Several algorithms are available to help calculating this likelihood. BRCA PRO, for example, is a statistical model that calculates the probability that an individual carries a germline mutation of the *BRCA1* and *BRCA2* genes. The model is based on family history of breast and ovarian cancer and uses a mendelian approach that assumes autosomal dominant inheritance.

The presence of specific mutations for certain populations allows testing for "ethnic-specific" alleles, facilitating genetic screening. In the Ashkenazi Jewish population, only 15% of *BRCA1* and *BRCA2* mutations are nonfounder mutations. However, in countries with ethnically mixed populations, such as the United States, the range of genetic variations is wide, making the search for cancer-causing genes more difficult. In general, the high frequency of mutations and the necessity to accurately communicate risks to patients before offering preventive options necessitates the estimation of penetrance of certain mutations. However, the penetrance of many mutations is still unclear. For example, the lifetime risk of developing breast or ovarian cancer is usually higher in *BRCA1* mutation carriers compared to carriers of the *BRCA2* mutation. In addition, the risk of ovarian cancer is not the same for all *BRCA2* mutations. Mutations in the central part of the gene, the OCCR, seem to confer a higher lifetime risk.

### Clinical Implications for *BRCA1*/*BRCA2* Mutation Carriers

The identification of *BRCA1*/*BRCA2* mutation carriers has important clinical implications that pertain to risk reduction interventions and characteristic features of *BRCA*-associated cancers. Several studies have by now confirmed the effect of prophylactic salpingo-oophorectomy to reduce the incidence of ovarian and breast cancer in women with *BRCA1* and *BRCA2* mutations.<sup>11</sup> In one of the largest trials to date, 551 women carrying mutations in the *BRCA1* or *BRCA2* gene underwent either surveillance or bilateral prophylactic oophorectomy. The incidence of ovarian cancer in the surveillance group was 19.9% after 9 years' follow-up. In the group who underwent bilateral prophylactic oophorectomy, early-stage ovarian cancer was identified at the time of surgery in 2.3% of women and primary peritoneal cancer developed in two other patients (0.8%). This data shows a significant risk reduction with prophylactic surgery. Interestingly, the incidence of breast cancer in these predisposed individuals was also shown to be significantly reduced, from 42.3% in the surveillance group to 21.2% in the prophylactic oophorectomy group, likely due to a deprivation of ovarian hormone stimulation to the breast tissue.

Ovarian cancers that develop on a *BRCA1*/*BRCA2* mutation background are usually serous papillary carcinomas, although endometrioid and clear cell carcinomas have also been described. Borderline ovarian carcinomas rarely harbor mutations in either gene. Compared to sporadic ovarian cancers, *BRCA1*/*BRCA2*-associated ovarian cancers seem to be more sensitive to chemotherapeutic agents, particularly DNA damage-inducing agents. Carboplatin, for example, induces double-stranded DNA breaks. Cancer cells that lack the correct function of *BRCA* proteins cannot efficiently repair these DNA breaks and are therefore

more sensitive to DNA damage. Several studies have shown an improved survival of patients with *BRCA1*-associated ovarian cancers compared to sporadic controls.<sup>12</sup> However, other studies have found no difference in survival.

### Genetics of Hereditary Endometrial Cancer

Approximately 5% to 10% of endometrial cancers are believed to be hereditary. The most important familial syndrome with a genetic predisposition for endometrial cancer is the hereditary nonpolyposis colorectal cancer (HNPCC) syndrome.<sup>13</sup> HNPCC, also known as Lynch II syndrome, is the most commonly occurring hereditary syndrome that predisposes to colorectal carcinoma. It accounts for approximately 2% to 7% of colorectal carcinoma diagnosed in the United States annually.<sup>14</sup>

Various extracolonic malignancies have been described in HNPCC families. Table 51-5 compares the incidence of HNPCC-associated cancers with the incidence of sporadic cancers. Individuals diagnosed with HNPCC have an up to 80% lifetime risk of colorectal cancer, a risk to develop endometrial cancer of about 60%, and a 12% lifetime risk of ovarian cancer. Another hallmark of HNPCC-affected individuals is the high incidence of second primary tumors. The most pronounced difference between endometrial cancer with genetic predisposition based on human mismatch repair gene mutations and sporadic cancer is the early age of onset in hereditary disease. The mean age of onset of endometrial cancer is about age 45 in women with HNPCC and age 68 for women with sporadic endometrial cancer.

HNPCC is caused by germline mutations of human mismatch repair genes like *MLH1*, *MSH2*, *MSH3*, *MSH6*, and *PMS2*.<sup>15</sup> The primary function of the mismatch repair genes is to eliminate base mismatches and insertion deletion loops that may arise during DNA replication. Repair of single base mismatches and insertion deletion loops requires at least six different mismatch repair proteins. For mismatched base recognition, the *MSH2* protein forms a heterodimer with either *MSH6* or *MSH3*. The proteins *MLH1* and *PMS2* form a heterodimer that coordinates the interplay between the mismatched recognition complex and other proteins necessary for mismatch repair.

**Table 51-5**  
**Cancer Risk for *MLH1* and *MSH2* Mutation Carriers**

Site	Population Risk	Hereditary Risk
Colon	Risk of colon cancer 0.25% by age 50 2.0% by age 70	Risk of colon cancer >25% by age 50 80% by age 70
	Risk of second cancer 3% within 10 yrs 5% within 15 yrs	Risk of second cancer 30% within 10 yrs 50% within 15 yrs
Endometrium	0.2% by age 50 1.5% by age 70	20% by age 50 61% by age 70
Stomach	1% by age 70	13% by age 70
Ovary	1.2% by age 70	12% by age 70
Urinary tract	<1% by age 70	4% by age 70
Biliary tract	<1% by age 70	2% by age 70
Small intestine	<1% by age 70	5% by age 70

Loss of DNA mismatch repair in cells leads to an accumulation of replication errors and genetic instability at short tandem repeat sequences known as *microsatellites*. This molecular phenotype, called *microsatellite instability*, is found in the majority of HNPCC-associated cancers and is a hallmark of DNA mismatch repair. Microsatellite instability has been demonstrated in 30% to 75% of endometrial and up to 100% of ovarian cancers from members of HNPCC families. In contrast, microsatellite instability is found in only 10% to 17% of sporadic ovarian cancers and 17% to 32% of sporadic endometrial cancers.<sup>16</sup> The decreased genomic stability in the absence of a correctly functioning mismatch repair system results in an elevated rate of mutations throughout the genome, including defects in tumor suppressor genes and inactivation of genes involved in DNA double-strand break repair. These mutations ultimately lead to the malignant phenotype. Germline mutations in one of the four major HNPCC-associated mismatch repair genes—*MLH1*, *MSH2*, *MSH6*, and *PMS2*—are detected in up to 80% of affected families. More than 400 different predisposing mismatch repair gene mutations are known, with 50% affecting *MLH1*, 40% *MSH2*, and 10% *MSH6*. Mutations in *PMS2* account for less than 5%.

#### **Genetic Screening for Hereditary Nonpolyposis Colorectal Cancer**

HNPCC is one of the most common cancer syndromes in humans. Cancers are usually diagnosed at an early age and transmitted as an autosomal dominant trait. The international diagnostic criteria for HNPCC are known as Amsterdam I criteria (based on colorectal cancer) and Amsterdam II criteria (based on extracolonic cancers from the endometrium, small bowel, ureter, and renal pelvis). The majority of families that fulfill the clinical criteria also meet the molecular definition of the syndrome, which requires the demonstration of a heritable defect in mismatch repair genes. Molecular identification involves testing for microsatellite instability and sequencing of mismatch repair genes.

Current recommendations for women with HNPCC involve annual screening with endometrial biopsies, transvaginal ultrasound, and CA 125.<sup>17</sup> Prophylactic hysterectomy should be considered after completion of childbearing. In addition, initiation of annual full colonoscopy is recommended between ages 20 and 25. Ongoing trials are investigating the effects of oral contra-

ceptives and progestins on the prevention of endometrial cancer in HNPCC women. Correction of the genetic defects in HNPCC families is a long-term goal that will require the development of efficient stem cell gene therapeutic approaches.

The following is the Amsterdam II Criteria for the identification of HNPCC families:

- Three or more relatives with HNPCC-associated cancers, including colorectal cancer or cancer of the endometrium, small bowel, ureter, or renal pelvis, plus all of the following
- One affected person is a first-degree relative of the other two
- Two or more successive generations are affected
- Cancer in one or more affected relatives diagnosed before age 50
- Exclusion of familial adenomatous polyposis in any cases of colorectal cancer
- Tumors verified by pathologic examination

#### **TUMOR ONCOGENES**

Oncogenes encode proteins that are able to transform cells in cultures or induce cancer in animals. The word stems from the Greek work *onkos*, meaning a bulk or mass. Most oncogenes derive from genes whose products play a role in normal cell growth. Oncoproteins are either mutant forms or the same as the associated proto-oncogene product. A variety of oncogenes have been found to play a role in gynecologic malignancies (Table 51-6).

#### **K-RAS**

The *RAS* genes acquire transforming activity either by enhanced expression or by a single point mutation. The predominant single base pair mutation site in ovarian tumors is found at codons 12 and 13. Mucinous ovarian neoplasms exhibit a higher incidence of *K-ras* mutations compared to the serous tumors.<sup>18</sup> *K-ras* codon 12 and 13 point mutations are found in up to 70% of mucinous ovarian neoplasms, including borderline tumors. In contrast, only about 10% of serous ovarian tumors harbor *K-ras* mutations. *K-ras* activation also plays a role in endometrial cancer, because expression of *K-ras* is found in endometrial hyperplasia and in invasive endometrial cancer. Mutations are found in 10% to 30% of endometrial cancer specimens and are associated with

**Table 51-6**  
**Tumor Oncogenes in Gynecologic Malignancies**

Gene	Protein	Function	Activation
<i>K-ras</i>	G protein	Activation of signal transduction proteins	Mutation, overexpression
<i>Akt</i>	Protein kinase	Phosphorylation and activation of various proteins that promote cell survival and decrease apoptosis	Amplification
<i>PIK3CA</i>	Phosphoinositide 3 kinase	Phosphorylation of membrane-bound lipids	Amplification
<i>c-myc (MYC)</i>	Transcription factor	Transcriptional activation of genes that promote cell proliferation, regulation of apoptosis	Overexpression
<i>HER-2/neu</i>	Transmembrane tyrosine kinase	Activation of signal transduction pathways involved in regulation of cellular proliferation, differentiation, and survival	Amplification, overexpression

## Gynecologic Oncology

the presence of lymph node metastasis. In cervical cancer, mucin-producing tumors have a greater incidence of *K-ras* mutations compared to nonmucin-secreting tumors.

### **PIK3CA**

Activation of the phosphatidylinositol 3-kinase (PI3-kinase) pathway either via down-regulation of *PTEN* expression or increased PI3-kinase activity plays an important role in certain subtypes of ovarian cancer. The *PIK3CA* gene encodes for the p110 $\alpha$  subunit of PI3-kinase and is found at increased copy numbers in ovarian cancer specimens. *PIK3CA* functions as an oncogene, increasing the expression of PI3-kinase and subsequently the activation of Akt.<sup>19</sup> Activation of Akt is found in about one third of ovarian cancer specimens, with highest frequency in serous adenocarcinomas.

### **HER2/Neu**

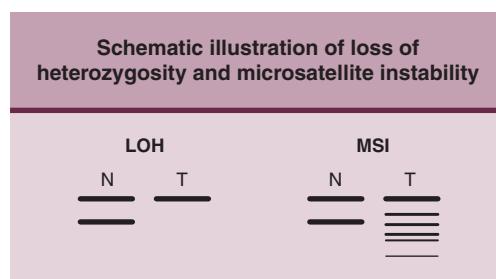

The *HER2/Neu* proto-oncogene, also known as *ERBB2* and *HER2*, is located on the long arm of chromosome 17 and encodes a 185 kDa transmembrane glycoprotein with intrinsic tyrosine kinase activity. It belongs to a family of transmembrane receptor genes that includes the epidermal growth factor receptor (*ERBB1*), *ERBB3*, and *ERBB4*. *HER2/Neu* has complex activation pathways and interacts with a variety of different cellular proteins that in general increase cell proliferation. Overexpression of *HER2/Neu* has been demonstrated in about 30% of breast cancers, 20% of advanced ovarian cancers, and up to 50% of endometrial cancers.<sup>20</sup> High tissue expression of *HER2/Neu* is correlated with a decreased overall survival, particularly in patients with endometrial cancer. Monoclonal antibodies against *HER2/Neu* can decrease growth of breast and ovarian cancer cells and have shown significant antitumor responses in breast cancer patients.

### **c-myc**

The *c-myc* (*MYC*) oncogene plays an important role in the malignant transformation of a variety of tumors, including breast, colon, and small cell lung cancers and lymphoma. The *MYC* gene encodes a transcription factor that in general activates genes that are involved in growth, protein synthesis, and mitochondrial function. Amplification and overexpression of the *MYC* gene is associated with poor prognosis and decreased survival. In ovarian cancer, amplification of the *MYC* gene is found in about 50% of cancers, particularly in advanced stages.<sup>21</sup> *MYC* is also implicated in the pathogenesis of cervical cancer.

## TUMOR SUPPRESSOR GENES

Tumor suppressor genes oppose the action of oncogenes via different pathways. In general, tumor suppressor activity is a result of inhibition of cell-cycle progression, stimulation of apoptosis, or promotion of senescence. Tumor suppressor genes are recessive and require biallelic inactivation for loss of function. They are frequently found to be inactivated in cancers and play a causal role in the initiation and progression of cancer. The reconstitution of tumor suppressor gene function in a cancer cell can reverse the malignant phenotype and induce growth arrest and cell death. Transgenic mouse models have provided insight

**Figure 51-2 Schematic illustration of loss of heterozygosity (LOH) and microsatellite instability (MSI).** DNA from tumor tissue (T) and normal tissue (N) can be analyzed using specific allelic markers. Separation of the DNA using gel electrophoresis will produce a specific band pattern for LOH and MSI. LOH is evident in DNA from tumor tissue compared to normal control tissue as lack of one of the allelic bands. In MSI, additional allelic bands are visible in the tumor tissue.

into critical pathways affected by tumor suppressor genes. For example, abrogation of *TP53* expression in *p53* knockout mice results in the development of various tumors by age 4 to 6 months. This model is similar to the human Li-Fraumeni syndrome.

A hallmark signature of tumor suppressor genes is an event known as *loss of heterozygosity* (LOH). LOH might be defined as a genetic event that can occur in the dividing cells of a diploid organism heterozygous for one or more markers, in which a daughter cell becomes homozygous or hemizygous for one or more alleles through mitotic recombination, deletion, or gene conversion. In the case of tumor suppressor genes, a cell heterozygous for one mutant and one normal allele loses heterozygosity if either the mutant or the normal allele is deleted. If the normal allele is lost, the correct function of the tumor suppressor activity for this gene is abrogated. Screening for LOH in tumor specimens using markers for specific DNA sequences is a common technique used to identify novel tumor suppressor gene (Fig. 51-2).

Tumor suppressor genes play a significant role in gynecologic malignancies. The most common genes, their proteins, and associated functions are summarized in Table 51-7. The

**Table 51-7**  
**Tumor Suppressor Genes in Gynecologic Malignancies**

Gene	Protein	Function
<i>TP53</i>	Nuclear protein p53	Transcription factor, involved in various cellular processes, including apoptosis, DNA damage response, angiogenesis
<i>PTEN</i>	Dual specificity phosphatase	Dephosphorylation of both lipids and proteins, down-regulation of the PI3-kinase/Akt pathway with negative effect on cell growth
<i>P16INK4a</i> ( <i>CDKN2A</i> )	P16	Binds to cyclin-CDK4 complex inhibiting cell-cycle progression
<i>FHIT</i>	Fragile histidine triad gene	Tumor suppressor function via unknown mechanisms

importance of individual tumor suppressor genes in gynecologic cancers depends on the tissue of origin and its histology. For example, the *TP53* tumor suppressor gene plays a significant role in a large percentage of ovarian cancers, but only a few endometrial cancers harbor *TP53* mutations. In contrast, *PTEN* is found to be mutated in a high percentage of endometrioid adenocarcinomas of the uterus, but does not play a significant role in uterine papillary serous cancers or most other epithelial ovarian cancers. The *FHIT* gene is a frequent integration site for the human papillomavirus (HPV) and is of considerable importance in cervical cancers but is not likely to be a major factor in endometrial and ovarian cancer.

### TP53

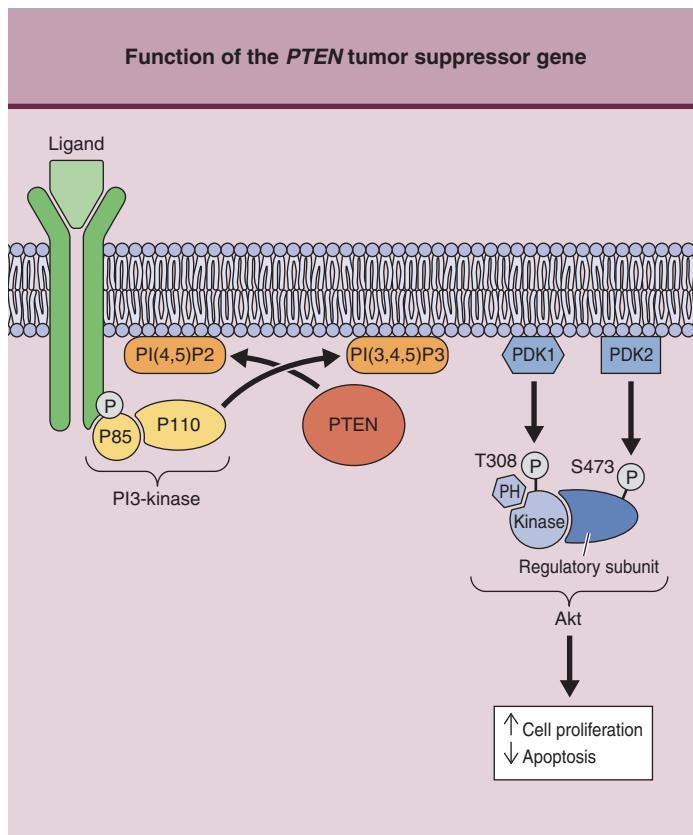

The *TP53* tumor suppressor gene is located on chromosome 17p13.1 and encodes for a phosphoprotein that is generally detectable in the nucleus of normal cells. On DNA damage, *p53* can arrest cell-cycle progression to allow the DNA to be repaired or undergo apoptosis. The lack of function of normal *p53* within a cancer cell results in a loss of control of cell proliferation, with inefficient DNA repair and genetic instability.

Mutations of the *TP53* gene occur in 40% to 80% of epithelial ovarian cancers, but these mutations are not present in borderline malignancy, benign tumors, or normal surface epithelium.<sup>22</sup> Mutant *TP53* functions as a dominant negative oncogene because introduction of mutant *TP53* into cancer cells can lead to transformation into a more aggressive phenotype. *TP53* overexpression is seen in approximately 4% to 17% of borderline tumors, 10% to 15% of early cancers, and 40% to 60% of advanced cancers. Overexpression of mutant *TP53* is significantly higher in advanced stages of ovarian cancer (40% to 60%) relative to expression of *TP53* in early stages (10% to 20%), suggesting that this is a late event in ovarian carcinogenesis.<sup>23</sup> Furthermore, mutant *TP53* overexpression has been associated with worse survival, poor histologic grade and differentiation, and a high proliferative fraction. One explanation for the poorer survival is possibly the chemoresistant phenotype in *TP53* mutated tumors.

### PTEN

The *PTEN* (phosphatase and tensin homolog deleted on chromosome 10) gene is a tumor suppressor gene that is located on chromosome 10q23 and encodes a dual-specificity phosphatase for both lipid and protein substrates. Germline mutations have been identified in patients with Cowden syndrome and Bannayan-Zonana syndrome, two rare, autosomal dominant familial cancer syndromes with multiple abnormalities, including hamartomas and breast cancer.<sup>24</sup> Somatic mutations of *PTEN* have been found in glioblastomas, melanomas, and prostate, endometrium, and ovarian cancer.

The *PTEN* protein is an important factor in the PI3-kinase pathway, an important pathway that promotes the proliferation of cancer cells in vitro and in vivo<sup>25</sup> (Fig. 51-3). Activation of PI3-kinase by various ligands such as PDGF and IGF results in an increase of intracellular, membrane-bound phosphatidylinositol-3,4-diphosphate ( $\text{PIP}_2$ ) and phosphatidylinositol-3,4,5-triphosphate ( $\text{PIP}_3$ ). Akt is recruited to the membrane-bound  $\text{PIP}_3$  with its N-terminal Pleckstrin homology domain and is phosphorylated by  $\text{PIP}_3$ -dependent kinase 1 (PDK-1) at threonine 308 (T308) and PDK-2 kinase at serine 473 (S473) for full activation. Activated Akt is released from the membrane and elicits downstream effects by phosphorylating signal-transduction proteins. *PTEN* acts as a dual-specificity phosphatase that can dephosphorylate proteins and phospholipids. In the PI3K/Akt pathway, *PTEN* dephosphorylates  $\text{PIP}_2$  and  $\text{PIP}_3$  and, therefore, counteracts the function of PI3K.

**Figure 51-3 Function of the *PTEN* tumor suppressor gene.** Activation of PI3-kinase by various ligands, such as platelet-derived growth factor or insulin growth factor, results in an increase of intracellular, membrane-bound phosphatidylinositol-(3,4)-diphosphate ( $\text{PIP}_2$ ) and phosphatidylinositol-(3,4,5)-triphosphate ( $\text{PIP}_3$ ). Akt is recruited to the membrane bound  $\text{PIP}_3$  with its N-terminal Pleckstrin homology (PH) domain and is phosphorylated by  $\text{PIP}_3$ -dependent kinase 1 (PDK-1) at threonine 308 (T308) and PDK-2 kinase at serine 473 (S473) for full activation. Activated Akt is released from the membrane and elicits downstream effects by phosphorylating signal-transduction proteins. *PTEN* acts as a dual-specificity phosphatase that can dephosphorylate proteins and phospholipids. In the PI3K/Akt pathway, *PTEN* dephosphorylates  $\text{PIP}_2$  and  $\text{PIP}_3$  and, therefore, counteracts the function of PI3K.

threonine 308 (T308) and PDK-2 kinase at serine 473 (S473) for full activation. Activated Akt is released from the membrane and elicits downstream effects by phosphorylating signal transduction proteins. These effects lead to an increase in cell proliferation, prevention of apoptosis, invasiveness, drug resistance, and neoangiogenesis.<sup>26</sup> *PTEN* acts as a dual-specificity phosphatase that can dephosphorylate proteins and phospholipids. In the PI3K/Akt pathway, *PTEN* dephosphorylates  $\text{PIP}_2$  and  $\text{PIP}_3$  and therefore counteracts the function of PI3K.

Mutations of the *PTEN* gene have been identified as the most frequently mutated tumor suppressor pathway in endometrial cancer. Among the endometrioid histologic subtype of endometrial cancer, up to 50% contain mutations of *PTEN*. *PTEN* mutations are also found in about 20% of endometrial cancer precursors such as complex atypical hyperplasia, suggesting that *PTEN* plays a role in early pathogenesis of these tumors. In

ovarian cancer, mutations of *PTEN* have been described in about 7% to 21%, with a higher frequency in the endometrioid subtype.<sup>27</sup> Other studies in human ovarian cancer specimens have shown frequent loss of *PTEN* protein expression.

### TGF- $\beta$ Receptor 2

The transforming growth factor- $\beta$  receptor 2 (*TGF- $\beta$ R2*) tumor suppressor gene is part of the TGF- $\beta$  growth inhibitory pathway. Mutations in the *TGF- $\beta$ R2* genes cause loss of growth inhibition and enhance tumorigenicity in epithelial tumor cells. Mutations are found in about 25% of ovarian cancer cases and are more frequent in endometrioid carcinomas than other histologic subtypes.<sup>28</sup>

### FHIT

The fragile histidine triad (*FHIT*) gene is located on chromosome 3p14.2, the most common active fragile site of the human genome.<sup>29</sup> *FHIT* is a common target of chromosomal aberrations and a frequent HPV integration site involving the long arm of chromosome 3. It has been found to be inactivated in about 60% of all malignancies, including cancers of the lung, stomach, breast, and kidney. The *FHIT* protein functions as a tumor suppressor gene. Reconstitution of *FHIT* expression in *FHIT*-negative tumor cells suppresses the tumorigenicity of these cells and induces apoptosis. The exact mechanism of tumor suppression is still under investigation.

Alterations in the *FHIT* gene are found in various precursor lesions, including early cervical lesions. About 20% to 50% of high-grade squamous epithelial lesions show loss of *FHIT* function, suggesting an important role for *FHIT* in cervical carcinogenesis. An important mechanism that might explain the loss of *FHIT* function in cervical epithelium is related to the frequent infection with HPV. HPV can insert its genome into the chromosome 3 fragile site FRA3B and delete DNA sequences, including the *FHIT* gene.

### P16

The *p16INK4a* (*CDKN2A*) gene encodes for the p16 protein, which functions as a negative cell-cycle regulator. P16 binds to the cyclin-dependent kinase CDK4, inhibiting the catalytic activity of the CDK4–cyclin D complex. Mutations in the *p16INK4A* gene are rare in gynecologic cancers. The lack of p16 protein expression is, however, found in 20% to 70% of ovarian and endometrial cancers and is mostly a consequence of hypermethylation. In endometrial cancer, the loss of p16 protein expression has been associated with a higher proliferative index and poorer survival.<sup>30</sup>

## Section 8 Reproductive Endocrinology and Infertility

### Chapter 52

# Female Infertility and the Evaluation of the Infertile Couple

Ertug Kovanci, MD, and Sandra A. Carson, MD

The desire to produce an offspring is a basic human instinct that facilitates the continuity of our species. However, people have suffered from infertility for as long as the human species has existed. Social, medical, and economic aspects of infertility have evolved throughout history as the condition has gone from being considered a source for disgrace, as in the case of Rachel in the Book of Genesis, to merely another medical condition. Advances in medicine and science have revolutionized the diagnosis and treatment of infertility and allowed couples who could not have reproduced two decades ago an opportunity to be parents. However, infertility treatments do have limitations and potential undesired effects that couples should understand before undertaking treatment.

#### EPIDEMIOLOGY, RISK FACTORS, AND PATHOGENESIS

Although infertility does not pose a serious public health risk, it has significant psychological and economic consequences at both personal and societal levels. Therefore, U.S. public health organizations perform infertility data surveillance to improve prevention and treatment. Standard fertility terminology is utilized by these organizations and other investigators to classify infertility, follow its prevalence, and determine treatment efficacy (Table 52-1).

The number of women who require infertility services has been increasing over the past decade. In the United States, the proportion of women between ages 15 and 44 who received any kind of infertility service was approximately 15% of all women, about 9 million, in 1995 compared to 12% in 1988. Of those, 1% underwent advanced fertility treatments. About 7% of married couples, 2.1 million, reported that they were infertile in 1995.<sup>1</sup>

Fertility rates in the United States have also been declining since 1980 and reached the lowest rate, 64.8 births per 1000 women aged 15 to 44, in 2002.<sup>2</sup> The birth rate for women ages 35 to 39 has been increasing over the past three decades and peaked at 41.4 births per 1000 women in 2002, despite the overall U.S. birth rate reaching its lowest point ever—13.9 births per 1000 total population—during that year. At the same point, women aged 40 to 44 had the highest birth rate in three decades, 8.3 births per 1000 women. Postponement of marriage, delayed childbearing, increased use of birth control, availability of new infertility treatments, and increased media attention to treatments have contributed to the infertility epidemic. The

U.S. Department of Health and Human Services' objective is to reduce impaired fecundity to 10% by the year 2010.<sup>3</sup>

The *fecundability rate* (i.e., the probability of becoming pregnant in one menstrual cycle) is about 20% to 25% in normal couples. Mathematically, 25% of normal couples are expected to get pregnant in one cycle. Of women who did not get pregnant (75% of the initial group), 25% will get pregnant in the following cycle. Therefore, 43.75% of the initial couples will conceive after 2 months. In the third cycle, 25% of the remaining women (56.25% of the initial group) who did not get pregnant in the first two cycles will get pregnant. Cumulative pregnancy rate after 3 months will be approximately 58%, and 98% of the couples should be expected to conceive in 13 cycles. However, fecundability rate declines in normal populations after the first 2 to 3 months. This is likely due to the heterogeneity of the initial population. The couples with high fecundability rates conceive rapidly, leaving the couples with low fecundability rates, thus decreasing the fecundability rate for the remainder of the population.

Multiple systems work in harmony to achieve an optimal fecundability rate. Close interaction among the ovary, pituitary, and hypothalamus is necessary to develop a mature oocyte. This interaction encompasses ovarian negative and positive feedback actions on the pituitary, as well as the pituitary response to these feedbacks. Initially decreased estradiol levels after menses stimulate follicle-stimulating hormone (FSH) secretion, which induces follicular growth. When one of the follicles reaches maturation, the ovary signals the pituitary to secrete increased amounts of luteinizing hormone (LH), establishing the LH surge and triggering ovulation. Thus, the “ovarian clock” enables selection of the mature oocyte. Following ovulation, the fallopian tube picks up the released mature oocyte to introduce it to the waiting sperm, which have traveled through the cervical mucus, uterus, and fallopian tube after deposition in the vagina. The sperm should also be produced in sufficient quality and quantity by the male gonad. After fertilization of the oocyte, the resulting embryo is propelled to the uterus. The endometrium, prepared by the sequential cascade of ovarian hormones, allows implantation and embryo growth. Potential problems at any level of this complex process may impair fertility.

#### Cervical Factor Infertility

The cervix plays a number of roles in human fertility. Cervical mucus enhances the transport of sperm from the vagina to the uterus during the ovulation window by forming parallel channels

**Table 52-1**  
**Standard Fertility Terminology**

Fertility rate	The ratio of livebirths in an area to the number of women aged 15 to 44; expressed per 1000 population per year
Birth rate	The ratio of live births in an area to the population of that area; expressed per 1000 population per year
Fecundability	The probability of achieving a pregnancy in one menstrual cycle
Fecundity	The capacity for bringing forth young; fertility
Cumulative pregnancy rate	The probability of becoming pregnant within a given time, e.g., over 1 year

of micelles. It facilitates sperm capacitation and serves as a reservoir for normal sperm. Developmental anomalies, trauma, and cervical procedures such as cone biopsy may impair mucus production or may cause cervical stenosis. The resultant hostile environment for sperm may block sperm transport to the upper genital tract altogether. However, diagnosis and treatment of cervical factor remains controversial.

### Uterine Factor Infertility

Sperm is transported toward the oocyte faster than can be accounted for by its motility alone. Uterine and tubal peristalsis/contractility is responsible for this rapid transport of the sperm to the upper genital tract. The uterus is also the site for the implantation of the embryo. Therefore, a normal uterine cavity is important for fertility. Uterine fibroids, depending on their location and size, may distort the uterine cavity and may impair implantation or cause pregnancy wastage. Submucosal fibroids and intramural fibroids measuring greater than 7 cm in diameter have been associated with infertility and pregnancy loss.

It is not surprising that fibroids distorting the uterine cavity decrease pregnancy rates in women undergoing in vitro fertilization (IVF).<sup>4-7</sup> Pregnancy rates in women with fibroids compared to women with no fibroids were 30% versus 41%, respectively, but the odds ratio (OR) was 0.73 (95% CI, 0.49 to 1.19,  $p = 0.2$ ) after controlling for age and other risk factors.<sup>7</sup> However, even fibroids in the presence of a normal cavity reduced success rates in IVF.<sup>8-10</sup> Hart and colleagues, in a prospective study, found that intramural fibroids with no distortion of the uterine cavity reduced ongoing pregnancy rates from 28% to 15% compared to controls (OR, 0.46; 95% CI, 0.24 to 0.88,  $p = 0.02$ ).<sup>8</sup> In contrast, Jun and colleagues, in their retrospective study, showed that fibroids smaller than 7 cm in diameter with a normal uterine cavity do not decrease pregnancy rates in women undergoing IVF. Therefore, the effect of subserosal and small intramural fibroids on fertility is controversial, although submucosal and large intramural fibroids distorting the cavity are clearly associated with decreased fertility.

Developmental anomalies of the reproductive tract, such as a septate uterus, bicornuate uterus, and didelphic uterus, also appear to be associated with delayed spontaneous conception

and are correlated with poor pregnancy outcome, including pregnancy loss and preterm delivery.<sup>11</sup> Müllerian duct aplasia syndromes result in infertility because oocyte and sperm proximity cannot be attained and a uterus is not present.

### Tubal Factor Infertility

The fallopian tubes are essential for transport of the oocyte, sperm, and embryo. Damaged tubes preclude the marriage of oocytes and sperm. Pelvic inflammatory disease (PID), adhesions from previous tubal or pelvic surgery, endometriosis, ruptured appendix, and septic abortion are risk factors for tubal disease. After three PID episodes, the rate of infertility has been estimated to exceed 50%.<sup>12</sup> Silent chlamydia infections are also strongly correlated with tubal damage. Up to 86% of women with tubal infertility have been reported to have serum IgG antibodies against *Chlamydia trachomatis*, which is significantly higher than the percentage of fertile women with the same type of antibodies.<sup>13</sup>

Previous abdominal surgery is a strong risk factor for pelvic adhesions. Approximately 23% of women who had undergone abdominal surgery were found to have significant pelvic adhesions during laparoscopic sterilization, compared to 2.7% of controls.<sup>14</sup> Adhesion formation can occur in up to 60% of women after tubal surgery for infertility.<sup>15</sup> Also, tubal polyps and intratubal debris or mucus plug may cause transient tubal occlusion. The incidence of tubal polyps is approximately 3% to 11%.<sup>16,17</sup> Salpingitis isthmica nodosa is characterized by bilateral diverticula of the tubal epithelium in the isthmic region. It is associated with pelvic infections and tuberculosis leading to mucosal damage and may involve the muscular layer, leading to occlusion of the tubal lumen.

### Endometriosis

Endometriosis is the presence of endometrial tissue outside the uterus. The most common sites for endometriosis are peritoneal surfaces covering the posterior cul-de-sac, uterosacral ligaments, pelvic side walls, bladder, and uterus. Tubes and ovaries are also frequently involved. The American Society for Reproductive Medicine (ASRM) has developed a staging system to determine the degree of endometriosis. This system divides the disease into four stages. Stages III and IV reflect the most severe cases, with extensive pelvic adhesions and anatomic distortion of the pelvic structures, including tubes and ovaries. A cause and effect relationship is clear in women with Stages III or IV endometriosis, when anatomical distortion interferes with oocyte release from the ovary, tubal pickup of the oocyte, and sperm transport to the proximity of the oocyte. However, the relationship with infertility is less clear in Stages I and II (minimal to mild) endometriosis, when such distortion is absent. Therefore, functional abnormalities have been suggested.

The proposed mechanisms of impaired infertility in the presence of mild to moderate endometriosis include changes in the contents of the peritoneal fluid that may interfere with sperm function, fertilization, and tubal function. Decreased oocyte quality and impaired implantation have also been implicated in the reduced fertility that may be associated with minimal to mild endometriosis.<sup>18,19</sup> Some investigators have suggested that impaired endometrial receptivity may be responsible for the decreased implantation rates.<sup>20</sup> However,

## Female Infertility and the Evaluation of the Infertile Couple

when donor oocytes are used in patients with and without endometriosis, pregnancy rates have been found to be similar.<sup>21</sup> Women with endometriosis also have a similar response to gonadotropins compared to women without the disease.<sup>22,23</sup> Numerous studies reported that peritoneal fluid activated macrophage concentrations and that their secretory products, including interleukin-1, tumor necrosis factor, and proteases, are elevated in endometriosis.

Impaired sperm function due to the detrimental effects of peritoneal fluid from women with endometriosis has also been postulated. However, multiple studies in the literature reporting on sperm motility after culture with peritoneal fluid from endometriosis patients have conflicting results. In their well-designed study, Stone and Himsl showed that peritoneal recovery of motile sperm did not change in the presence of endometriosis compared to controls.<sup>24</sup> A detrimental effect of peritoneal fluid on embryo development, so-called *embryotoxicity*, has also been suggested. However, when donor oocytes are used, attainment of similar pregnancy rates in women with endometriosis compared to controls appears to oppose the embryotoxicity hypothesis.<sup>25</sup> Even though mild endometriosis is more commonly encountered in patients with infertility compared to controls<sup>26</sup> and the probability of pregnancy is lower in women with minimal to mild endometriosis compared to women with unexplained infertility,<sup>27</sup> improved pregnancy rates after medical or surgical treatment of minimal to mild endometriosis have been reported in only one multicenter study.<sup>28</sup> Therefore, the association between infertility and minimal or mild endometriosis remains controversial.

### Ovarian Factor Infertility

Anovulation is the most common etiologic factor in infertility. Various conditions may lead to anovulation which can be divided into three groups: hypogonadotropic, eugonadotropic, and hypergonadotropic anovulation. The most common type is eugonadotropic anovulation, which includes polycystic ovary syndrome (PCOS). PCOS, defined as oligomenorrhea and hyperandrogenism, accounts for approximately 75% of anovulatory infertility.<sup>29</sup> Although tonic levels of LH and inadequate FSH secretion lead to follicular maturation arrest, LH and FSH levels remain within the normal range. PCOS is discussed in detail in Chapter 61.

Other causes of anovulation include hypothalamic dysfunction, pituitary disease, premature ovarian failure, and endocrine disorders. Hypothalamic anovulation is caused by impaired pulsatile gonadotropin-releasing hormone (GnRH) secretion. This, in turn, results in decreased LH and FSH secretion. Without cyclic gonadotropin production, the ovarian follicles do not mature the oocyte and anovulation occurs. Extreme weight loss, vigorous exercise, and emotional stress may induce hypothalamic anovulation. Infiltrating diseases such as histiocytosis X and sarcoidosis or tumors localized in the hypothalamic-pituitary region may rarely lead to hypothalamic anovulation. *Functional hypothalamic anovulation* is defined as the cessation of ovulation with no identifiable organic causes. Insufficient caloric intake induced by diet or exercise, eating disorders, and emotional stress caused by performance pressure and dysfunctional attitudes may act synergistically to disrupt pulsatile GnRH secretion, causing functional hypothalamic amenorrhea.<sup>30</sup>

Kallmann syndrome, an inherited disorder with X-linked, autosomal dominant, and autosomal recessive variants, is characterized by isolated GnRH deficiency induced by impaired migration of GnRH neurons from the olfactory placode to the basal hypothalamus during embryonic development. Both genders can be involved. Patients with Kallmann syndrome present with absent or incomplete puberty and show irregular or low GnRH pulse amplitude and frequency. Kallmann syndrome is often associated with anosmia or hyposmia and midline defects such as cleft palate.

Elevated serum prolactin (PRL) levels inhibit pituitary LH and FSH secretion, thus causing anovulation. Pituitary PRL secretion is controlled by the tonic inhibitory effects of dopamine. Any central nervous system lesion or drug that impairs dopamine secretion may cause elevated PRL levels. However, hyperprolactinemia is most commonly induced by PRL-producing pituitary tumors, or prolactinomas. The majority of these tumors are microadenomas (i.e., <10 mm in diameter). Elevated PRL levels inhibit pulsatile secretion of GnRH and cause hypogonadotropic anovulation. Hypothalamic dopamine and opioid dysfunction may play a role in the inhibition of GnRH secretion. Other tumors of the pituitary, pituitary stalk transection, empty sella syndrome, and drugs such as antipsychotics (phenothiazines, butyrophenones) and centrally acting antihypertensives (reserpine, methyldopa) may induce hyperprolactinemia.

Sheehan's syndrome is characterized by hypopituitarism due to pituitary necrosis following severe postpartum hemorrhage. The degree of Sheehan's syndrome ranges from partial hypopituitarism involving only growth hormone and/or gonadotropin deficiency to panhypopituitarism with lack of all pituitary hormones. Hypogonadotropic anovulation is frequently present. This condition can be life-threatening and may require replacement of multiple hormones.

*Premature ovarian failure* is defined as the irreversible cessation of ovulation and menses before age 40. The prevalence of premature ovarian failure is approximately 1%. Genetic or autoimmune disorders may result in the loss of ovarian follicles and premature ovarian failure. Fragile X syndrome and 45,X (Turner's syndrome) are the most commonly identified genetic abnormalities that may cause premature ovarian failure. When autoimmunity is the underlying factor, premature ovarian failure is frequently associated with other autoimmune disorders including hypothyroidism, insulin-dependent diabetes mellitus (IDDM), adrenal insufficiency, pernicious anemia, and hypoparathyroidism. The most common autoimmune disorder occurring in women with premature ovarian failure is hypothyroidism. However, no underlying factor can be identified in many premature ovarian failure patients.

### Age

Today, many women delay parenthood until their fourth and fifth decades of life, and age-related fertility decline in women is well-documented by multiple studies on natural populations.<sup>31</sup> This decline accelerates markedly after age 35. Women undergoing donor sperm insemination demonstrate marked fertility decline starting at age 35.<sup>32,33</sup> However, Dunson and colleagues reported that pregnancy probability starts decreasing after age 26.<sup>34</sup> Unfortunately, this study utilized arbitrary age groups, such as age 19 to 26, age 27 to 34, and age 35 to 39. Therefore,

## Reproductive Endocrinology and Infertility

it is difficult to interpret at exactly what age fertility begins to decline. Miscarriage rates also increase with maternal age. Baseline miscarriage rate is approximately 15% to 17%. This rate exceeds 30% by age 40 and 50% by age 45.<sup>35,36</sup>

Several mechanisms are involved in the detrimental effects of aging on fertility. The number of follicles significantly declines with age. This decline starts in utero and continues throughout reproductive life. The number of oogonia is approximately 6 to 7 million in the second trimester; during the third trimester this number declines, reaching approximately 2 million oogonia at birth. This attrition of germ cells continues after birth, resulting in only 300,000 oocytes at puberty. Oocyte exhaustion accelerates after age 35. The quality of oocytes is also impaired by age. Oocytes obtained from older women demonstrate higher rates of meiotic spindle and microtubular abnormalities compared to younger women, 47% versus 25%, respectively.<sup>37</sup> This may be one of the factors that cause the increased incidence of chromosomal aneuploidy in older women. Significantly lower pregnancy rates in older animals that received oocytes from younger animals suggest that impaired uterine receptivity might play a role in age-related infertility. Early IVF studies also demonstrated lower pregnancy rates in older women undergoing oocyte donation compared to younger women. However, a later study showed that older and younger patients had similar pregnancy rates when they received oocytes from the same donor,<sup>38</sup> which was confirmed by other studies. Intercourse frequency also declines with advancing age, which may contribute to the decreased fecundity in older couples.

### Endocrine Disorders and Infertility

Any endocrine disorder that affects the hypothalamic-pituitary-ovarian axis may cause anovulation and infertility.

The most common endocrine disorder that causes menstrual irregularity, anovulation, and infertility is thyroid disease. Both hypothyroidism and hyperthyroidism may lead to menstrual irregularity and infertility. Menstrual irregularity in thyroid disease ranges from amenorrhea to polymenorrhea.

The prevalence of hypothyroidism in reproductive age women is approximately 2% to 4%. Autoimmune thyroid disease is the most common etiologic factor. The frequency of menstrual irregularity in hypothyroidism ranges from 23% to 80%.<sup>39</sup> Overt hypothyroidism is usually associated with oligomenorrhea, and subclinical hypothyroidism generally causes menorrhagia, which may precede hypothyroidism symptoms. Infertility due to anovulation is more common in severe hypothyroidism than milder forms. Increased thyrotropin-releasing hormone (TRH) levels in long-standing primary hypothyroidism and decreased dopamine secretion in the hypothalamus may also stimulate PRL secretion, which can further contribute to anovulatory infertility in hypothyroidism. The prevalence of galactorrhea in women with hypothyroidism is 1% to 3%, which can be reversed with thyroid hormone replacement.

Menstrual irregularity in hyperthyroidism was first noted by von Basedow in 1840. The frequency of menstrual disturbances in hyperthyroidism ranges from 21% to 64%.<sup>39,40</sup> The most common menstrual abnormality is oligomenorrhea, followed by amenorrhea and polymenorrhea. Increased sex hormone-binding globulin production in hyperthyroidism leads to elevated estrogen and total testosterone levels in serum. LH and

FSH secretion is also increased, and midcycle LH peak is lost in hyperthyroidism, leading to anovulation. These changes in gonadotropin metabolism may be due to hypersensitivity of the pituitary to GnRH. The frequency of infertility in patients with hyperthyroidism is not well-established, although one study reported that approximately 6% of women with hyperthyroidism experienced infertility.<sup>40</sup>

The association between thyroid antibodies and infertility is controversial. Some investigators reported a higher incidence of thyroid antibodies in women with infertility compared to controls (17% vs. 8%, respectively),<sup>41</sup> but other investigators did not confirm this finding (19% vs. 15%, respectively).<sup>42</sup> Furthermore, the presence of thyroid antibodies does not affect pregnancy rates in infertile women undergoing assisted reproductive technology (ART) such as IVF.<sup>43</sup> Therefore, thyroid antibodies are unlikely to play a role in the pathogenesis of infertility.

Women with untreated IDDM may also suffer from hypogonadism, amenorrhea, and infertility. Insulin and gonadotropin metabolisms are closely intertwined. Numerous animal studies have shown that streptozotocin-induced diabetes leads to loss of LH surge and blunted LH response to GnRH. Insulin administration reverses this effect and lowers the frequency of reproductive problems. The effects of insulin appear to be central; intracerebroventricular insulin injection in rats with streptozotocin-induced diabetes is able to restore LH surge.<sup>44</sup> Similarly, hyperinsulinemic disorders such as PCOS result in increased LH pulse frequency and amplitude. When the insulin receptor was knocked out in the mouse central nervous system, elevated plasma insulin levels along with exaggerated LH response to exogenous GnRH was also observed.<sup>45</sup> Moreover, approximately 50% of women with noninsulin-dependent diabetes mellitus demonstrate PCOS features, including menstrual irregularity and hyperandrogenism.<sup>46</sup> Thus, either insufficient or increased amounts of insulin may interfere with the hypothalamic-pituitary-ovarian axis, leading to anovulatory infertility.

Both adrenal insufficiency and adrenal hyperplasia may also lead to hypothalamic-pituitary-ovarian axis dysfunction and infertility. Gonadotropin secretion and LH response to GnRH are suppressed in congenital adrenal hyperplasia (CAH) and Cushing's syndrome because of hyperandrogenemia and hyperadrenocorticism, respectively. Sexual dysfunction and anatomic defects may also contribute to infertility in CAH. Adrenal insufficiency may be associated with amenorrhea in 25% of women secondary to weight loss, chronic illness, or autoimmune premature ovarian failure. Libido is also decreased in adrenal insufficiency. Both adrenal hyperplasia and insufficiency may result in hyperprolactinemia, which may also suppress ovulation.

Acromegaly is caused by a growth hormone-secreting pituitary adenoma in most cases. Pituitary mass effect of these adenomas may result in suppressed gonadotropin secretion and anovulation. Hyperprolactinemia may also accompany acromegaly.

### Unexplained Infertility

Unexplained infertility is defined as the inability to conceive with no identifiable causes for infertility using standard investigations. Numerous factors may contribute to unexplained infertility. Couples who are at the lower limits of the normal fecundability distribution curve may fall into this category,

## Female Infertility and the Evaluation of the Infertile Couple

although the duration of infertility is similar in these couples compared to those with other infertility diagnoses. Female partner age greater than 30 years may also be responsible for decreased fertility. However, the age distribution of couples with unexplained infertility does not differ significantly from that of couples with other infertility diagnoses.<sup>47</sup> The majority of couples with unexplained infertility probably suffer from a defect that is undetectable by current diagnostic approaches.

### **Genetics of Infertility**

Multiple mutations and chromosomal abnormalities affecting the hypothalamic-pituitary-ovarian axis have been described. Some of these mutations are very rare and reported as case series, whereas others affecting the gonads, such as 45,X, can be as common as 1:2500 live female births.

Mutations involving the hypothalamic function include mutations of *KAL1*, *KAL2*, leptin (*LEP*), and leptin receptor (*LEPR*) genes.<sup>48–51</sup> Mutations in the *KAL1* and *KAL2* genes are the etiologic factor with hypogonadotropic hypogonadism and anosmia, (Kallmann syndrome) in some women. X-linked, autosomal dominant, and autosomal recessive inheritance modes have been suggested in Kallmann syndrome. *LEP* and *LEPR* mutations are associated with hypogonadotropic hypogonadism, obesity, and hyperinsulinemia. However, these mutations are extremely rare.

Gene mutations interfere with pituitary functions. GnRH receptor gene (*GNRHR*) mutations result in hypogonadotropic hypogonadism, ranging from partial function loss of the receptor to the complete loss of function.<sup>52</sup> The mutations of the genes coding the beta subunit of the gonadotropins have also been described. *FSHβ* gene mutations cause infertility, with primary amenorrhea in females and azoospermia in males.<sup>53</sup> There has been one case report with the *LHβ* gene mutation,<sup>54</sup> a male who presented with delayed puberty, low testosterone, and small testes. Gonadotropin levels were elevated in this patient because of a missense mutation of the *LHβ* gene. Mutations of other genes such as *PROP1*, *HESX1*, and *LHX3* also result in lack of gonadotropins or combined pituitary hormone deficiency.

Multiple mutations and chromosomal abnormalities involve both the female and male gonad, causing gonadal failure and infertility. Pubertal development is normal in most men with gonadal infertility whereas it is usually impaired in women. The mutations involving the gonads can be gonosomal or autosomal. The most common gonosomal mutations in men involve the *SRY*, *DAZ*, *DDX3Y*, and *USP9Y* genes.<sup>55</sup> The most common gonosomal chromosomal abnormalities or mutations in women include 45,X and mutations of the *FMR1*, *POF1*, and *DIAPH2* genes.<sup>55</sup> FSH receptor (*FSHR*) and LH receptor (*LHR*) gene mutations are autosomal and result in infertility in both women and men.<sup>56–59</sup> Other autosomal mutations that cause infertility in women and men involve multiple genes, including *CYP17*, *CYP19*, *AIRE*, *WT1*, *NR5A1*, and *DHH*.<sup>55</sup>

Women with müllerian duct agenesis have vaginal aplasia and a rudimentary uterus with normal functioning ovaries. Mutations involving genes such as hepatic nuclear factor 1β, or the transcription factor 2 (*TCF2*) gene and Kaufman-McKusick syndrome (*MKKS*) gene may cause müllerian agenesis.<sup>60</sup> However, molecular defect in other müllerian agenesis syndromes,

including Mayer-Rokitansky-Küster-Hauser syndrome, is unknown. Mutations involving cystic fibrosis transmembrane conductance regulator (*CFTR*) gene may result in congenital bilateral absence of vas deferens (CBAVD).<sup>61</sup> The majority of men with CBAVD are compound heterozygotes, which is defined as having a single copy of two different mutations. These men present with obstructive azoospermia and normal spermatogenesis although they do not have cystic fibrosis.

### **Male Factor Infertility**

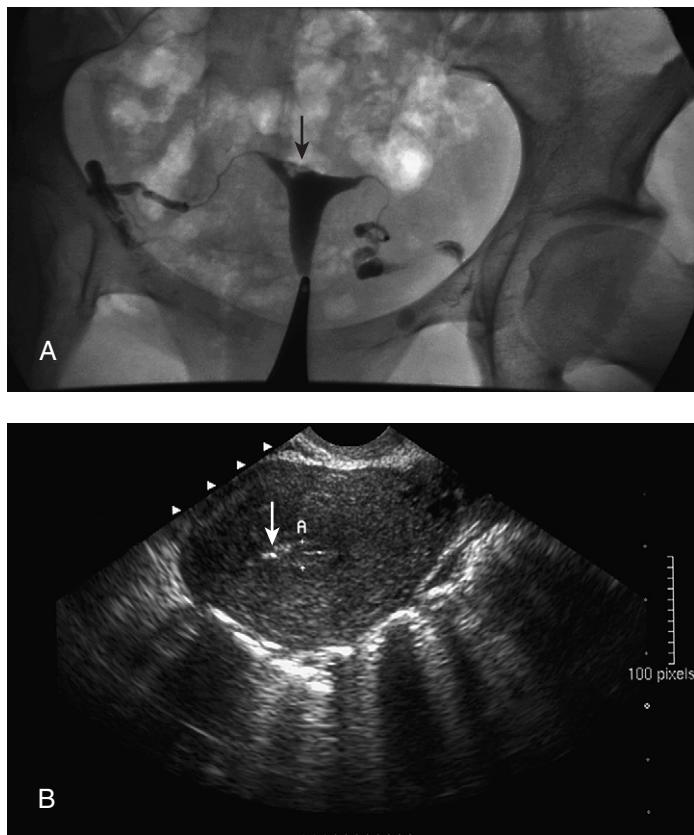

Multiple genetic or acquired disorders may lead to male factor infertility. Endocrine disorders, genetic disorders, varicocele, cryptorchidism, disorders of ejaculation and erection, male aging, exposure to environmental toxins, and outflow obstruction are the etiologic factors that may cause male infertility. However, the cause of infertility can be identified in only 50% of infertile men. This topic is discussed in detail in Chapter 53.

### **CLINICAL FEATURES AND DIAGNOSIS**

Infertility is defined as the inability to conceive after 12 or more months of regular unprotected intercourse. An investigation should be started after 1 year of unsuccessful trying unless medical history or physical examination findings support an earlier evaluation or treatment (Table 52-2). Often, in women over age 35 an infertility evaluation is started after 6 months. A detailed history and physical examination should be performed in all couples because etiologic factors such as sexually transmitted diseases, uterine fibroids, and endometriosis may be revealed.

**Table 52-2**  
**Diagnostic Evaluation of the Infertile Couple**

	Diagnostic Test	Recommendation
Cervical factor	Postcoital test	Routine use unnecessary
Uterine factor	Hysterosalpingography, ultrasound, hysteroscopy	An integral part of the evaluation
Tubal factor	Hysterosalpingography, sonohysterography, laparoscopy with chromoperturbation	An integral part of the evaluation
Endometriosis	Ultrasound, laparoscopy	Indicated if strong suspicion
Ovarian factor	Menstrual history, basal body temperature, serum progesterone, urinary luteinizing hormone, serial transvaginal ultrasound and/or endometrial biopsy	An integral part of the evaluation
Age	Day 3 follicle-stimulating hormone level	Indicated in women older than age 35 and poor responders
Endocrine	Thyrotropin level, prolactin level	Indicated if suspicion
Male factor	Semen analysis	An integral part of the evaluation

**Figure 52-1** A, A filling defect in the right fundal region of the uterus on hysterosalpingography. B, The appearance of the same filling defect on ultrasound; hyperechoic area in the fundus.

### Cervical Factor Infertility

Women with cervical factor infertility may present with a history of a cervical procedure, trauma, or exposure to drugs such as diethylstilbestrol. Physical examination may reveal anatomic distortion of the cervix. One of the most controversial diagnostic tests in female infertility is the postcoital test, which is also the oldest one, introduced by James Marion Sims in 1866. However, there is still no consensus on the correct timing of the postcoital test, cutoff for a normal result, and treatment

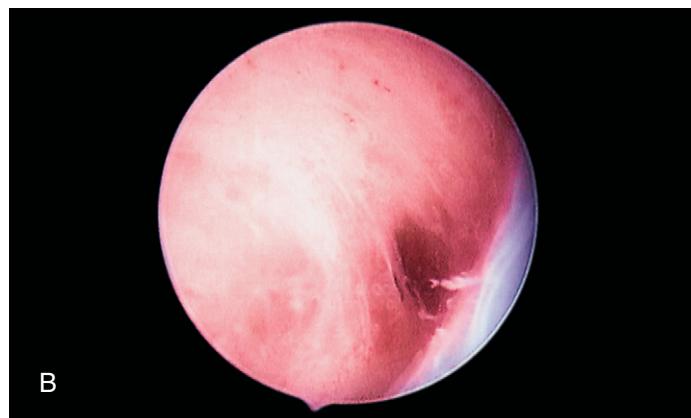

for an abnormal result. A multinational study reported a large variation in the timing of the postcoital test, both with reference to the menstrual cycle and time after intercourse.<sup>62</sup> Moreover, the microscopic magnification used and the definition of a normal result varied significantly; more than 10 different treatment strategies were utilized among different centers. Sensitivity and specificity of the postcoital test also show a large variation, ranging from 10% to 97%. A well-designed randomized controlled study revealed similar pregnancy rates between women who underwent postcoital test and the control group.<sup>63</sup> Furthermore, widespread use of intrauterine insemination (IUI) and IVF have rendered the postcoital test ineffective in the prediction of pregnancy. Although the postcoital test is no longer part of the standard infertility evaluation, it may be useful in some couples to ascertain the ability to have timed intercourse and to confirm that the sperm is entering the cervical mucus.

### Uterine Factor Infertility

A history of increased menstrual flow and frequency, pelvic pressure, or enlarged abdominal girth may be present in women with uterine fibroids. Endometrial polyps may also cause irregular vaginal bleeding. Physical examination may reveal an enlarged uterus with an irregular contour in women with fibroids. Pelvic ultrasound is the preferred imaging modality for evaluation of uterine fibroids. Size, location, and number of fibroids can be identified using ultrasound imaging. If a more thorough analysis of the fibroids is desired, magnetic resonance imaging (MRI) is the most accurate imaging modality.<sup>64</sup> Some investigators advocate routine use of hysterosalpingography (HSG) or hysteroscopy as part of an infertility evaluation to image the uterus because 10% to 45% of women with infertility may have an intrauterine lesion.<sup>65,66</sup> Submucosal fibroids, endometrial polyps, or intrauterine synechia may be visualized as filling defects on HSG (Fig. 52-1). Hysteroscopy is recommended to characterize the lesion when HSG shows an abnormal cavity. Furthermore, submucosal fibroids or endometrial polyps can be removed using operative hysteroscopy (Fig. 52-2).

### Tubal Factor Infertility

A careful history may reveal a past history of sexually transmitted diseases (STD) or past symptoms of STD. Although

**Figure 52-2** A, A submucosal fibroid visualized via hysteroscopy. B, Intrauterine synechia developed after dilatation and curettage visualized via hysteroscopy.

## Female Infertility and the Evaluation of the Infertile Couple

clinical usefulness of history taking in tubal factor infertility has been questioned due to the low specificity (29%) and sensitivity (84%),<sup>67</sup> many investigators strongly recommend a detailed history taking as an integral part of infertility evaluation.<sup>68,69</sup> Chlamydia antibody testing has been proposed to evaluate tubal patency noninvasively. However, sensitivity values ranging from 50% to 75% and restricted information obtained from antibody testing limit its use.

Hysterosalpingography is the most commonly used imaging modality to evaluate tubal patency, although laparoscopy with chromoperturbation is considered the gold standard. A meta-analysis found that the sensitivity and specificity of HSG are 65% and 83%, respectively for the prediction of tubal patency compared to diagnostic laparoscopy.<sup>70</sup> Thus, it is a good predictor of tubal obstruction but not tubal patency. HSG also was not reliable for the evaluation of peritubal adhesions. However, a later study reported that after a normal HSG, laparoscopy was not likely to reveal tubal disease.<sup>71</sup> Of the 794 patients who underwent HSG and laparoscopy in this prospective study, only 12 had patent tubes on HSG and bilaterally blocked tubes during laparoscopy, although the best predictor of future fertility was laparoscopy. The sensitivity and specificity of HSG were 72% and 82%, respectively, for the detection of bilateral obstruction. HSG can be performed using oil-soluble or water-soluble contrast media. Water-soluble contrast media is superior to oil-soluble media in the evaluation of tubal structure. Oil-soluble media also has a higher incidence of complications, such as granulomatous inflammation of the tubes and pulmonary embolism, especially in women with tubal pathology. However, a meta-analysis reported higher pregnancy rates after flushing the tubes with oil-soluble media.<sup>72</sup> Therefore, flushing the tubes with oil-soluble media is recommended after HSG is found to be normal using water-soluble media. The advantages of HSG over laparoscopy with chromoperturbation include the annulment of surgical morbidity and complications, the lack of necessity for anesthesia and increased chances of spontaneous pregnancy after HSG.

Sonohysterography is an alternative imaging modality to HSG for the assessment of the uterine cavity and tubal patency. Ultrasound imaging of the uterus and tubes after insufflating with a contrast media such as normal saline, a galactose solution, or air-contrast after normal saline injection has comparable sensitivity and specificity to HSG,<sup>73</sup> but is usually reserved for women with iodine allergy. Sonohysterography offers the advantage of the ability to detect other uterine and adnexal abnormalities, including intramural or subserosal fibroids and ovarian masses. However, complete tubal anatomy usually cannot be evaluated during sonohysterography. Salpingoscopy, the visualization of the tubal mucosa using a rigid or flexible endoscope, has also been introduced. Although comparable results to HSG have been reported, this procedure has not gained widespread use because of the technical difficulties and high rates of incomplete procedures.

### Endometriosis

Chronic pelvic pain, dyspareunia, and dysmenorrhea are frequently encountered in endometriosis. The frequency of endometriosis in women with chronic pelvic pain ranges from 15% to 32%.<sup>74,75</sup> Dyspareunia in endometriosis is usually deep

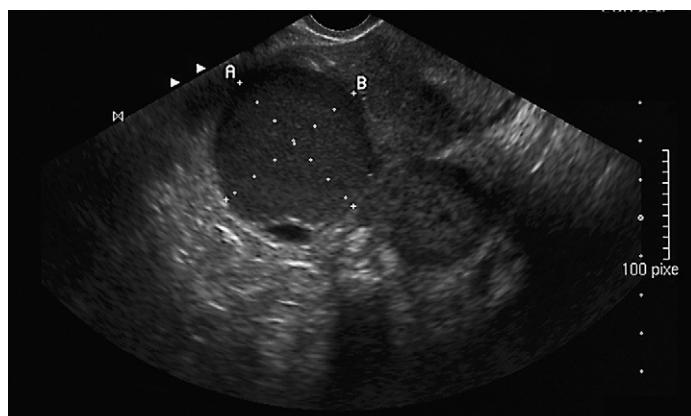

and associated with rectovaginal involvement of the disease. Pain after intercourse may also be reported by women with endometriosis. Dysmenorrhea is considered the most common symptom in endometriosis.<sup>76</sup> The risk of endometriosis is associated with the total number of menstrual cycles. Endometriosis is less frequently diagnosed in women who have longer menstrual cycles (>27 days) or a higher number of pregnancies compared to women with shorter cycles or nulliparity. Women with a family history of endometriosis are more likely to have endometriosis compared to controls; a polygenic/ multifactorial inheritance has been suggested.<sup>77</sup> Rarely, symptoms related to the extrapelvic involvement of endometriosis, such as intestinal tract, urinary tract, lungs, and central nervous system involvement, may be encountered.

A wide range of physical examination findings have been reported in endometriosis, including uterosacral nodularity and pain, reduced uterine mobility, deviated or retroverted uterus, cervical motion tenderness, and adnexal mass. However, these findings have poor sensitivity and specificity.<sup>78,79</sup> Even if the endometriosis is deeply infiltrating, a palpable nodule is noted in only 43% of women.<sup>80</sup> Therefore, a normal physical examination does not rule out endometriosis. Moreover, the presence of the physical signs is not diagnostic.

Laboratory tests such as CA 125, CA 15-3, and CA 19-9 have been suggested as diagnostic tools. However, none of them has adequate sensitivity and specificity. A meta-analysis showed that CA 125 has a poor sensitivity for endometriosis and a high false-positive rate, 50% and 28%, respectively.<sup>81</sup>

A recent review of eight studies that evaluated the accuracy of ultrasound in the diagnosis of endometriosis reported moderate accuracy, with a high likelihood ratio (LR; 7.6–29.8) to rule in the diagnosis of endometrioma.<sup>82</sup> The sensitivity of ultrasound in the same review ranged from 64% to 89%; specificity ranged from 89% to 100% (Fig. 52-3). However, ultrasound has a limited role in the diagnosis of superficial peritoneal lesions and adhesions.

Magnetic resonance imaging has also been evaluated for the diagnosis of endometriosis. The sensitivity and specificity of MRI in the detection of all stages of endometriosis are 69% and 75%, respectively.<sup>83</sup> MRI has a better sensitivity and specificity in the detection of endometriomas, 90% and 98%, respectively.<sup>84</sup>

**Figure 52-3** The appearance of an endometrioma on ultrasound; cystic structure with internal echoes.

## Reproductive Endocrinology and Infertility

However, a recent study showed that rectal endoscopic ultrasound has a better sensitivity and negative predictive value in the diagnosis of deeply infiltrating rectovaginal endometriosis compared to MRI, 97% versus 76% and 97% versus 85%, respectively.<sup>85</sup>

The gold standard for the diagnosis of endometriosis is laparoscopy with biopsy for histologic examination. The classic appearance of endometrial peritoneal implants is characterized by blue-black powder-burn lesions. However, endometrial implants have multiple appearances, including nonpigmented white lesions, red flamelike lesions, papular or vesicular lesions with serous or hemorrhagic content, peritoneal defects or pockets, and subovarian adhesions. The implants are commonly encountered over the uterosacral ligaments, posterior cul-de-sac, pelvic side walls, and ovarian fossa. Endometriomas, ovarian cysts filled with old blood of endometriosis, can be identified readily during laparoscopy.

### Ovarian Factor Infertility

A history of regular menstrual cycles suggests normal ovulation in greater than 90% of cycles.<sup>86</sup> Anovulation normally results in oligomenorrhea. In the absence of pregnancy, secondary amenorrhea, the cessation of menses after menarche, may be caused by PCOS, hyperprolactinemia, hypothalamic amenorrhea, or other endocrine disorders. Symptoms such as galactorrhea, hirsutism, and acne are helpful in the differential diagnosis. Physical examination is focused on the signs of these disorders, such as hair and skin changes, nipple discharge, and body composition.

Initial laboratory evaluation in secondary amenorrhea should include serum thyrotropin, PRL, and FSH levels to rule out thyroid disorders, hyperprolactinemia, and premature ovarian failure.

Multiple methods have been investigated for the detection or prediction of ovulation, such as basal body temperature (BBT) charts, midluteal progesterone levels, ultrasound, and LH levels. BBT charts may be useful in women who have regular cycles without ovulation. The rectal or oral temperature should be taken in the morning before getting out of bed. The BBT is usually lower than 98.6°F in the follicular phase. It reaches a nadir around the time of LH surge, although it is generally difficult to detect this nadir. A temperature rise is noted after ovulation because of the increased progesterone levels. However, monophasic or uninterpretable graphs can be noted in approximately 20% of ovulatory cycles.<sup>87</sup> Moreover, interpretation of the charts is often difficult; at any rate, BBT cannot identify ovulation prospectively.

Serial transvaginal ultrasound scanning has been used as an accurate predictor of ovulation since the early 1980s.<sup>88</sup> The mean follicular diameter 1 day prior to ovulation is approximately 21 mm, and decreases dramatically after ovulation.<sup>89</sup> Ultrasound predicts ovulation in 85% to 96% of regularly cycling women.<sup>87,90</sup> The disadvantages of ovulation prediction using ultrasound are its high cost and the requirement for serial visits to the ultrasound center.

Another method is the measurement of midluteal (7 days prior to the next period) progesterone. A concentration greater than 3 ng/mL is consistent with ovulation. The sensitivity of a single midluteal progesterone measurement for ovulation detec-

tion is approximately 80%, because progesterone is secreted in a pulsatile manner and the luteal phase length may vary.<sup>87</sup>

Histologic examination of endometrial biopsy material obtained using a plastic suction cannula is also a reliable method to detect ovulation. However, endometrial biopsy performed in the luteal phase identifies ovulation retrospectively, similar to serum progesterone.

The World Health Organization (WHO) task force in 1980 selected serum LH surge as the best marker for impending ovulation and serum estradiol rise as the sign of the potentially fertile period.<sup>91</sup> However, serial daily serum LH measurements are not practical; this has been replaced by daily urine LH testing, based on data from later studies funded by WHO.<sup>92</sup> The sensitivity of urine LH testing is approximately 100% in infertile women with regular cycles.<sup>87</sup> Urine LH testing predicts ovulation approximately 20 hours before it occurs. However, ovulation may take place 14 to 26 hours after a positive test.<sup>93</sup> The highest probability of clinical pregnancy is achieved with intercourse 1 day prior to ovulation. Randomized controlled trials comparing IUI cycles by urine LH testing, BBT charts, ultrasound, or timing of hCG administration showed these methods to be equally effective.<sup>94–96</sup> Numerous one-step urine LH kits are commercially available, all easy to use.

Other less commonly applied methods to detect ovulation include monitoring of salivary ferning, cervical mucus score and urinary estrone-3-glucuronide measurement. However, these methods have not gained popularity because of the low accuracy and difficulty of use.

### Age

Women older than age 35 experience a rapid decline in fertility. The length of menstrual cycles becomes shorter after age 35 indicating diminished luteal phase length and oocyte quality. The intercourse frequency and sexual function should be elicited during the medical history. Decline in frequency and sexual dysfunction may contribute to the diminished fertility in older couples.

Numerous methods have been proposed to determine the ovarian reserve in older women, including female age, cycle day 3 or basal serum FSH level, cycle day 3 serum estradiol level, cycle day 3 serum inhibin B level, GnRH agonist stimulation test, the clomiphene citrate challenge test, exogenous FSH ovarian reserve test, total antral follicle count, ovarian stromal blood flow, ovarian volume, and ovarian biopsy. All these tests have similar efficacy in the prediction of a clinical pregnancy. Female age alone is not a good predictor of ovarian response to treatment, although it is an important factor in the infertility prognosis. If age 40 is selected as the threshold, the LR of not becoming pregnant is very high (12.5).<sup>97</sup> The two most commonly used tests are the basal serum FSH level and the clomiphene citrate challenge test. Basal serum FSH level is a single measurement obtained on day 3 of the menstrual cycle. In the clomiphene citrate challenge test, clomiphene citrate at 100 mg is administered daily between cycle day 5 and 9; this is followed by a serum FSH measurement on day 10. Many investigators also obtain a day 3 FSH level with the clomiphene citrate challenge test. Various threshold values have been proposed for each test. These values range from 10 to 17 IU/L for basal serum FSH and 10 to 26 IU/L for the clomiphene

## Female Infertility and the Evaluation of the Infertile Couple

citrato challenge test. A recent meta-analysis comparing these two methods revealed that both tests have poor sensitivities, 6.6% and 25.9%, respectively, and high specificities, 99.6% and 98.1%, respectively.<sup>98</sup> Therefore, a normal result from either test does not rule out poor ovarian response, however, an abnormal result indicates that ovaries will not respond to treatment.

### **Endocrine Disorders and Infertility**

Signs and symptoms of endocrine disorders may be helpful in establishing the diagnosis. Women with hypothyroidism may present with the following signs and symptoms: fatigue, weight gain in the presence of decreased appetite, cold intolerance, hair loss, dry skin, constipation, prolonged relaxation of the deep tendon reflexes, and intellectual slowness or depression. A serum thyrotropin level above the reference range with a serum free T<sub>4</sub> concentration below the reference range indicates hypothyroidism.

The signs and symptoms of hyperthyroidism include tremors, heat intolerance, tachycardia, palpitations, increased appetite with weight loss, and frequent stools. A serum thyrotropin level below the reference range with a serum free T<sub>4</sub> level above the reference range is consistent with hyperthyroidism.

The classic symptoms of diabetes mellitus are polyuria, polydipsia and weight loss. Fasting plasma glucose concentration greater than 125 mg/dL is consistent with diabetes; a concentration between 110 and 125 mg/dL indicates impaired glucose tolerance. Similarly, plasma glucose concentration between 140 and 200 mg/dL 2 hours after ingestion of 75 g of glucose is indicative of impaired glucose tolerance, and a concentration above 200 mg/dL is diagnostic for diabetes.

The classic features of Cushing's syndrome include amenorrhea, central obesity, moon facies, hirsutism, and purple striae. Diagnosis is usually established with an elevated 24-hour urinary free cortisol. Females with CAH may present with various signs and symptoms, ranging from in utero virilization in the classic salt-wasting form to adult hirsutism in the nonclassic form. Women with congenital lipoid adrenal hyperplasia usually present with abnormal pubertal development or premature ovarian failure. An elevated morning 17-hydroxyprogesterone level above 800 ng/dL is diagnostic. Clinical features of adrenal insufficiency include fatigue, anorexia, weight loss, hyperpigmentation, hypotension, and gastrointestinal symptoms such as nausea and vomiting. A corticotropin stimulation test is performed to confirm the diagnosis.

Typical presentation of patients with acromegaly is characterized by enlarged extremities and facial changes, such as frontal skull bossing, prognathism, enlarged nose, and tongue. An elevated morning level of growth hormone is diagnostic for acromegaly.

### **Unexplained Infertility**

Unexplained infertility is a diagnosis of exclusion that occurs in 15% of infertility evaluations. It should be considered in a couple with ovulatory cycles, patent tubes, and a normal semen analysis. Ovulation can be confirmed with measurement of serum progesterone in the luteal phase. Tubal patency is usually assessed by HSG or laparoscopy. A normal semen analysis, including sperm concentration, motility, and morphology, is sufficient to rule out male infertility.

The use of other infertility tests such as the postcoital test, antisperm antibodies, varicocele assessment, *Chlamydia* testing, and sperm function tests such as zona-free hamster egg penetration test to confirm unexplained infertility are controversial because these tests do not correlate consistently with pregnancy.<sup>99</sup> Moreover, many of these tests are interdependent, which increases false-positive results exponentially when multiple tests are performed. They are also rarely helpful to establish a treatment plan. Therefore, it is prudent to avoid expensive unnecessary tests and procedures that will not have an effect on the management plan.

### **Male Factor Infertility**

Semen analysis is an integral part of the evaluation of the infertile couple. The basic parameters of a semen analysis include sperm concentration, motility, and morphology. Sperm morphology may be assessed under low magnification without staining using standard WHO criteria. A more precise method is to evaluate sperm morphology under high magnification after staining of the sperm head using Kruger criteria. This method, known as *strict morphology*, has been shown to correlate with fertilization rates.<sup>100</sup>

Any abnormal semen analysis value should prompt additional clinical and laboratory evaluation of the patient. This may include physical examination, endocrine testing (FSH, testosterone), postejaculatory urinalysis, scrotal ultrasound, specialized semen and sperm tests ( $\alpha$ -glucosidase, fructose, antisperm antibodies, sperm viability and penetration tests, and the zona-free hamster egg penetration test), and genetic screening depending on the abnormality detected.

All semen and sperm tests have the same pitfalls. Men who fall outside the reference ranges may be fertile; conversely, men with normal values may be infertile. Moreover, application of these tests precludes the use of the same sperm for ART. Non-destructive sperm tests are needed to select good-quality sperm for use in ART.

Evaluation of male infertility is discussed at length in Chapter 53.

## **TREATMENT**

Recent advances in medicine and science often generate unrealistic expectations regarding pregnancy rates. These expectations increase the pressure on physicians and frequently result in application of empirical therapy, such as the treatment of minimal to mild endometriosis, varicocelectomy, and IVF. However, infertility specialists have much more to offer to their patients today compared to two decades ago (Table 52-3). Nonetheless, the basic principles of diagnosis-directed evidence-based treatment should guide the choice of therapy.

### **Cervical Factor Infertility**

If cervical stenosis is suspected, dilatation of the cervix is performed. Intrauterine insemination is recommended when a history of cervical surgery, cryotherapy, or other anatomic defects are present and no sperm is detected on the postcoital test. If other factors are involved in infertility such as tubal factors and male factors, IVF is the preferred treatment.

Table 52-3 Most Commonly Used Assisted Reproductive Technologies		
Type of ART	Procedure	Main Indication
Intrauterine insemination	Placement of washed sperm into uterus	Unexplained infertility
In vitro fertilization	Retrieval of superovulated eggs and placement of sperm with these eggs outside body, followed by transfer of resultant embryos into uterus	Tubal factor infertility
In vitro fertilization with intracytoplasmic sperm injection	Retrieval of superovulated eggs and injection of each egg with a single sperm followed by transfer of resultant embryos	Male factor infertility
ART, assisted reproductive technology.		

### Uterine Factor Infertility

Submucosal fibroids and endometrial polyps are best confirmed and removed via hysteroscopy. When intramural or subserosal fibroids are present, myomectomy may be considered, depending on the size and location of the fibroids. Treatment strategy for developmental anomalies is based on the type of anomaly. When a septate uterus is detected, hysteroscopic resection of the septum is recommended. Other anomalies, such as bicornuate and didelphic uterus, are managed expectantly. Surgery may be considered if the couple is unable to become pregnant or miscarry recurrently. The only option for women with vaginal aplasia and uterine hypoplasia is surrogacy.

### Tubal Factor Infertility

Surgical tubal reconstruction such as fimbrioplasty, lysis of adhesions, and salpingoneoplasty used to be the only option for women with tubal damage. However, low pregnancy rates after surgery and the advent of IVF rendered tubal reconstruction a choice only for selected couples who are known to have normal tubal mucosa and are adverse to IVF.

In vitro fertilization is now the preferred therapy for couples with tubal factor infertility. Of 99,989 women who started ART treatment in 2000, 39,437 underwent IVF for etiologies other than male factor infertility such as tubal factor and unexplained infertility. Pregnancy and delivery rates per oocyte retrieval were 35% and 29%, respectively.<sup>101</sup> Removal of tubes prior to IVF is recommended in women with hydrosalpinx; as a recent meta-analysis reported that laparoscopic salpingectomy increases pregnancy and live birth rates significantly in these women (OR, 1.75; 95% CI, 1.07 to 2.86; and OR, 2.13; 95% CI, 1.24 to 3.65, respectively).<sup>102</sup> Increased risks for multiple pregnancy, ovarian hyperstimulation syndrome, ectopic pregnancy and preterm delivery are encountered with IVF therapy.

### Endometriosis

Medical treatment of minimal to mild endometriosis with ovulation-suppressing agents, including medroxyprogesterone

acetate, oral contraceptive pills (OCPs), GnRH agonists and danazol offers no benefit to infertile women because these therapies do not increase pregnancy rates but delay potential spontaneous pregnancies or successful treatment with IVF.<sup>103</sup>

Laparoscopic ablation or removal of minimal to mild endometriosis using electrocautery or laser to improve pregnancy rates has been debated. There are only two contradicting randomized clinical trials in the literature. Marcoux and colleagues in their larger multicenter trial showed an improvement in pregnancy rates after surgical intervention<sup>28</sup> whereas Gruppo Italiano reported no significant improvement.<sup>104</sup> A meta-analysis combining the two showed increased pregnancy rates.<sup>105</sup> However, 8 women need to undergo surgery to achieve 1 additional pregnancy. Therefore, laparoscopic therapy offers modest improvement in pregnancy rates compared to no therapy.

When endometriosis is advanced, with significant pelvic adhesive disease and tubal damage, IVF is the best therapy available. However, removal of endometriomas prior to IVF has been controversial. Some authors advocate the resection of endometriomas because surgery did not negatively affect the ovarian response during IVF,<sup>106</sup> whereas others reported no improvement in pregnancy rates or poor ovarian response after surgery.<sup>107,108</sup> Postoperative medical treatment does not improve pregnancy rates. Therefore, it is not recommended. Therapy for endometriomas should be individualized based on patient history and physical examination findings.

### Ovarian Factor Infertility

#### Eugonadotropic Anovulation

The majority of anovulatory women with normal gonadotropin levels have PCOS. Diet and exercise resulting in 10% decline in the BMI may resume ovulation in up to 90% of patients.<sup>109</sup> However, difficulty in achieving weight loss drives women and physicians to use readily available ovulation-inducing medications. Clomiphene citrate, an estrogen antagonist, remains the first-line agent for anovulatory infertility in PCOS for some clinicians. Clomiphene citrate stimulates FSH secretion by the pituitary, resulting in the development of mature follicles. The starting dose of clomiphene citrate is usually 50 mg/day between cycle days 3 and 7. Ovulation usually occurs 7 days after the last pill. If there is no response, the dose may be increased by 50-mg increments up to 200 to 250 mg/day. Approximately 75% of pregnancies with clomiphene citrate occur in the first three treatment cycles; 50% of patients conceive at the 50-mg dose.<sup>110</sup>

Recently, the use of metformin, an insulin-sensitizing agent, for ovulation induction has dramatically changed the treatment of chronic anovulation in PCOS. Its mechanism of action on insulin metabolism is unknown. However, metformin improves insulin sensitivity, resulting in lower serum insulin and glucose levels. It does not induce hypoglycemia because insulin levels are not elevated. A meta-analysis including 13 randomized clinical trials comparing metformin to placebo or clomiphene citrate reported improved pregnancy rates, with metformin replacing clomiphene citrate as a first-line agent<sup>111</sup> Metformin is usually administered 500 mg three times daily by mouth. However, a starting dose of 500 mg daily gradually increased by 500-mg increments may be considered because of the gastrointestinal side effects such as nausea, vomiting, and bloating. Side effects

## Female Infertility and the Evaluation of the Infertile Couple

of metformin are discussed in detail in chapter 61. Other insulin-sensitizing agents, including troglitazone, rosiglitazone, and pioglitazone, are peroxisome proliferator activator receptor  $\gamma$  inhibitors. Troglitazone was withdrawn from the market because of hepatic side effects, but the largest randomized trial involving an insulin-sensitizing agent reported that troglitazone was effective in ovulation induction.<sup>112</sup> There is only limited data on the other two agents.

Gonadotropins are administered in women who do not respond to metformin or clomiphene citrate. However, these women are at risk for ovarian hyperstimulation syndrome and multiple pregnancy when they respond to gonadotropins. Low-dose, step-up FSH therapy has been suggested to prevent ovarian hyperstimulation syndrome and multiple pregnancy.<sup>113</sup>

Another agent that has gained attention recently is the aromatase inhibitor, letrozole, which blocks the conversion of androgens to estrogens and therefore acts in a similar way with clomiphene citrate. However, only preliminary studies have been conducted to date. Dexamethasone treatment in combination with clomiphene citrate has been shown to be effective in women with elevated dehydroepiandrosterone sulfate levels. The addition of metformin may be preferable to dexamethasone because of its better side effect profile. The combination of metformin with gonadotropins has also been suggested to improve pregnancy rates and decrease ovarian hyperstimulation syndrome. However, current preliminary data is not sufficient to make definitive conclusions on the combination therapy.

Ovarian wedge resection, once used to treat clomiphene citrate-resistant PCOS patients, can result in significant post-operative peritubal and periovarian adhesion formation. Recently, a less invasive technique, laparoscopic ovarian drilling using electrocautery or laser, has been suggested. However, recombinant FSH alone was more effective than ovarian drilling in a randomized trial. Because the multiple pregnancy rate was significantly lower in women treated with ovarian drilling compared to the recombinant FSH group,<sup>114</sup> this technique may be useful for couples who desire to avoid multiple pregnancy.

### **Hypergonadotropic Anovulation (Premature Ovarian Failure)**

There is no treatment available to resume ovulation after ovarian failure, although spontaneous pregnancies may occur even in women taking OCPs or hormone replacement therapy. IVF with donor oocytes and adoption are the only options for these couples. However, women who underwent IVF with donor oocytes had the highest pregnancy and delivery rates, 51% and 43% per embryo transfer, respectively, among women who underwent ART nationwide in 2000.<sup>101</sup>

### **Hypogonadotropic Anovulation**

Hypothalamic anovulation and other central etiologies may cause hypogonadism with resultant anovulation. Treatment of underlying etiology, such as weight gain, cessation of strenuous exercise, or treatment of the infiltrating disease or tumor, should be considered initially. If medical therapy is necessary for ovulation induction, gonadotropins are the first-line agents. Most women become pregnant on gonadotropins. Pulsatile GnRH therapy has been investigated for hypothalamic anovulation. Although pulsatile GnRH administration is very cumbersome, it

is successful in achieving pregnancy and has the advantage of a relatively low multiple pregnancy rate.

### **Hyperprolactinemic Anovulation**

The classic treatment for hyperprolactinemia is bromocriptine. Bromocriptine is a dopamine agonist that acts through the stimulation of dopamine (D<sub>2</sub>) receptors. It decreases PRL synthesis and adenoma size. Normoprolactinemia and ovulatory cycles are achieved in 80% to 90% of the women.<sup>115</sup> The starting dose of bromocriptine is 2.5 to 5.0 mg/day by mouth, which can be titrated after normoprolactinemia is achieved. The most common side effects are nausea and vomiting. Headache, dizziness, orthostatic hypotension, and depression are the other side effects of dopamine agonists. The dose may be gradually increased or administered intravaginally to minimize the side effects. Cabergoline is another ergot derivative with a longer half-life and better side effect profile. The usual dose is 0.5 to 1 mg twice weekly by mouth. It may be administered intravaginally to minimize side effects. A multicenter randomized trial showed that normoprolactinemia and the resumption of menses were achieved in 83% and 91% of women, respectively, on twice-weekly cabergoline compared to 59% and 83% for the bromocriptine group, respectively.<sup>116</sup> Moreover, cabergoline was better tolerated than bromocriptine. However, there is less data on the fetal safety of cabergoline compared to bromocriptine.

### **Age**

If initial attempts at ovulation induction and IVF fail because of poor ovarian response or the day 3 FSH value is elevated, as occurs more commonly in women older than age 35, the use of donor oocytes or adoption should be considered. Spontaneous abortion rates remain unchanged in women who use donor oocytes, whereas they increase exponentially in women who undergo IVF with their own eggs after age 36.<sup>117</sup>

### **Endocrine Disorders and Infertility**

Treatment of the underlying endocrine disorder is the goal of therapy. If ovulation is not restored, ovulation induction can be achieved using various agents ranging from clomiphene citrate to gonadotropins depending on the patient's presentation.

### **Unexplained Infertility**

Expectant management may be considered in couples who have been infertile for less than 3 years and the female age is younger than age 35. Approximately 32% of couples with unexplained infertility become pregnant within the first 3 years of infertility. However, the chances of pregnancy decline significantly after 3 years. Clomiphene citrate and IUI may be considered as the initial treatment in unexplained infertility. The pregnancy rate with this approach is 9.5% per cycle.<sup>118</sup> A multicenter randomized trial reported a pregnancy rate of 9% per cycle with FSH stimulation and IUI, which was significantly higher than pregnancy rates with FSH stimulation and intracervical insemination, intracervical insemination only, and IUI only (4%, 2%, and 5% per cycle, respectively).<sup>119</sup> Approximately 33% of the couples who received FSH stimulation and IUI became pregnant. However, increased risk of multiple pregnancy is a disadvantage of FSH stimulation. If pregnancy is not achieved with clomiphene citrate and IUI or FSH and IUI, IVF is recommended.

### Male Factor Infertility

Contrary to female infertility, the underlying problem, such as hypogonadotropic hypogonadism, disorders of ejaculation and erection, and obstructive azoospermia, can be treated in a small percentage of infertile men. The majority of men with abnormal semen parameters require IVF with intracytoplasmic sperm injection (ICSI). This topic is discussed in detail in Chapter 53.

### CLINICAL COURSE AND PROGRESSION

The duration of infertility, female age, and a history of a previous pregnancy are important prognostic determinants for an infertile couple. However, it is not possible to predict whether a couple will become pregnant with or without treatment. After 3 years of infertility, pregnancy rates decrease significantly every month (by 2%) in couples with unexplained infertility.<sup>47</sup> Treatment success also declines in repeated cycles. Couples have the highest chances of pregnancy in the first three or four cycles of treatment regardless of the type of treatment. It is prudent to avoid the exploitation of the couple with repeated cycles of unsuccessful therapies before exploring other options such as donor oocytes, donor sperm, and adoption. Some couples may become pregnant spontaneously even after adopting a child. However, pregnancy rates after adoption is not different from that for nonadopting couples.<sup>120</sup>

An association between infertility and cancer has been suggested. Treatment for infertility has also been investigated as a risk factor for female cancers. Two recent multicenter retrospective studies involving the same patient population (12,193 women) have investigated the ovarian cancer risk in women with infertility and women who received ovulation-stimulating agents.<sup>121,122</sup> Overall, infertile women had a significantly higher risk for developing ovarian cancer than the general population (standardized incidence ratio, 1.98; 95% CI, 1.4 to 2.6). This risk was even higher in women with primary infertility or endometriosis. However, infertility treatment—defined as the use of clomiphene citrate or gonadotropins—did not increase the risk of ovarian cancer (standardized incidence ratios, 0.82; 95% CI, 0.4 to 1.5; and 1.09; 95% CI, 0.4 to 2.8, respectively).

These investigators also examined the risk of breast cancer in the same population.<sup>123</sup> Infertile women had a higher risk for breast cancer compared to the general population (standardized incidence ratio, 1.29; 95% CI, 1.1 to 1.4), whereas treatment with clomiphene citrate or gonadotropins did not affect the risk of breast cancer (standardized incidence ratios, 1.02 and 1.07, respectively). A different group of investigators from Europe confirmed that the treatment for infertility did not increase the breast cancer risk (RR, 0.95; 95% CI, 0.82 to 1.11).<sup>124</sup>

### PITFALLS AND CONTROVERSIES

Advances in the treatment of infertility have enabled many couples to have children who otherwise would not be able to experience parenthood. The goal of infertility treatment is the birth of a singleton healthy baby by a healthy mother.

However, treatment of infertility is not risk free. Ovarian hyperstimulation syndrome, multiple pregnancy, low birth weight, preterm delivery, and plausible risk for chromosomal

anomalies are potential complications that may lead to morbidity and mortality in both the baby and mother. Moreover, men with severe oligospermia or azoospermia have an increased risk of chromosomal anomalies or single gene mutations. IVF with ICSI enables these men to have children. Therefore, one can argue that genetically caused infertility may be perpetuated using infertility treatment. However, these children will have access to the same, if not better, treatment, and attempts at improving the genetic quality of the population may have eugenic implications. Infertility interest groups support the idea that having a child is a basic biologic value and every person's right.<sup>125</sup> The ASRM describes infertility as a disease.<sup>126</sup> Therefore, one can argue that it is the infertile couples' right to give informed consent for infertility treatments that may result in potential complications, just as any other therapy with side effects or complications.

Another debated issue is the accessibility of infertility treatments. Although infertility treatment with ART is no longer an experimental procedure, couples still do not have universal access to ART because of the lack of comprehensive insurance coverage for infertility. Lack of comprehensive insurance coverage may also have an impact on ART outcome. Limited patient resources preclude more than one attempt at treatment. But adequate coverage may relieve the pressure on physicians to achieve pregnancy in one attempt, leading to a decrease in the number of embryos transferred. This may improve multiple pregnancy rates as the number of embryos transferred is strongly correlated with the success rate and multiple pregnancy rate. However, insurance coverage alone cannot diminish the multiple pregnancy rate. Although the need for the regulation of infertility treatment is clear, a strict government control, as seen in Europe, can be counterproductive because it may lead to suboptimal practices, such as the transfer of two embryos in a 42-year-old woman with a history of failed IVF cycles.<sup>127</sup> Rigorous regulations by professional societies and health organizations such as The American Society for Reproductive Medicine and the Centers for Disease Control and Prevention may be the best approach to minimize the risks of infertility treatment and improve pregnancy rates.

# Chapter 53

# Assisted Reproductive Technologies/ In Vitro Fertilization

Randall S. Hines, MD, and Bryan D. Cowan, MD

## KEY POINTS

- In vitro fertilization (IVF) has become a common infertility therapy.
- Age is the most powerful predictor of IVF success.
- Hydrosalpinx and uterine myoma may impair IVF success.
- Gonadotropins combined with GnRH agonists or antagonists provide the best pregnancy rates.
- Ovarian hyperstimulation and multiple pregnancy are the two most important complications of IVF.

IVF was a remarkable medical breakthrough in 1978 that resulted in the birth of Louise Brown. This revolutionary technique consists of medical stimulation of the ovaries, transvaginal oocyte retrieval, in vitro gamete processing, embryo culture, and embryo transfer, and it has become a common therapy around the world. Estimates of children born from this procedure are at 1.2 million worldwide, and there were over 115,000 treatment cycles and over 45,000 infants born from IVF in the year 2002 based on data collected by the Society for Assisted Reproductive Technology (SART, a subsociety of the American Society for Reproductive Medicine).<sup>1</sup> This approach to the treatment of infertility has made it possible to establish families in couples for whom reproduction appeared hopeless. Advances in techniques have led to new approaches for other conditions, such as preimplantation genetic diagnosis for inherited disorders. We address the IVF process, from patient preparation to advances in laboratory techniques.

The goal of any IVF program should be to provide patient friendly and successful therapy for assisted reproduction. Because IVF is often an expensive and complex therapy, efforts to reduce obstacles to patient care become paramount. In many parts of the United States, insurance coverage for infertility is limited and out-of-pocket expenses for IVF are high. In addition, the IVF process can be an emotionally trying experience for many couples. Innovations that simplify treatment protocols and lessen the strain on patients are important.

IVF success has increased dramatically over the years, with current pregnancy rates in many clinics at 40% to 50% per embryo transfer. Pregnancy rates per retrieval in patients under 35 years of age increased from 28.4% in 1996 to 33% in 2000.<sup>2</sup>

## PREPARATION FOR IN VITRO FERTILIZATION CYCLE

### Patient Selection

In vitro fertilization has become such a routine and successful part of the infertility practice, an argument could be made that any patient with infertility not caused by anovulation is a candidate for this therapy. While IVF is restricted to more entrenched infertility in most practices, IVF has become the final common pathway for patients who do not achieve pregnancy via other means. Standard indications include tubal disease and male factor (Fig. 53-1). With patent fallopian tubes ovulation disorders are treated first with ovulation induction agents, but when these fail IVF is offered.

### Age and Success

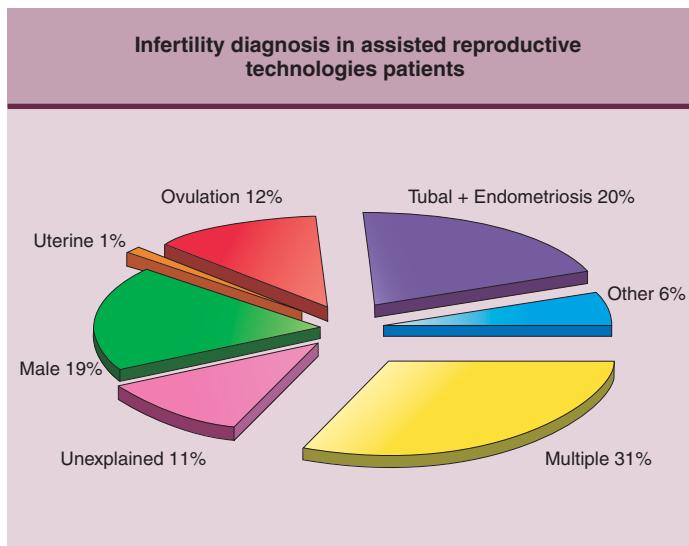

Age is the most powerful predictor of success in an IVF treatment cycle. Historical information from populations attempting spontaneous pregnancies without the availability of contraception demonstrates the impact of age on natural fecundity. In the Mormon population, pregnancy rates fall dramatically at age 35 (Fig. 53-2).

In IVF, the same effect of age is seen. Data from the SART registry reveals a significant decline in pregnancy rates for women over age 35 and an abrupt decline for women over age 40 (Fig. 53-3). Based on the SART 2000 data, women over age 40 had a 70% lower chance of delivery than women less than 35 years of age.<sup>2</sup> Pregnancies in women over age 45 are rare. Advancing age is also associated with increasing rates of miscarriage and a small but significant increase in the risk of chromosomal abnormalities in liveborns.

These dramatic changes with age lead some clinicians to offer donor oocyte cycles at age 40. Clinics vary with regard to specific recommendations, but as the expected endogenous pregnancy rate falls below 10%, the donor oocyte rate of 50% to 60% becomes an attractive option for many patients. Finally, there is an effect of paternal age on IVF success, although this effect is not so dramatic as that seen in women<sup>3</sup> (see Fig. 53-3).

### Uterine Evaluation

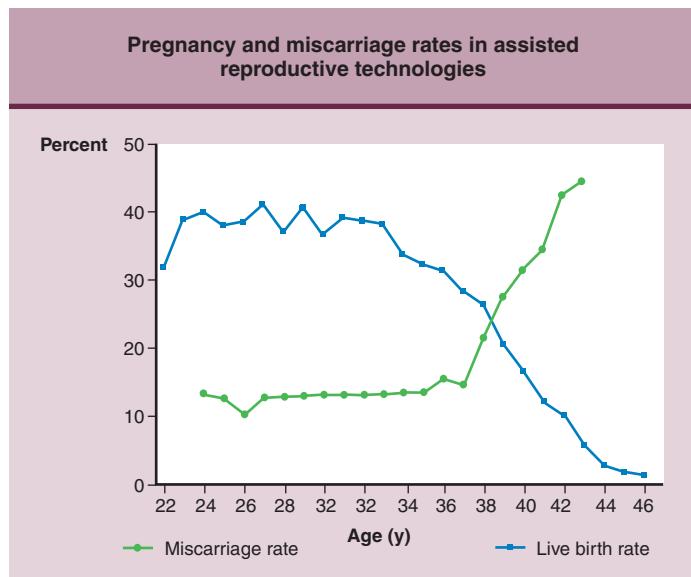

Candidates for IVF should have an imaging study to evaluate the uterine cavity. Endometrial polyps, uterine myoma, and congenital uterine abnormalities such as uterine septum should

**Figure 53-1 Infertility diagnosis reported among couples who had assisted reproductive technologies (ART) procedures using fresh nondonor eggs or embryos in 2002.** Diagnosis procedures may vary from one clinic to another, so the categorization may be inexact. (Modified from Centers for Disease Control: 2002 Assisted Reproductive Technology Success Rates. Dec 2004. Available at <http://www.cdc.gov/reproductivehealth/ART02/index.htm>. Accessed 5/22/05.)

be diagnosed prior to beginning the IVF treatment cycle. Hysterosalpingography was commonly utilized in the early days of IVF, but sonohysterography (SHG) is now the most widely used technique for uterine screening. SHG requires vaginal ultrasound and a uterine catheter for saline instillation, is not expensive, and is well tolerated by the patient. Office hysteroscopy has also been used.

In a study of 72 women undergoing IVF, SHG appeared to be effective and was less expensive than other uterine screening methods, although not all patients were evaluated by multiple

**Figure 53-3 Pregnancy and miscarriage rates adjusted for age during treatment cycles in women undergoing assisted reproductive technologies (ART) procedures using fresh nondonor eggs or embryos in 2002.** Pregnancy rate per IVF cycle is in blue, and miscarriage rate is in green. (Modified from Centers for Disease Control: 2002 Assisted Reproductive Technology Success Rates. Dec 2004. Available at <http://www.cdc.gov/reproductivehealth/ART02/index.htm>. Accessed 5/22/05.)

techniques.<sup>4</sup> Uterine lesions were detected in 11% of cases. When hysteroscopy was performed on those cases of uterine abnormalities, six of eight cases were confirmed. IVF pregnancy rates were not different for patients undergoing SHG as compared with those patients in the same time period who had a uterine evaluation by a different method. The estimated cost savings per patient undergoing sonohysterography instead of in-office hysteroscopy was \$275.

#### Surgical Adjuncts to In Vitro Fertilization

If uterine myoma are detected on SHG, the location and size of the myoma often dictate the need for surgical therapy. Submucosal myomas are thought to impair implantation, and there is universal acceptance that hysteroscopic resection is indicated before the IVF cycle.<sup>5</sup> Subserosal myomas do not impair pregnancy and are generally not treated unless symptoms are significant. Management of intramural myomas is controversial. The proximity to the endometrial cavity, size, and number of myomas may influence the decision for myomectomy. In a retrospective study, women with subserosal myomas had the same pregnancy rate as controls, women with submucosal myomas had a low implantation and pregnancy rate, and women with intramural myomas had pregnancy rates between the subserosal and submucosal groups.<sup>6</sup>

For some time, it has been recognized that patients with hydrosalpinx had a lower than expected pregnancy rate when undergoing IVF therapy. Since IVF was created for patients with tubal disease, this finding was surprising. The reasons for the decrease in expected pregnancy rates in patients with hydrosalpinx are not completely known. Hypotheses include a mechanical

Please refer to the printed publication.

**Figure 53-2 Mormon genealogical fertility data.** (From Mineau GP, Trussell J: A specification of marital fertility by parents' age, age at marriage and marital duration. Demography 1982;19:335-350.)

effect of fluid regressing into the cavity and a toxic effect from fluid on embryo development. A multicenter, randomized controlled trial demonstrated improvement in the pregnancy rate for patients with hydrosalpinx who underwent surgery for salpingectomy, or at least proximal tubal occlusion, before the IVF treatment cycle.<sup>7</sup> Although the overall pregnancy rate was improved with surgery, it did not reach statistical significance. However, the subgroup analysis indicated a dramatic and statistically significant improvement in pregnancy rates for those patients with bilateral hydrosalpinges documented by ultrasound who underwent surgical intervention before IVF. A follow-up of this same study group confirmed the efficacy of this approach.<sup>8</sup> In the follow-up study, patients who had previously been randomized to IVF without surgery and then were unable to achieve pregnancy were taken to surgery for salpingectomy and had subsequent IVF cycles. The pregnancy rate in this group was statistically improved.

The current recommendation is to counsel patients known to have hydrosalpinx that their best chance of success is to proceed with surgical removal or occlusion and then undergo IVF. This poses a dilemma for the practicing obstetrician/gynecologist, who must now include in the consent for laparoscopy, the possibility of salpingectomy for significant tubal disease in the patient who desires future fertility. An important factor in making the decision for salpingectomy is the fact that pregnancy rates following neosalpingostomy may be as low as 5%. Another option for tubal occlusion currently being tested is a hysteroscopic approach.

### Laboratory Testing

General hormonal testing is unlikely to be of benefit prior to IVF. During an infertility evaluation for anovulation, prolactin and thyroid-stimulating hormone measurements are warranted. Without specific complaints or physical manifestations, hormonal testing should be limited.

Diminished ovarian reserve is the inability of the ovary to respond to stimulation and produce mature oocytes resulting in healthy embryos and pregnancies. In preparation for an IVF cycle, the evaluation of ovarian function is designed to identify patients who may have a poor response. This information could then be used to counsel patients on expected prognosis, alter treatment protocols, or offer patients alternative therapy such as donor oocyte cycles. Denying therapy to patients on the basis of such testing is not recommended.

Ovarian reserve testing is now common practice although the choice of testing is debated. The modalities currently employed include cycle day 3 follicle-stimulating hormone (FSH), clomiphene citrate challenge test (CCCT), antral follicle counts (AFCs), and inhibin B testing. CCCT consists of day 3 FSH followed by clomiphene citrate at 100 mg on days 5 to 9. Day 10 FSH completes the test. An abnormal test may be defined by different values depending on the assay used, but a value over 16 mIU/mL is usually abnormal. CCCT is typically reserved for patients over age 35 or over age 30 with unexplained infertility. In a study of some 500 patients attempting pregnancy through a variety of methods, the pregnancy rate for those with a normal CCCT was 40% and for those with an abnormal test, 5%.<sup>9</sup> Day 3 FSH values, independent of age, are advocated by some IVF clinics to identify patients with abnormal ovarian

reserve. Other screening modalities include AFC in the early follicular phase.

A study investigating the predictive accuracy and clinical value of various ovarian reserve tests compared a single or a repeated CCCT in predicting poor response in IVF versus day 3 FSH, inhibin B, and AFC in 63 patients undergoing their first IVF cycle.<sup>10</sup> A first CCCT was performed in which FSH and inhibin B levels were measured on cycle day 10. A second CCCT was performed after a washout period of one cycle. In all patients the tests were followed by an IVF treatment cycle. Parameters examined included poor response (<4 oocytes or cancellation due to impaired [<3 follicles] or absent follicular growth). Both the single day 3 FSH as well as the repeated CCCT markers had rather good discriminative potential for the prediction of poor response, with day 10 FSH and day 10 inhibin B demonstrating similar efficacy. This compared well with the performance of the basal markers (FSH, inhibin B, and AFC). In a multivariate analysis on only the basal variables, FSH day 3 and AFC were selected. Only stepwise forward analysis on the repeated CCCT variables revealed a better discriminating potential for the prediction of poor response. At a specificity level of approximately 0.97, sensitivity and the positive predictive value were marginally improved in the CCCT models. The authors concluded that performing CCCT (single or repeated) has a good ability to predict poor response in IVF. The use of basal FSH and AFC appeared to be as predictive. In a meta-analysis to evaluate pregnancy with treatment, a normal test was not helpful, but an abnormal test strongly predicted a failed outcome.<sup>11</sup>

Ovarian reserve testing is best used in counseling the patient prior to IVF treatment. An older patient who has a low probability of pregnancy might choose donor oocytes if she also has diminished ovarian reserve. A younger patient with abnormal testing may benefit from a different stimulation protocol. Unfortunately, there is no one best treatment protocol for the poor responder.

### Male Evaluation

The precycle IVF evaluation requires an assessment of male factor infertility. Standard semen analysis with attention to count, morphology, and motility will identify many patients requiring intracytoplasmic sperm injection (ICSI), although subtle male factor infertility can exist even with normal numbers. Additional testing in the form of a sperm chromatin structure assay is now being offered.<sup>12</sup> Abnormal testing in light of an otherwise normal semen analysis is felt to be another indication for ICSI. Males with azoospermia can undergo surgical sperm retrieval in the form of epididymal aspiration or testicular biopsy in an outpatient setting. Pregnancy rates for males with severe oligospermia are equivalent to the pregnancy rates seen in other diagnoses, particularly if there is not an additional female factor.

## STIMULATION PROTOCOLS

### Follicular Stimulation

At the beginning of a menstrual cycle, gonadotropin-releasing hormone (GnRH) stimulates the anterior pituitary to release a mixture of FSH and LH (luteinizing hormone). The effect of these rising hormones on the ovary is to recruit a group of

## Reproductive Endocrinology and Infertility

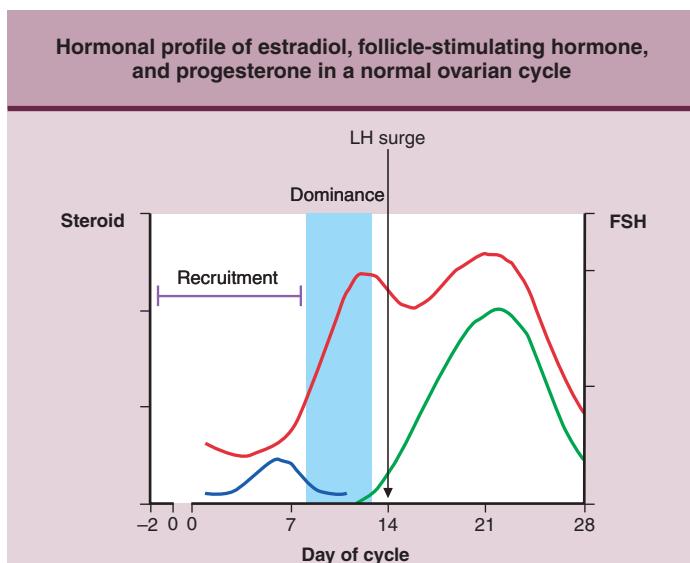

primordial follicles. As the follicles grow, FSH (and LH) receptor activity is increased in the follicles. As a result of the increase in FSH receptor activity in the follicular phase, estradiol is secreted in higher concentrations. The rising estradiol has a negative feedback effect on release of FSH, and FSH falls. The combined effect of (1) follicle acquisition of increased sensitivity to FSH and (2) the negative effect of estradiol on FSH secretion results in follicle dominance by which follicles recruited earlier in the cycle with high FSH levels are now unable to continue growth when estradiol-mediated FSH levels fall and only one (usual) follicle develops. In essence, the follicle that acquires the greatest (and crescendo) sensitivity to FSH will continue to increase estradiol production, and the less sensitive follicles will perish when FSH levels diminish (Fig. 53-4).

Pharmaceutical preparations that are generally available for follicular development include FSH, LH, and modified GnRH analogs. These preparations have been used nationally and internationally to produce multiple, mature fertilizable oocytes for assisted reproduction in IVF.

### Natural Cycle

Many factors influence the success of in vitro fertilization–embryo transfer (IVF-ET) including the age of the female partner, evidence of ovarian reserve, and the number of oocytes retrieved. An important determinant of IVF-ET success is the ovarian stimulation regimen employed. Successful fertilization of a human oocyte resulted in the birth of a baby girl, Louise Brown, in 1978.<sup>13</sup>

The first birth from IVF-ET used a single oocyte obtained from a natural cycle. Recent studies demonstrate that the pregnancy rate is low when natural cycles are compared with follicular stimulation cycles. IVF success was compared using a natural

**Figure 53-4 Hormonal profile of estradiol ( $E_2$ ), follicle-stimulating hormone (FSH), and progesterone in a normal ovarian cycle.** Follicular recruitment is determined by the rise of FSH in the early follicular phase, and follicular dominance is determined by the decline of FSH when  $E_2$  begins to rise. Recruitment usually starts 1 to 2 days before the onset of a new cycle.  $E_2$  is in red; progesterone is in green; and FSH is in blue.

**Table 53-1**  
Type of Ovarian and Hormonal Responses During Follicular Stimulation for IVF-ET

Follicular Stimulation	Follicles	Pregnancy Rate	Inhibition of LH surge
Normal	1–2	0–6	No
Clomiphene	2–4	6–10	No
FSH	Multiple	20–50	No
FSH with GnRH agonist	Multiple	30–60	Yes

FSH, follicle-stimulating hormone; IVF-ET, in vitro fertilization–embryo transfer; LH, luteinizing hormone.

cycle versus a clomiphene citrate–stimulated cycle. In the group of women with natural cycles, no pregnancies occurred, and 6% of the clomiphene group achieved a pregnancy. This low success rate makes natural cycle IVF-ET unsuitable for clinical use, except in unusual cases (Table 53-1).

Clomiphene citrate as a single agent has been evaluated for ovarian stimulation in IVF-ET in few clinical trials.<sup>14</sup> These pregnancy rates are lower than those achieved by stimulation protocols that use exogenous gonadotropins for ovarian stimulation. Clomiphene has also been used in conjunction with pulsatile administration of GnRH, resulted in several large follicles, and can be associated with pregnancy. Use of pulsatile GnRH requires a programmable infusion pump and chronic parenteral access, which has limited its use in IVF-ET.

### Gonadotropins

Most IVF programs now utilize exogenous gonadotropins for ovarian stimulation. Gonadotropin preparations that are commonly used include human menopausal gonadotropins (Bravelle, Repronex, Ferring), and recombinant FSH (Gonal-F, Serono; Follistim, Organon). There are few randomized clinical trials that evaluate the efficacy of exogenous gonadotropins against clomiphene or natural cycles alone in IVF-ET.<sup>15</sup> However, in IVF-ET, ovarian stimulation regimens that include human gonadotropins are routinely associated with pregnancy rates per cycle in the range of 20% to 60%. These pregnancy rates are far greater than those observed when clomiphene or natural cycles are used (Table 53-2).

Hormonal control of reproductive function is mediated by LH and FSH, glycosylated proteins with a molecular weight of

**Table 53-2**  
Classification of Different Types of Human FSH Preparations

Menopausal Urine	FSH/LH Ratio	Administration
u-FSH	Yes	1:1
HP-FSH	Yes	75:1
r-FSH	No	No LH

FSH, follicle-stimulating hormone; HP highly purified (monoclonal antibody); LH, luteinizing hormone; r, recombinant; u, urine.

28,000 to 30,000 Da. Both have an alpha and beta subunit, and the alpha subunit (92 amino acids) is common to LH, hCG, and TSH. Neither subunit has any biological activity individually. Secreted FSH has a plasma half-life about 149 minutes, which is five times longer than the approximate 30-minute half-life of LH. Once secreted, FSH is bound by granulosa cell receptors and increases follicular aromatase activity, which transforms theca-derived androgens (under LH stimulation) into estradiol.

To prepare pharmacologic preparations of FSH,<sup>16</sup> human menopausal urine is centrifuged, filtered, chromatographed, and biologically tested. Approximately 4 to 5 L of urine is needed to make a 75-unit ampule of urinary FSH (u-FSH). To improve the purity of FSH preparations (by isolating FSH) a highly specific monoclonal antibody to FSH was developed. The product derived from this extraction (HP-FSH) could be injected subcutaneously.

Worldwide demand led to an increase in the collection of postmenopausal urine and nearly exhausted its supply. As a result, Ares-Serono collaborated with an American laboratory, Integrate Genetics, to synthesize human gonadotropins FSH, LH, and hCG using genetic engineering techniques. The first step was to construct the entire DNA sequences required to produce recombinant human FSH (r-FSH). The second step was to develop a clonal cell line that synthesizes FSH (see Table 53-2). In 1988, r-FSH was successfully expressed in a hamster ovary cell line, and in 1991 the first clinical pharmacology tests began with a twin pregnancy born one year later.

Daya and Gumbey<sup>17</sup> published a meta-analysis of 12 trials (2875 cases, of which 1556 were treated with r-FSH and 1319 with u-FSH) that compared the use of r-FSH with u-FSH in women undergoing treatment for an IVF or ICSI cycle. The overall conclusion was that r-FSH significantly increased clinical pregnancies. In several studies r-FSH was more effective than HP-FSH or u-FSH to reduce FSH requirements, days of stimulation, and successful egg recovery.

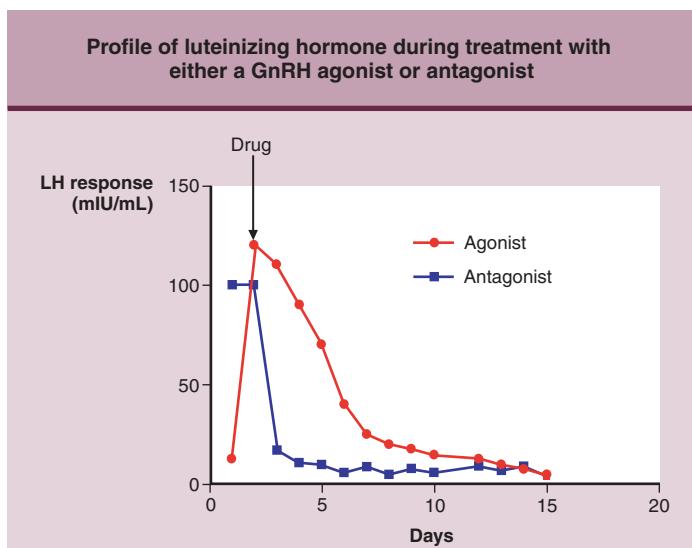

### GnRH Analogs

Approximately 20% of stimulated cycles within an IVF program are canceled owing to premature LH surges when gonadotropins are used as the sole medication. Most reproductive infertility clinics attempt to minimize this premature LH surge by using pituitary down-regulation. To achieve this, GnRH agonists were introduced into IVF superovulation regimens in the late 1980s and have become established as a component of standard regimens in most centers worldwide. GnRH is a decapeptide (pGlu-His-Trp-Ser-Tyr-Gly-Leu-Arg-Pro-Gly.NH<sub>2</sub>) and is secreted in a pulsatile fashion to stimulate the secretion of LH and FSH (Table 53-3). The amino acids of GnRH with crucial functions have been substituted (analogs) at positions 1, 2, 3, 5, 6, and 10. Position 6 is involved in enzymatic cleavage, positions 2 and 3 affect gonadotropin release, and positions 1, 6, and 10 impose the three-dimensional structure. Agonists initially stimulate release followed by suppression, while antagonists immediately suppress gonadotropin release (Fig. 53-5).

Many randomized clinical trials demonstrate that in IVF-ET, the combination of exogenous gonadotropin and a GnRH agonist is associated with higher pregnancy rates than is the use of gonadotropins without a GnRH agonist.<sup>18,19</sup> Most GnRH agonist analogs differ from the native decapeptide GnRH in amino acid positions 6 and 10 and are resistant to degradation by endopeptidases. In addition, the GnRH agonist analogs have high affinity for the receptor and long receptor occupancy. The initial administration of GnRH agonist analogs is associated with an increase in LH and FSH secretion (agonist phase). The addition of GnRH agonist analogs to regimens of gonadotropin stimulation for IVF-ET appears to be associated with an increase in the number of oocytes retrieved, the number of embryos transferred, and the clinical pregnancy rate. Thus, available data support the routine use of pituitary suppression in assisted reproduction including IVF-ET.

**Table 53-3**  
Structure and Amino Acid Substitutions of GnRH Agonist and Antagonist Medications

Medication	Agonist									
	1	2	3	4	5	6	7	8	9	10

**Figure 53-5 Profile of luteinizing hormone (LH) during treatment with either a GnRH agonist or a GnRH antagonist.** The action of the antagonist is seen (blue) when women with elevated gonadotropins (menopausal) are treated. The LH levels fall immediately. Cycling women (red) are treated with an agonist, and the “agonist” phase of the preparation increases hormone release and is followed by down-regulation.

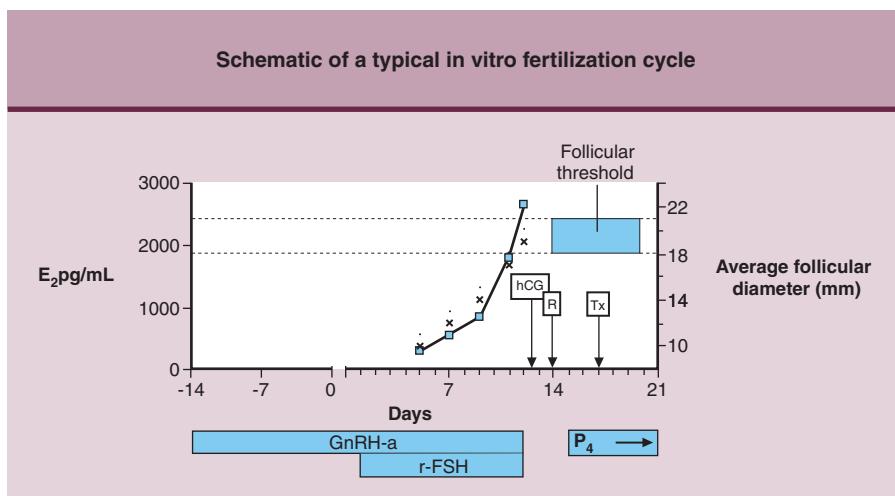

Figure 53-6 is a common protocol combining GnRH agonist suppression of pituitary gonadotropin secretion with exogenous gonadotropin administration to stimulate ovarian follicular growth. Surges of LH that occur before full follicle maturity may cause premature luteinization of the granulosa cells. In addition, a premature surge of LH may disrupt oocyte maturation. The inclusion of a GnRH agonist in ovarian stimulation protocols for assisted reproductive technologies (ART) has resulted in significant improvements in outcome (see Table 53-1). Use of the GnRH agonist to prevent LH surges in IVF-ET cycles decreased the cancellation rate to about 2% and concomitantly increased the IVF and pregnancy rate (PR) per cycle. The agonists, after an initial stimulatory effect (flare-up), led to desensitization of

the gonadotropin-secreting cells and a reduction in the number of GnRH-Rs on the cell membrane (down-regulation). Several treatment schedules currently are in use, and the long protocol begins with GnRH agonists in the luteal phase of the cycle preceding follicular stimulation.

GnRH antagonists inhibit the reproductive system through competition with endogenous GnRH for the receptor and are used in control of follicular stimulation in IVF.<sup>20</sup> Synthetic GnRH with a deletion or substitution of the histidine in position 2 is a GnRH antagonist. Additional substitutions at positions 1, 3, 6, 8, and 10 in the molecule have resulted in progressive increases in antagonistic potency. Thus, the structures of the antagonists, unlike the agonists, substantially differ from that of GnRH (see Table 53-3).

The clinical usefulness of the GnRH agonist drugs is based on their ability to reversibly block pituitary gonadotropin secretion, thereby preventing a premature surge of LH. The mechanisms of action of GnRH antagonists are completely different. The antagonists produce an immediate effect by competitive blockade of the GnRH-R. The adenohypophysis maintains its responsiveness to a GnRH stimulus (pituitary response). Owing to competitive blockage of GnRH-R by antagonist administration, LH (and to a lesser extent FSH) levels drop rapidly. Fortunately, pituitary function normalizes immediately following cessation of the antagonist. The direct and rapid action of GnRH antagonists, the dose-dependent suppression of LH and FSH, and the rapid restoration of hypophyseal function after cessation of the use of antagonists may simplify IVF follicular stimulation.

The first generation of GnRH antagonists had the disadvantage of producing adverse side effects including anaphylactic reactions due to histamine release. This side effect was greatly reduced by substituting amino acids at positions 5, 6, and 8 (see Table 53-3). Multidose treatment rapidly decreased serum levels of gonadotropins and estradiol ( $E_2$ ). Ongoing pregnancies have been reported in older women who received oocyte donation from young donors using a GnRH antagonist with human menopausal gonadotropin (hMG) and hCG to complete oocyte maturation. IVF patients older than 40 years undergoing IVF-ET cycles were treated with mid-cycle GnRH antagonists. Cancellation rates were significantly lower with GnRH antagonists (about 20%)

**Figure 53-6 Schematic of a typical in vitro fertilization (IVF) treatment cycle using a GnRH agonist and recombinant gonadotropins.** Depicted are the approximate time frames, representative ultrasound and estradiol ( $E_2$ ) measurements, and duration of medication.

compared with gonadotropin only (about 70%). However, the number of embryos transferred, cumulative embryo scores, implantation rates, and ongoing pregnancy rate did not differ from those of controls. Although these results were preliminary, the addition of GnRH antagonists avoided ovarian suppression at the start of follicular stimulation and prevented the premature LH surge at mid-cycle.

### Oocyte Retrieval

In the early days of IVF, surgical retrieval of oocytes required laparoscopy. Transabdominal approaches using the bladder window were also used. Today, almost all retrievals follow a transvaginal approach made possible by the use of high-resolution transvaginal scanners and attached needle guides (Fig. 53-7). Aspiration of the follicular fluid is possible with a small-gauge needle attached to suction. Oocyte recovery ranges from 50% to 80% of follicles producing oocytes. The retrieval is quick, often accomplished in 20 to 30 minutes, and complications are infrequent.

The type of anesthesia used ranges from conscious sedation with midazolam and fentanyl, to deeper sedation with propofol, and in some clinics general anesthesia is used. The choice hinges on patient and physician preference, but light intravenous (IV) sedation provides adequate pain relief and is cost effective.

Retrieval is most often accomplished in a room adjacent to the embryo culture room, for rapid transport of the follicular fluid to the laboratory environment. Postoperative recovery time is short and depends on the type of anesthesia used.

### Embryo Transfer

Embryo transfer is the final step in the IVF process and has received considerable attention as a possible factor in pregnancy success. Obviously, embryos must be successfully transferred for pregnancy to occur. A gray area surrounds the significance of the type of transfer catheter, the use of ultrasound, the exact location in the cavity for embryo placement, and other factors that potentially contribute to this process. Clinical experience reveals that the most difficult transfers are sometimes successful, while other factors presumably prevent pregnancy in the majority of smooth, atraumatic transfers.

Debate continues about the value of trial or mock transfer. In many clinics, trial transfer is used to preset the length of the transfer catheter for a more efficient transfer. In addition, patients with a potentially difficult transfer can be identified ahead of time. For some cases, alternative transfer catheters can be selected. Mock transfers have been performed with and without sonogram guidance. While randomized trials are lacking, a number of studies have looked at the distance from the fundus

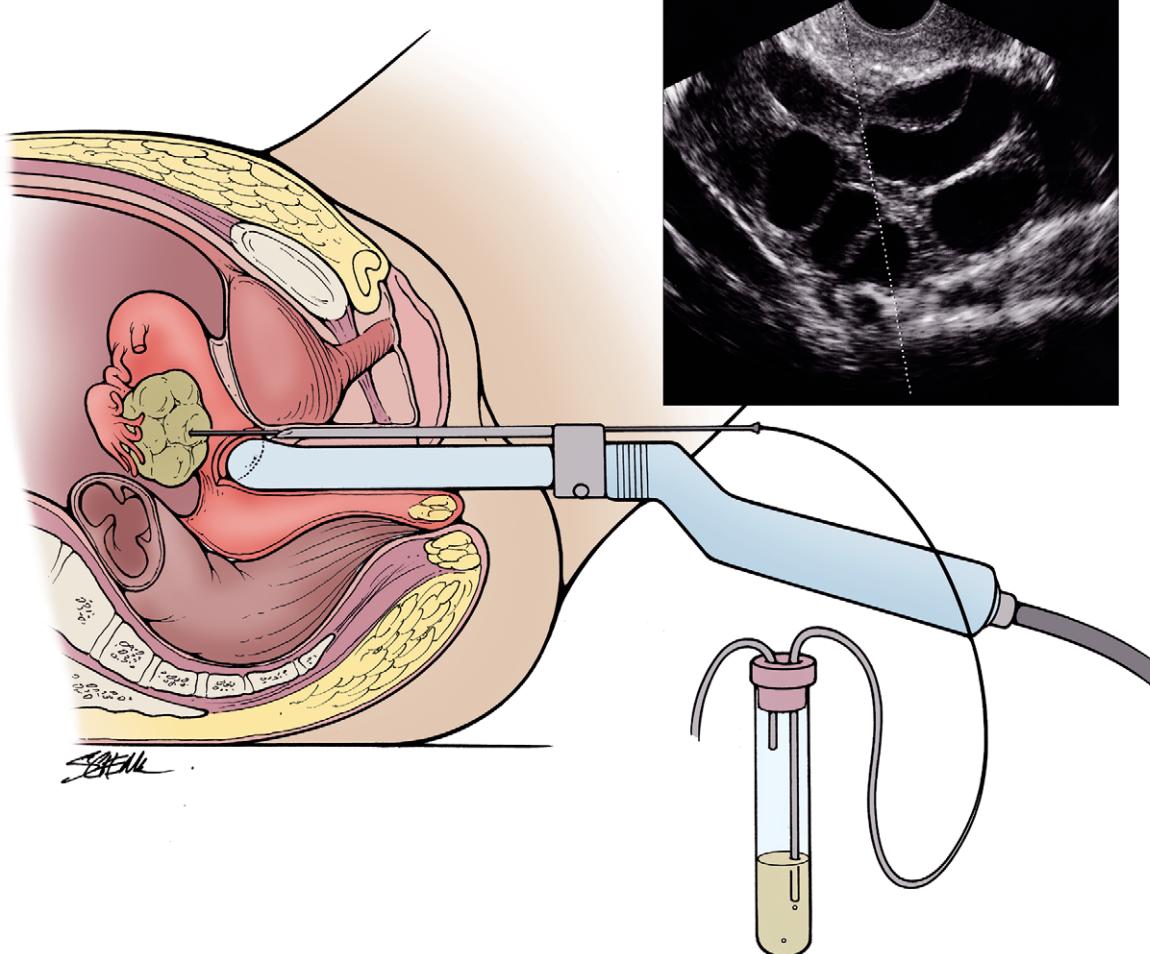

Figure 53-7 Transvaginal oocyte retrieval.

## Reproductive Endocrinology and Infertility

for embryo placement. In a retrospective study involving 699 embryo transfers, distance from the fundus as measured by ultrasound was better correlated with pregnancy than was the distance derived by clinical touch at mock transfer.<sup>21</sup> These authors concluded that ultrasound-guided trial or mock transfer was beneficial.

At the time of actual embryo transfer, randomized controlled trials indicate a benefit in the use of ultrasound to guide the transfer catheter.<sup>22,23</sup> In addition, this factor has been examined with the use of cryopreserved embryos. In a study of 184 randomized patients undergoing thawed embryo transfer cycles with hormone replacement under pituitary suppression, ultrasound-guided transfer was compared with clinical touch.<sup>24</sup> Both pregnancy and implantation rates in the ultrasound group (34.4% and 19.8%, respectively) were significantly higher than the corresponding values (19.7% and 11.9%, respectively) in the clinical touch group.

### Luteal Support

Luteal support is important for IVF success. Long GnRH agonist protocols appear to create a luteal phase defect. The most common modalities used have been oral, vaginal, and intramuscular (IM) progesterone. A meta-analysis suggests that of these routes of administration, oral progesterone is the least effective.<sup>25</sup> IM progesterone carries a slight benefit over the vaginal route, although there is a fair amount of disagreement on this point. In comparison with placebo, delivery rates were improved with the addition of IM progesterone, with an RR of 5.50 (95% CI 1.25–35.53). In the meta-analysis, delivery rates were compared between IM and vaginal progesterone, and the IM route conferred an RR of 2.06 (95% CI 1.48–2.88). The most common vaginal progesterones used have been micronized progesterone capsules and gel preparation (Crinone), the latter an FDA-approved product. Luteal support with hCG has been used and produced excellent ongoing pregnancy rates. However, the rate of hyperstimulation was unacceptable, and this practice has largely been abandoned. Other forms of progesterone, including a progesterone-containing vaginal ring and 17-hydroxycaproate, appear to be effective. The duration of therapy has not been adequately determined, and studies have examined use from as short as the first positive pregnancy test through the first 12 weeks of pregnancy.

## COMPLICATIONS OF IN VITRO FERTILIZATION

### Ovarian Hyperstimulation Syndrome

Ovarian hyperstimulation syndrome (OHSS) is an exaggerated response to ovulation induction therapy.<sup>26</sup> OHSS is associated with exogenous gonadotropin stimulation followed by hCG and is rarely observed with other agents (clomiphene citrate and GnRH). Clinicians who prescribe ovulation-inducing agents must recognize and manage OHSS.<sup>27–29</sup> Fortunately, OHSS usually is a self-limiting disorder that resolves spontaneously, but it may persist for longer periods in conception cycles.

### Pathophysiology

The hallmark of OHSS is an increase in capillary permeability resulting in a fluid shift from the intravascular space to third

space compartments.<sup>30,31</sup> Vascular endothelial growth factor (VEGF) has emerged as one of the factors most likely involved in the pathophysiology of OHSS.<sup>32</sup> Other factors including angiotensin II, insulinlike growth factor 1 (IGF-1), epidermal growth factor (EGF), transforming growth factor (TGF), basic fibroblast growth factor (BFGF), platelet-derived growth factor (PDGF), interleukin 1 (IL-1), and interleukin 6 (IL-6)<sup>33</sup> may also be involved.

### Risk Factors

The following factors increase the risk for developing OHSS<sup>34</sup>:

- Young age
- Low body weight
- Polycystic ovary syndrome (PCOS)
- High doses of gonadotropins
- Rapidly rising serum estradiol levels
- Previous episodes of OHSS

Risk also increases when repeated doses of exogenous hCG are administered in superovulation and ART cycles (for luteal-phase support) and decreases when exogenous progesterone, rather than hCG, is used to support the luteal phase. Pregnancy increases the likelihood, duration, and severity of OHSS symptoms.

### Clinical Features

OHSS has been classified as mild, moderate, or severe.<sup>35</sup> However, the clinical symptoms and signs of OHSS exhibit a continuum of scope and severity that defies attempts at specific classification or staging. Mild manifestations of OHSS are relatively common and include transient lower abdominal discomfort, mild nausea, vomiting, diarrhea, or abdominal distention. Moderate illness is recognized when symptoms persist, worsen, or include ascites that may be demonstrated by increasing abdominal girth or ultrasound evaluation. Serious illness exists when extreme pain occurs with rapid weight gain, tense ascites, hemodynamic instability, and respiratory difficulty, oliguria, or laboratory abnormalities. Risk of thromboembolism is increased as a result of hemoconcentration, diminished peripheral blood flow, and inactivity due to abdominal distention and pain. Life-threatening complications of OHSS include renal failure, adult respiratory distress syndrome (ARDS), hemorrhage from ovarian rupture, and thromboembolism.

### Outpatient Management

Patients with mild manifestations of OHSS can be managed with oral analgesics. Intercourse should be avoided. Daily weight measurements and serial laboratory assessment of hematocrit, electrolytes, and serum creatinine can monitor progression.

Recommendations for the outpatient management of persistent and worsening OHSS include the following:

- Oral fluid intake (commercially available electrolyte-supplemented drink) should be maintained at more than 1 L/day.
- Strenuous physical activity should be avoided.
- Weight should be recorded daily.
- Weight gain of more than 2 pounds per day or decreasing urinary frequency (output) should prompt an evaluation.

## Hospitalization

Hospitalization is required based on severity of symptoms, analgesic requirements, and other social considerations (availability of responsible adult supervision, support, and assistance with child care).<sup>36,37</sup> Given the scope of symptoms and the potential for complications, most women with severe OHSS merit hospitalization for more treatment.

## Fluid Management

Hospitalized patients require IV fluid management to address the acute need for volume expansion while also considering the marked increase in vascular permeability that accompanies severe OHSS. Renal and pulmonary function must be carefully monitored. Rapid initial hydration may be accomplished with a bolus of IV fluid (500 to 1000 mL). Fluids should be administered in the volumes necessary to maintain adequate urine output (>20 to 30 mL/h). Five percent dextrose in normal saline is preferable to lactated Ringer's solution. Correction of hypovolemia, hypotension, and oliguria has the highest priority, given that fluid administration may contribute to the accumulation of ascites.

## Paracentesis

Ultrasound-guided paracentesis or transvaginal culdocentesis may be indicated for patients with ascites that causes pain, compromised pulmonary function, or oliguria/anuria. Rapid removal of large volumes of ascitic fluid has been observed to trigger dangerous compensatory fluid shifts in elderly patients with malignant ascites, but the risk of this complication in women with OHSS is small. Serial paracentesis may be required to maintain adequate renal and pulmonary function.

## Complications

Thromboembolism is a life-threatening complication of severe OHSS. Full-length venous support stockings or an intermittent pneumatic compression device are recommended, and prophylactic heparin therapy (5000 U subcutaneously every 12 hours) should be seriously considered. Patients with severe OHSS who may require surgery for a ruptured ovarian cyst with hemorrhage, torsion, or an ectopic pregnancy present a unique challenge for the anesthesiologist who is unlikely to be familiar with the pathophysiology of the syndrome and must minimize the additional risks involved.

## Prevention

The keys to preventing OHSS are experience with ovulation induction therapy and recognition of risk factors for OHSS. Withholding further gonadotropin stimulation and delaying hCG administration until estradiol levels plateau or decrease significantly can reduce risks of OHSS.<sup>38</sup> Available evidence suggests that such "coasting" does not adversely affect outcome in IVF cycles unless it is prolonged (>3 days).<sup>39</sup> Given the evidence suggesting that hCG may play a pivotal role in the development of OHSS, a lower dose of hCG (e.g., 5000 IU vs. the standard 10,000 IU dose) may be prudent for patients judged to be at high risk for OHSS. Alternatively, a GnRH agonist (e.g., leuprolide 0.5 to 1.0 mg subcutaneously) rather than hCG might be used to stimulate an endogenous LH surge to promote final oocyte maturation and induce ovulation. This approach would

be useful only in cycles not involving previous down-regulation or use of a GnRH antagonist (e.g., ganirelix, cetrorelix). Regardless of whether hCG or a GnRH agonist is administered at mid-cycle, the use of progesterone for luteal phase support rather than supplemental doses of hCG may further reduce the risk of OHSS. Prophylactic IV administration of albumin at oocyte retrieval has been suggested as a means to reduce the risk of OHSS.<sup>40</sup> Studies of its efficacy have mixed results, and albumin treatment risks exacerbation of ascites, allergic reactions, and virus/prion transmission. However, albumin infusion may be expected to prevent one case of severe OHSS for every 18 women at risk who are treated.

## Multifetal Pregnancy

The incidence of multiple pregnancy and delivery has increased dramatically over the past decades in many developed countries. In IVF, the usual practice of transferring two or more embryos to achieve higher pregnancy rates results in a high incidence of multiple births. In the World Collaborative Report on IVF figures for 1995 showed that 24.7% of the pregnancies were twin, 4.1% were triplet, and 0.2% were quadruplet. Multiple pregnancy carries additional risks for both mother and offspring and requires more elaborate monitoring of the pregnancy. Obstetric complications associated with multiple pregnancy include prenatal screening problems, an increased incidence of preeclampsia and eclampsia, antepartum hemorrhage, preterm labor, intrauterine growth retardation, and surgical and assisted delivery. Among neonatal complications the most common are low birth weight due to prematurity or placental dysfunction and congenital malformations. The perinatal mortality is five to six times higher among twins compared with singletons.

The pregnancy and neonatal complications observed in IVF pregnancies were almost entirely due to multiple pregnancies, the majority of which were twin pregnancies. The rate of prematurity (<37 weeks) among twin pregnancies was 47.3% compared with 11.2% among singletons.

## Malformations

Multiple pregnancies are also associated with infant and childhood morbidity such as cerebral palsy and mental retardation.<sup>41</sup> Two recent studies of the incidence of cerebral palsy reported dramatically increased risks in multiple births: twins had risks approximately 5 times higher and triplets 17 times higher than singletons, and the risk of producing at least one child with cerebral palsy was estimated to 1% to 5% for twin, 8% for triplet, and almost 50% for quadruplet pregnancies.<sup>42,43</sup>

Most studies of child development after IVF carried out to date include relatively small numbers of children and have a limited period of follow-up, and consequently the risks for long-term handicap are not well established.

Which methods are available today to reduce the number of multiple births after ART? An overall change in transfer policy to transfer only one embryo at a time would certainly result in mainly singletons.<sup>44,45</sup> This might be unacceptable to both patients and practitioners, who aim at the best possible rates of success. An alternative to an overall one-embryo transfer would be an individualized embryo transfer policy. It seems possible to identify a subgroup of patients having an increased risk of multiple birth and offer them one-embryo transfers. In a recent

## Reproductive Endocrinology and Infertility

publication, elective one-embryo transfer showed a satisfactory pregnancy rate (29.7% per transfer) in a selected group of patients, the pregnancy rate being similar to that of the routine two-embryo transfer program.

Embryo/fetal reduction, as a third strategy to reduce the number of multiple births, has been used worldwide.<sup>46</sup> Despite the fact that collaborative data have reported satisfactory outcome for the children and limited risks for the mother, this kind of intervention raises serious ethical and psychological problems. It may be indicated in cases of particularly high-order multiple pregnancies but can never be justified for reduction of twins.

### LABORATORY TECHNIQUES

Despite all the effort and research devoted to follicular stimulation, retrieval, and embryo transfer, the most important part of any IVF program is the laboratory. The initial laboratory steps in an IVF treatment cycle are oocyte identification and preparation for fertilization. The technique of combining oocyte and sperm in the laboratory has evolved over the years. Standard insemination occurs in the Petri dish and may be facilitated by insemination under oil. The most remarkable change in assisted reproductive technology in the last decade has been the development and universal adoption of intracytoplasmic sperm injection (ICSI). Initial attempts at micromanipulation led to the development of subzonal insertion and breaching of the zona pellucida. In 1990 the first use of direct injection of sperm into the cytoplasm of the oocyte was reported. Fertilization rates with ICSI are 80% to 90% and produce excellent pregnancy rates in couples with male infertility. In cases where there is only a single factor, male infertility can be corrected in more successful fashion than almost any other diagnosis. The additional use of surgical retrieval of sperm in cases of azoospermia has created a remarkable change from the time when male factor infertility had no effective therapy. Surgical sperm retrieval includes percutaneous aspiration of the vas deferens and testicular biopsy. Males with cystic fibrosis provide the classic indication for testicular biopsy, since they have normal sperm production but an ejaculatory obstruction.

Laboratory changes in culture media have led to longer in vitro culture periods. Embryos are now routinely transferred after 3 days of culture when the embryos may be at the 6- to 12-cell stage. Alternatively, blastocyst stage transfer on days 5 to 6 has also been effective. A number of randomized trials have been performed, and overall the pregnancy rates with blastocyst transfer are not different, although multiple pregnancy rates do differ. Day 3 transfers are often performed with a higher number of embryos, yielding higher multiple pregnancy rates. When the number of embryos transferred is the same, pregnancy and multiple pregnancy rates do not differ.<sup>47</sup> Cancellation rates for transfer are higher when embryo culture is extended to the blastocyst stage, and most clinics use specific criteria before moving to blastocyst transfer.

Excess embryos resulting from an IVF cycle are cryopreserved for future attempts at pregnancy. Embryos that are frozen have a lower probability of implanting, and typical pregnancy rates are half those of "fresh" embryo transfer pregnancy rates. Cryopreservation of oocytes has been problematic, but pregnancies have been reported from frozen eggs.<sup>48</sup>

Assisted hatching is a laboratory technique that holds promise for improving fertility in certain populations. The blastocyst develops within the zona pellucida, and this membrane must break down in order for the trophoblast to invade the decidua and establish pregnancy. Assisted hatching was conceived to help with this process and has been demonstrated to improve implantation rates.<sup>49</sup> In large studies, assisted hatching has not been shown to be beneficial when used in all IVF populations.<sup>50</sup> It does seem to be effective in selected cases of advanced maternal age, thick zonae, and repeated implantation failure.<sup>51</sup> The use of a laser for assisted hatching, in place of chemical or mechanical means, may offer some advantages.<sup>52</sup>

The efforts to enhance laboratory techniques and quality control have led to accreditation of laboratories and to certification of laboratory directors in IVF programs. Evidence of certification of the laboratory by the College of American Pathologists (CAP) and the Clinical Laboratory Improvement Act (CLIA), as well as a designation as a High Complexity Laboratory Director for the embryologist in charge by the American Board of Bioanalysts, is critical in today's environment. Mechanisms for quality control have created a great deal of standardization of pregnancy rates in laboratories around the United States among patients who are expected to have a good outcome.

### Complex Reproductive Solutions

The advent of improved laboratory techniques and the enhancement of clinical IVF has given clinicians and patients the ability to create pregnancies in ways that were previously not recognized. One of the earliest approaches in circumventing reproductive disorders with a complex solution was the use of donor sperm for azo- or oligospermia. This technique has been accepted worldwide for some time, and for many years the use of frozen sperm has improved the safety and convenience of this approach. Donor insemination has to some degree been replaced by advances in ICSI and surgical sperm retrieval but remains a valid option for couples with male factor infertility.

Donor oocyte cycles are a solution for poor egg quality or failed ovarian function. Oocytes obtained from a donor in an IVF treatment cycle are fertilized with sperm from the recipient's husband, and embryos resulting from this process are transferred to the recipient. All the clinical steps in this approach are part of the routine IVF protocol. The legal and ethical issues are the aspects of this treatment that can be complicated. Fortunately, there rarely are legal disputes over gametes, unlike the situation in pregnancies resulting from gestational carriers. Donor oocytes can be from either known or anonymous donors, depending on the wishes of the couple. While pregnancies have been reported in recipients over age 50, most programs favor restricting this practice to recipients who have yet to go through natural menopause.

If the fertility problem lies not with the ovary but with the uterus, then either a gestational carrier or a surrogate can be used. These cases have drawn the attention of the public, since disputes over parenthood do occur when the woman delivering the child is not the genetic parent. Gestational carriers are the recipients of an embryo transfer, usually in a case where the embryo is created by eggs and sperm from an infertile couple. Most commonly, this technique would be used in the case of an

extreme uterine abnormality or absence of the uterus. The couple would go through standard IVF with oocyte retrieval and fertilization occurring with their eggs and sperm. The resulting embryos would then be transferred to the gestational carrier, and pregnancy and delivery would be routine. This process, while requiring attention to legal and social issues, does not present any unusual clinical approaches. Gestational surrogates are typically used when both the uterus and the ovary are defective in the infertile woman. In surrogacy, the woman carrying the pregnancy is impregnated via insemination and, once pregnant, carries and delivers a child that is genetically related.

Cryopreservation of embryos is an important technique for enhancing pregnancy rates, by allowing all the mature oocytes from a cycle to be inseminated, and then allowing biology to dictate which oocytes will produce healthy embryos. This eliminates the need to restrict the fertilization process at a biological point in time when judging quality may be difficult. Once fertilized, most programs then utilize all healthy embryos for either a "fresh" transfer or for freezing and subsequent frozen/thawed embryo transfer. Embryos resulting from this process may become available for embryo donation, if the couple creating the embryos is finished with childbearing or their relationship is dissolved. Embryo donation follows the same clinical steps as a routine frozen embryo transfer: preparation of the recipient with hormonal stimulation and then embryo transfer. Embryo donation can be a responsible and ethical solution for the difficult problem of "excess" embryos.

## IN VITRO FERTILIZATION CASE HISTORY

To understand the IVF treatment process, consider a 32-year-old gravida 0 who presents for an infertility evaluation. Her prior record includes a hysterosalpingogram revealing bilateral hydro-salpinges, and semen analysis reveals restrictive oligospermia. Ultrasound confirms fluid-filled adnexal structures consistent with tubal pathology. The patient reports regular cycles and has a midluteal progesterone of 20 ng/mL. Infectious disease screening is negative.

She elects to proceed with IVF and ICSI secondary to tubal disease and male factor. The pretreatment sonohysterogram and trial transfer are normal, and she had bilateral salpingectomy prior to therapy.

A long down-regulation protocol is chosen for follicular stimulation, and the patient receives GnRH agonist subcutaneously from day 21 of a cycle prior to gonadotropin stimulation. Two weeks later, she reports menses, and an ultrasound of the reproductive tract is unremarkable. Daily injections of r-FSH are started in addition to the concomitant GnRH agonist. On day 5 of stimulation, estradiol measurement confirms a brisk response to stimulation and the patient decreases her gonadotropin dose. On day 8 and again on day 10, ultrasound and estradiol measurements confirm a rise in estradiol and growth of the follicles at approximately 2 mm per day (see Fig. 53-6). When an estradiol measurement reflects 300 pg/mL per mature follicle, and follicular measurements demonstrate at least two follicles that are 18 mm or greater, the patient is scheduled for transvaginal oocyte retrieval. She self-administers hCG (10,000 IU) 37 hours prior to her planned procedure and stops the GnRH agonist on

the day of hCG administration. hCG will trigger final maturation of the oocyte so that metaphase II oocytes are obtained at the time of retrieval.

Immediately after oocyte retrieval, ICSI is performed on mature oocytes because of the history of a restrictive male factor. The following day (day 1), fertilization is confirmed when two extruded polar bodies and two pronuclei are identified within the zygote. In this case, a check for cleavage the next day confirmed that 80% of the zygotes have now become embryos at the 2- to 4-cell stage. On day 3, an embryo transfer of two, 8-cell embryos was performed, and four additional dividing embryos were cryopreserved for potential later attempts at pregnancy. Progesterone supplementation for luteal support, started on the day after retrieval (day 1), is continued past the positive pregnancy test and typically maintained until the ovarian-placental shift of hormone production occurs (around week 8 to 10 of gestation). An ultrasound confirms a single intrauterine pregnancy.

## KEY POINTS

- From 40% to 50% of infertile couples are infertile because of a significantly impaired male factor.
- Approximately 20% of couples are infertile *solely* because of a male factor.
- Etiologies for male infertility can be simply classified as pretesticular, testicular, and post-testicular causes.
- The advancement of assisted reproductive technologies not only has revolutionized the field of male infertility, but now also offers reproductive options to men who could not have conceived several years ago.

Infertility is defined as the inability to conceive after 1 year of unprotected, adequately timed intercourse. Approximately 15% of all couples are infertile. In up to 50% of these infertile couples, the infertility has a male factor component; 20% of couples will not be able to conceive solely because of a male factor.

Traditionally, the initial evaluation of the male was performed only when the couple had been unable to conceive after 1 year of unprotected intercourse. However, because many couples are now postponing parenthood, and because the risk of a female's infertility increases as she passes age 35, most male infertility evaluations are performed on initial presentation (six months of unprotected intercourse). A detailed history and physical examination and a semen analysis are essential initial steps in diagnosing the infertile male. With the advancement of assisted reproductive technologies (ARTs), a variety of treatment options are now available for the infertile couple.

## ETIOLOGY

Causes of male infertility can be simply classified into three categories: pretesticular, testicular, and post-testicular. Pretesticular causes of infertility are generally associated with endocrinopathies. These endocrinopathies, which include multi-organ syndromes, androgen receptor and conversion disorders, neoplasms, and exogenous hormones, have numerous causes. Testicular causes of infertility include genetic disorders, varicoceles, gonadotoxins, cryptorchidism, androgen synthesis disorders, impaired sperm motility, and certain acquired disorders. Finally, post-testicular causes of infertility involve obstruction of sperm passage, ejaculatory dysfunction, and erectile dysfunction. It is important to remember that the etiology of infertility is unknown in 25% of infertile males.

## Pretesticular Causes of Infertility

### *Endocrinopathies*

Causes of endocrinopathies include congenital disorders, neoplasms, systemic diseases, use of exogenous steroids, and certain androgen disorders (Table 54-1). Note that except for androgen disorders, which are associated with hypergonadotropic hypogonadism, most endocrinopathies are associated with hypogonadotropic hypogonadism. To understand how endocrine disorders can lead to infertility, one must first have a basic understanding of how the hypothalamic-pituitary-gonadal (HPG) axis functions and how it affects the testis.

### *Hypothalamic-Pituitary-Gonadal Axis*

The hypothalamus receives input from the central nervous system in the form of neurotransmitters (dopamine, serotonin, acetylcholine, and norepinephrine) and neuropeptides (endogenous opioids). It also receives feedback from the testes and adrenal glands in the form of steroids (i.e., estradiol and testosterone) and protein hormones (i.e., inhibin). In turn, the hypothalamus secretes gonadotropin-releasing hormone (GnRH) in a pulsatile fashion from the preoptic and arcuate nucleus. GnRH is released into the portal hypophyseal venous system that leads into the anterior pituitary (Fig. 54-1).

The anterior pituitary secretes luteinizing hormone (LH) and follicle-stimulating hormone (FSH) in response to GnRH. LH binds to receptors on Leydig cells in the testis to cause the release of testosterone. Testosterone enters the circulation and can be converted to either dihydrotestosterone (DHT), by the enzyme 5 $\alpha$ -reductase, or to estradiol. Testosterone, DHT, and estradiol act independently to modulate LH secretion. It is believed that testosterone acts at the hypothalamic level while estrogen acts at the pituitary level, and both cause negative feedback inhibition. The initiation and maintenance of spermatogenesis by the seminiferous tubules is dependent on testosterone as well as on the binding of FSH to receptors on Sertoli cells. Sertoli cells release inhibin and activin, which provide negative and positive feedback, respectively, to the hypothalamus and to the anterior pituitary.

Prolactin has several effects on the HPG axis. Hyperprolactinemia has been shown to inhibit GnRH secretion as well as inhibit the effects of testosterone. Patients with elevated prolactin and low testosterone levels do not show improvement in libido and sexual function when given testosterone supplementation. In addition, these patients have low LH levels, indicating that the hypothalamus does not respond to the low testosterone levels. Finally, hyperprolactinemia has been shown to alter the production of DHT. It is therefore important to

check prolactin levels in all infertile males when an endocrine problem is suspected.

### Congenital Disorders

Kallmann syndrome occurs in approximately 1 in 10,000 to 1 in 60,000 live births and is the most common X-linked disorder associated with male infertility. Most occurrences, however, are of the "sporadic" type. Kallmann syndrome consists of congenital, isolated idiopathic hypogonadotropic hypogonadism and anosmia. Other clinical features may also include congenital deafness, cleft palate, cerebellar dysfunction, renal abnormalities, cryptorchidism, and diabetes mellitus. The *KAL1* gene, located on chromosome Xp22.3, is responsible for the X-linked form of this syndrome. This gene encodes the protein anosmin, which plays a critical role in the migration of GnRH neurons and olfactory nerves to the hypothalamus. Because these patients lack FSH and LH stimulation to the testis, testosterone production and spermatogenesis are absent. Through hormone replacement therapy with FSH and human chorionic gonadotropin (hCG), many of these patients can become fertile.

Prader-Willi syndrome is associated with idiopathic hypogonadotropic hypogonadism, mild to moderate mental retardation, obesity, and infantile hypotonia. The syndrome is caused by a mutation or deletion on the short arm of chromosome 15 when it is inherited from the patient's father, or less commonly, when two chromosomal copies of this locus are inherited from the patient's mother. Treatment involves hormone replacement therapy with FSH and hCG.

Gene mutations associated with hypogonadotropic hypogonadism include mutations in the *DAX1* and *PC1* genes. The

**Figure 54-1 Hypothalamic-pituitary-gonadal axis.** Testosterone is aromatized (\*) to estradiol in the brain and peripheral circulation. Note that testosterone may also have a small inhibitory effect on the anterior pituitary to decrease luteinizing hormone secretion.

*DAX1* gene is found on the X chromosome and encodes for a nuclear hormone receptor that has a critical role in the development of the hypothalamus, adrenals, pituitary, and gonads. This gene also appears to function in maintaining the epithelial integrity of the testis and spermatogenesis.<sup>1</sup> Mutations with the *DAX1* gene are associated with congenital adrenal hyperplasia and idiopathic hypogonadotropic hypogonadism. The *PC1* gene, a convertase-1 gene, influences GnRH secretion by the hypothalamus. Mutations in this gene are associated with idiopathic hypogonadotropic hypogonadism, obesity, and diabetes mellitus.

### Neoplasms

Neoplasms such as pituitary adenomas and prolactinomas have been associated with hypogonadotropic hypogonadism and infertility. Pituitary adenomas can cause a decrease in gonadotropin release via direct compression of the portal system or by decreased LH/FSH secretion. These patients may present with peripheral visual field defects, headaches, and decreased libido. A pituitary adenoma must be considered in any patient experiencing these symptoms and a decreased testosterone level along with a low serum LH level. A magnetic resonance imaging

(MRI) scan of the head should be obtained for these patients. Large lesions are generally treated via transsphenoidal surgical resection.

Prolactin microadenomas cause an elevation of prolactin and a subsequent inhibition of LH and FSH secretion. Hyperprolactinemia can also result in altered DHT production, leading to impaired spermatogenesis. Management may consist of surgical excision of the adenoma or medications. Most patients are treated medically with cabergoline (Dostinex) or bromocriptine (Parlodel).

### **Systemic Disease**

Hypogonadotropic hypogonadism has been associated with systemic diseases such as renal and liver failure and primary hypothyroidism. Renal failure and associated uremia can lead to impotence, altered spermatogenesis, and decreased libido. These changes may be related to estrogen excess, elevated prolactin levels, or elevated parathyroid hormone and usually will be corrected by successful renal transplantation. Liver failure results in decreased testosterone levels, increased testosterone binding to plasma proteins, and increased plasma estrogen levels. Finally, primary hypothyroidism is associated with an elevation in thyrotropin levels. Because thyrotropin stimulates prolactin secretion, patients may suffer from impaired gonadotropin release and altered DHT production. Thyroxine replacement usually returns thyrotropin to normal levels.

### **Exogenous Steroids and Drugs**

Anabolic and androgenic steroid abuse are common causes of male infertility in athletes and body builders. Exogenous androgenic steroids suppress pituitary LH release, which results in decreased intratesticular testosterone production. Because normal spermatogenesis requires intratesticular testosterone, these patients usually are azoospermic. Although the effects may be reversible, this reversibility depends on the duration and dosage of exogenous steroid use. A mistake commonly made is to prescribe testosterone supplementation to a patient who has a low serum testosterone level when the couple is trying to conceive. Other drugs that are associated with hypogonadotropic hypogonadism include selective serotonin reuptake inhibitors, which cause an increase in prolactin levels. Table 54-2 lists medications and drugs that can cause male infertility.

### **Androgen Disorders**

Androgen disorders can be classified as disorders of androgen synthesis, androgen receptors, or androgen conversion. Androgen receptor and conversion disorders are considered pretesticular causes of male infertility, and androgen synthesis disorders are classified as testicular causes of male infertility.

Androgen receptor disorders, also known as androgen insensitivity syndromes, are a group of X-linked disorders that include Rosewater's syndrome, Reifenstein's syndrome, testicular feminization (male pseudohermaphroditism), and Lub syndrome. These syndromes are inherited as X-linked recessive traits because the androgen receptor gene is located on the X chromosome at Xq11–12. Complete androgen insensitivity leads to a female phenotype with intra-abdominal testes; incomplete androgen insensitivity leads to ambiguous genitalia, hypospadias, and micropenis.

**Table 54-2**

<b>Decreases sperm fertilization capacity</b>	
Calcium channel blockers	

Disorders in androgen conversion disorders include  $5\alpha$ -reductase deficiencies. The enzyme  $5\alpha$ -reductase is involved in the conversion of testosterone to DHT. DHT is responsible for the development of the external male genitalia and the prostate. Newborns present as male pseudohermaphrodites with severe perineoscrotal hypospadias and a blind vaginal pouch that opens into a urogenital sinus. These patients are generally infertile because they are unable to effectively deliver sperm and their sperm counts are low. However, there has been a report of paternity by intrauterine insemination with sperm from a man with  $5\alpha$ -reductase deficiency.<sup>2</sup>

### **Testicular Causes**

Testicular causes of infertility are generally associated with hypergonadotropic hypogonadism. They include varicoceles, cryptorchidism, genetic abnormalities, gonadotoxins, multiorgan syndromes, androgen synthesis disorders, impaired sperm motility,

and certain acquired diseases that temporarily or permanently suppress spermatogenesis (Table 54-3).

### Varicoceles

Varicoceles are dilated internal spermatic veins (gonadal veins) that terminate as the pampiniform plexus and drain the testis. The dilation of these veins is thought to be secondary to incompetent venous valves. Varicoceles have an incidence of approximately 15% in the general population, increasing to up to 50% of men with primary infertility and up to 69% of men with secondary infertility.<sup>3</sup> These dilated veins are more commonly found on the left side or bilaterally than on the right side alone, possibly because of the greater length of the left internal spermatic vein and because of the left spermatic vein's perpendicular insertion into the left renal vein.

Many theories have been suggested to explain why varicoceles lead to impaired spermatogenesis and male infertility. One theory is that poor venous drainage leads to disruption of the countercurrent exchange of heat from the spermatic cord and thus elevates scrotal temperatures. The elevated scrotal temperatures lead to impaired spermatogenesis. Another theory is that poor venous drainage leads to impaired drainage of gonadotoxins from the testis.

Varicoceles have been shown to cause a progressive deterioration in semen parameters.<sup>3</sup> Subfertile males with varicoceles

have been found to have semen with decreased motility, decreased density, and abnormal morphology<sup>4</sup> as well as abnormal testosterone and FSH levels.<sup>5</sup>

### Cryptorchidism

The incidence of cryptorchidism in the full-term infant is approximately 3%. However, by age 1, 75% of these testicles will spontaneously descend and the overall incidence of cryptorchidism becomes approximately 0.8%. Testes that have not descended by the time an infant is age 6 months are not likely to descend. Patients with a history of cryptorchidism not only have decreased sperm concentrations, but they also demonstrate lower basal levels of LH and testosterone and have a worse response to GnRH stimulation.<sup>6</sup> These patients are also at a 40 times greater risk of developing testicular cancer.

The amount of time the cryptorchid testis is left in place can influence the degree of spermatogenesis. If the cryptorchid testis is surgically corrected postpubertally, 69% of testes will have no spermatogenesis, with either testicular agenesis, atrophy, or a Sertoli-cell-only histologic pattern.<sup>7</sup> Other studies have shown that if left untreated, 44% of men with unilateral cryptorchidism will be either oligospermic or azoospermic, as opposed to 100% of men with bilateral cryptorchidism.<sup>8</sup> In contrast, men who had an orchioectomy before puberty were found to have normal sperm densities (>20 million/mL) 62% and 30% of the time for unilateral and bilateral cryptorchidism, respectively.<sup>9</sup> Kumar and colleagues showed that in patients with surgically corrected cryptorchid testes, fertility rates ranged from 84% in those with unilateral cryptorchidism to 60% in those with bilateral cryptorchidism.<sup>10</sup>

### Genetics

#### Karyotype Abnormalities

Karyotype abnormalities have been found in 12% of azoospermic and severely oligospermic males.<sup>11</sup> Klinefelter's syndrome (47,XXY or 46,XY/XXY) is the most common sex chromosomal abnormality, occurring in approximately 1 in 650 live male births; it accounts for up to 11% of all cases of azoospermia.<sup>11,12</sup> This syndrome is due to paternal or maternal sex chromosomal nondisjunction during meiosis. Roughly 8% of patients will have a mosaic 46,XY/XXY karyotype, and approximately 92% will have the 47,XXY karyotype.<sup>11</sup> These patients present with some or all of the following: small firm testis, infertility, obesity, diabetes mellitus, decreased intelligence, decreased Leydig cell function, increased height, and an increased risk of leukemia, extragonadal germ cell tumors, and breast cancer. These patients are hypogonadotropic with low-normal serum testosterone levels. They have variable amounts of sperm production and are generally unable to conceive naturally.

Several other sex chromosomal defects occur less commonly. All of these can occur in phenotypically normal males. Men with the XYY chromosome pattern, occurring in approximately 1 in 850 live births, are phenotypically normal except for increased height.<sup>12</sup> Although some of these men may be fertile, most men are shown to have Sertoli-cell-only or maturation arrest histology on testicular biopsy. Males with 46,XX karyotype (XX male syndrome) also have a normal phenotype but are infertile. This syndrome occurs in approximately 1 in 9000 live births.<sup>12</sup> It is believed that these patients suffer from a translocation of the

SRY gene on the Y chromosome to the homologous region on the X chromosome. These patients exhibit Sertoli-cell-only histology on testis biopsy and are azoospermic. They can be born with ambiguous genitalia or hypospadias. Finally, patients with mixed gonadal dysgenesis can present as phenotypic males, females, or with ambiguous genitalia. They commonly have a 45,X/46,XY mosaic karyotype, although 33% may present with a normal karyotype. This mosaic pattern is thought to be due to loss of the Y chromosome early in development. Most patients have a testis and a streak gonad, which is at risk for later developing gonadoblastoma. Normal Leydig and Sertoli cells are usually present within the testis, but the seminiferous tubules lack germ cells.

#### Gene Mutations or Deletions

The Y chromosome is the smallest chromosome in the human genome. The short arm (Yp) is associated with the *SRY* gene, or the testis-determining factor. An absent or deficient *SRY* gene results in a 46,XY female. The long arm of the Y chromosome (Yq11) contains the azoospermia factor (*AZF*) region. Three distinct regions (*AZFa*, *AZFb*, *AZFc*) are responsible for encoding proteins involved in spermatogenesis. Microdeletions in any or all of these three regions will be found in infertile males. Pryor and colleagues showed that 7% of infertile males and 2% of normal males had an *AZF* microdeletion and that the size and position of the deletion did not correlate with the severity of spermatogenic failure.<sup>13</sup>

#### Gonadotoxins

Some gonadotoxins have been discussed earlier in this chapter. It is important to remember that recreational drugs, such as alcohol, cocaine, marijuana, and tobacco, have all been implicated as gonadotoxic agents. Thermal exposures, such as hot tubs, as well as radiation, chemotherapy, and environmental toxins have also all been shown to impair spermatogenesis. Table 54-2 provides a comprehensive listing of gonadotoxic agents.

#### Multorgan Syndromes

Noonan's syndrome is one example of a multorgan syndrome that causes hypergonadotropic hypogonadism. These patients have features similar to those found with Turner's syndrome, such as webbed neck, low-set ears, ptosis, hypertelorism, cubitus valgus, short stature, congenital heart disease, and hypogonadism. Most patients with Noonan's syndrome are infertile due to primary testicular failure. Table 54-3 lists other multorgan syndromes causing hypergonadotropic hypogonadism.

#### Androgen Synthesis Disorders

Androgen synthesis is a complex process that involves the transport of cholesterol into the mitochondria. This first rate-limiting step is under the regulation of the steroidogenic acute regulatory protein (StAR). Mutations of the StAR protein result in congenital lipid adrenal hyperplasia. Patients with this disorder have external female genitalia, irrespective of karyotype, and suffer from a severe salt-wasting form of adrenal hyperplasia. The disease is lethal if glucocorticosteroids are not administered.

The synthesis of testosterone from cholesterol requires five enzymes. A deficiency in any of the first three enzymes (20,22-desmolase, 3 $\beta$ -hydroxysteroid dehydrogenase, 17 $\alpha$ -hydroxylase)

results in congenital adrenal hyperplasia. Patients presenting with this deficiency have incomplete virilization due to defective androgen synthesis. A deficiency in the last two enzymes (17, 20-desmolase and 17 $\beta$ -hydroxysteroid dehydrogenase) leads to pseudohermaphroditism in males with ambiguous genitalia or completely feminized genitalia with cryptorchid testes.

#### Motility

Poor sperm motility, or asthenospermia, is most often seen with defects in sperm morphology, or teratospermia. However, 20% of patients will have isolated asthenospermia. Factors that can contribute to poor sperm motility are infections, varicoceles, antisperm antibodies, and certain genetic abnormalities. The classic syndrome associated with immotile sperm is Kartagener's syndrome, which consists of the triad of situs inversus, bronchiectasis, and chronic sinusitis. Kartagener's syndrome is a form of immotile cilia syndrome, which is associated with structural defects in the axoneme, the basic structure of the spermatozoon tail. Immotile cilia syndrome occurs in approximately 1 in 20,000 live births, and there have been reports of successful fertilization with in vitro fertilization (IVF) and intracytoplasmic sperm injection (ICSI) in patients with Kartagener's syndrome.<sup>14</sup>

#### Acquired Disorders

Certain acquired disorders can cause testicular damage and lead to hypergonadotropic hypogonadism. These acquired disorders include trauma to the testicles, testicular neoplasms, history of orchitis, and exposure to gonadotoxic agents (see Table 54-2). These disorders are generally associated with decreased spermatogenesis.

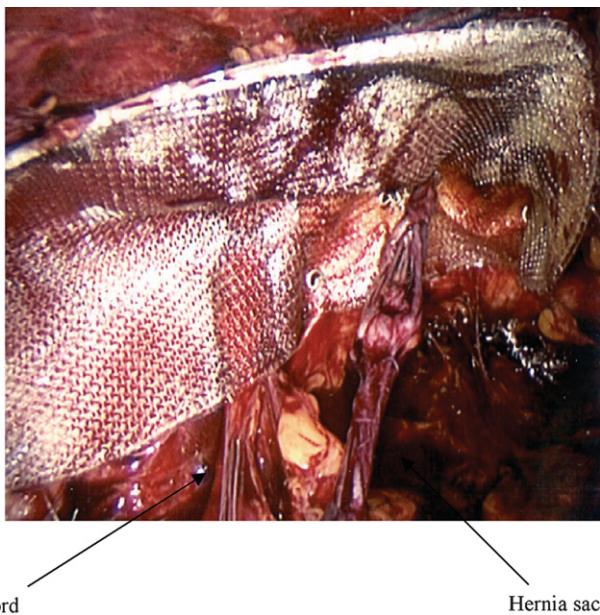

#### Post-Testicular Causes

##### Obstruction

Approximately 40% of azoospermic men have an obstructed ductal system.<sup>15</sup> Obstruction of sperm delivery can occur anywhere from the efferent ducts to the ejaculatory ducts. Causes of epididymal obstruction include chronic or recurrent epididymitis, orchiopepsy, hydrocelectomy, and other scrotal surgeries. Epididymal obstruction also is seen in men with Young's syndrome, which is characterized by bronchiectasis and inspissated epididymal secretions, causing gradual epididymal obstruction. The most frequent causes of vasal obstruction include any type of pelvic or inguinal surgery, such as herniorrhaphy and vasectomy (Fig. 54-2). Vasectomy is the leading cause of vasal obstruction in this country. Ejaculatory duct obstruction can be caused by a cyst (often a müllerian remnant), a wolffian duct malformation, prior prostatic inflammation and scarring (i.e., due to infection or trauma), prostate cancer, and stones or calcifications (Table 54-4).

Semen analysis and transrectal ultrasound (TRUS) are helpful in making the diagnosis. Because the seminal vesicles are responsible for making fructose and alkalinizing the seminal fluid, complete obstruction of the ejaculatory ducts will result in a low-volume, acidic, fructose-negative ejaculate. TRUS will support the diagnosis by showing dilated ejaculatory ducts and seminal vesicles. The seminal vesicles can be aspirated at this time to confirm the diagnosis.

In some cases, sperm passage is inhibited because of congenital bilateral absence of the vas deferens (CBAVD). CBAVD

**Figure 54-2 Hernia mesh causing vasal obstruction.**

is found in 2% of infertile males and in more than 90% of patients with cystic fibrosis. It is thought that CBAVD alone may in fact represent a milder form of cystic fibrosis. Cystic fibrosis is caused by a genetic mutation of the cystic fibrosis transmembrane conductance regulator (*CFTR*) gene; therefore, men with CBAVD and their wives should be screened for *CFTR* mutations and be referred to genetic counseling.

#### Ejaculatory Dysfunction

Ejaculatory dysfunction can be due to retrograde ejaculation or anejaculation. In order for a male to ejaculate, semen must be deposited in the prostatic urethra (emission). Coordinated

closure of the bladder neck and contraction of the pelvic floor and periurethral muscles are also necessary. Emission is controlled by the sympathetic nerves T10–L2 that course through the paravertebral sympathetic ganglion. The pudendal nerve (S2–S4) is responsible for contractions of the pelvic floor and periurethral muscles.

Retrograde ejaculation may be caused by pharmacologic, anatomic, or neurologic conditions. Medications that cause retrograde ejaculation include alpha-adrenergic antagonists used to treat benign prostatic hyperplasia and antihypertensive medications, such as prazosin and terazosin. Anatomic causes of retrograde ejaculation involve disruption of the bladder neck or internal sphincter; these are often iatrogenic following transurethral or bladder neck surgeries. Riehmann and colleagues showed that 68% of patients undergoing a transurethral resection of the prostate developed retrograde ejaculation.<sup>16</sup> Neurologic conditions that can lead to retrograde ejaculation include diabetes mellitus, spinal cord injury, and multiple sclerosis.

Anejaculation is typically seen with spinal cord injury or following retroperitoneal surgery; it can also have a psychological etiology. Ninety-five percent of spinal cord-injured patients have ejaculatory failure due to their nerve injury. Depending on the level of their spinal cord lesion, they can ejaculate through stimulation of their sympathetic nerves with electroejaculation or vibratory stimulation. Most retroperitoneal surgeries, such as a retroperitoneal lymph node dissection for testicular cancer, involve the risk of injuring the sympathetic nerves T10–L2. Injury to these nerves results in failure of emission. Finally, a psychological cause for anejaculation must be considered for any patient who suddenly is unable to ejaculate and for whom no other causes of ejaculatory dysfunction can be identified.

#### Erectile Dysfunction

Erectile dysfunction is defined as the persistent inability to achieve and maintain an erection sufficient for intercourse. Although erectile dysfunction can occur at any age, most men by age 45 have experienced erectile dysfunction at least some of the time. According to the Massachusetts Male Aging Study, complete impotence increases from 5% among men age 40 to 15% among men age 70 and older.<sup>17</sup>

The penis is composed of two dorsal cavernosal bodies and a ventral corpus spongiosum, which encompasses the urethra. Through central and peripheral stimulation, the parasympathetic nerves are activated, and the cavernosal muscles relax to allow blood to fill the cavernosal sinusoids. The expanding sinusoids compress the subtunical venous plexuses and prevent the outflow of blood. This corporal tumescence increases the intracavernosal pressure and allows for a rigid erection.

Erectile dysfunction has numerous causes, including neurogenic, endocrine, vascular, iatrogenic, and trauma-related causes. Vascular impotence can be caused by arterial insufficiency, seen in patients with atherosclerosis and diabetes, or by venous leaks, when the subtunical venous plexus is inadequately compressed to prevent the outflow of blood. Neurogenic disorders include spinal cord injury, Parkinson's disease, strokes, and peripheral neuropathy, as seen in chronic alcoholics and diabetics. Most endocrine disorders, as previously noted, can lead to decreased testosterone production and therefore decreased libido. Pelvic fractures and perineal trauma have also been

**Table 54-4

associated with erectile dysfunction because of arterial damage. Iatrogenic causes of impotence include surgical procedures such as radical prostatectomies or cystectomies, lumbar laminectomies, and abdominoperineal resections. Other iatrogenic causes of erectile dysfunction include pelvic irradiation and the use of certain medications, such as sympatholytics, anticholinergics, antiandrogens, and centrally acting agents such as tricyclic antidepressants and alcohol.

## DIAGNOSIS

Evaluation of the infertile male starts with a detailed history and physical examination. Because of the vast number of etiologies of male infertility, we advocate a systematic approach using a standard evaluation form (Fig. 54-3).

### History

Many diagnoses of male infertility can be made on the basis of a detailed history alone. It is important to inquire how long the couple has been trying to conceive, whether there is a history of pregnancy with the current or previous partners, and about frequency and timing of intercourse. When possible, a female history should be taken directly from the patient's partner. Often neither partner understands the menstrual cycle nor how to calculate the optimal time for intercourse. Patients should be instructed to have intercourse every 48 hours around the time of ovulation. This pattern is suggested because sperm have been shown to be viable for approximately 2 days in the cervical mucus and crypts. The use of lubricants should be discussed because products such as Lubifax, Surgilube, Keri Lotion, and K-Y Jelly have all been shown to decrease sperm motility in vitro; if needed, vegetable oil can be recommended.<sup>18</sup>

A complete childhood and developmental history is important in evaluating the subfertile male. Patients should be asked about the history of cryptorchidism, testicular torsion, testicular trauma, and the onset of puberty. Several studies have confirmed abnormal sperm production after testicular torsion, showing overall that 37% of patients had low sperm density, 56% had poor sperm motility, and 53% had poor sperm morphology.<sup>19</sup> Delayed puberty can often be a sign of an underlying endocrinopathy. A history of postpubertal mumps is also important because this can lead to orchitis in roughly 25% of males and cause severe testicular atrophy in up to 55% of these patients.<sup>20</sup>

Surgical procedures such as orchiopexy, retroperitoneal surgery, transurethral prostate surgery, herniorrhaphy, and Y-V plasty of the bladder neck have all been associated with male infertility. Most of these procedures will lead to ductal obstruction, anejaculation, or retrograde ejaculation.

The patient should be asked about any recent infections, particularly febrile viral illnesses, because these can impair spermatogenesis for up to 3 months. It takes approximately 74 days for type B spermatogonia to develop into mature spermatozoa and be seen in the ejaculate.<sup>21</sup> The clinician should elicit a family history and inquire about cystic fibrosis, testosterone deficiencies, and any first-degree infertile relatives. Finally, a thorough review of systems, questioning such symptoms as headaches, impaired visual field defects, anosmia, respiratory infections, and galactorrhea, can help diagnose other endocrinopathies.

### Physical Examination

Almost any systemic illness can impair spermatogenesis; therefore, every infertile patient should have a thorough physical examination, with focus on the male genitalia. The normospermic male has a testicular length greater than 4 cm and a volume of at least 20 mL<sup>3</sup>. Because 85% of the testis is involved in spermatogenesis, a decrease in testicular size indicates impaired spermatogenesis.<sup>22</sup> The epididymis should be palpated for any induration or irregularities. The spermatic cord should be carefully examined to identify the presence of a varicocele and the presence or absence of the vas deferens. Varicoceles are graded according to size on a scale from 1 to 3 (Table 54-5). Grade 1 varicoceles are often difficult to detect; a scrotal ultrasound can help with a suspected diagnosis. The penile meatus should be examined to identify any ulcerative lesions indicating infection or the presence of a hypospadias, which could lead to impairment of sperm delivery to the cervix. Finally, signs of gynecomastia and inadequate virilization, such as decreased body hair, should lead the clinician to consider an endocrine abnormality.

### Laboratory Evaluation

#### Semen Analysis

The initial laboratory assessment includes semen analysis. Ideally, a minimum of two semen samples should be obtained after 2 to 3 days of sexual abstinence. Longer periods of abstinence are associated with decreased sperm motility, and shorter periods of abstinence result in low volume and density. The specimen can be obtained by masturbation or by intercourse with special condoms that do not contain any spermicidal agents. Although samples can be collected at home, ideally they should be collected in the office, because the specimens need to be analyzed within 30 minutes to 1 hour after collection. It is always important to ask the patient if the entire specimen was collected, because partial sample loss can erroneously lead to reports of low semen volume and other impaired parameters.

Most laboratories use the set of standards established by the World Health Organization (WHO) to describe the minimal limits of semen parameters adequate for establishing a pregnancy<sup>23</sup> (Table 54-6). The five main semen parameters evaluated are ejaculate volume, sperm density, percent motility, forward progression (qualitative movement), and morphology. Statistically, fertility rates decrease as sperm counts fall below 20 million/mL. Many laboratories now use morphologic criteria described by Kruger as opposed to the WHO standards. Kruger's strict criteria involve evaluating each sperm's size and shape, the size of the acrosome, and the absence of cytoplasmic droplets. Kruger and colleagues noted that men with less than 4% normal morphologic spermatozoa had IVF success rates of 7.6%, whereas patients with normal sperm morphology between 4% and 14% had IVF success rates of 63.9%.<sup>24</sup>

Semen fructose level should also be measured in azoospermic men. Fructose is produced by the seminal vesicles, and the absence of fructose in the ejaculate indicates ejaculatory duct obstruction, seminal vesicle dysfunction, or hypoplasia.

#### Semen Function Tests

##### Sperm Viability Testing

A test commonly used to check for sperm viability is the hypoosmotic swelling test. Spermatozoa are placed in a hypo-osmotic

medium where viable sperm will absorb the fluid and swell, causing a curling of their tails. Nonviable sperm will not manifest these signs. The hypo-osmotic swelling test does not have any toxic effects on the sperm and is used to select viable sperm for ICSI. Another test of sperm viability is the use of stains such as eosin Y and trypan blue to determine whether the plasma membrane is intact.

#### Sperm Penetration Assay

The sperm penetration assay (SPA) measures the fertilization potential of the sperm. This in vitro test, performed with hamster oocytes that have had their zona pellucida enzymatically removed, enables interspecies generation of the sperm into the oocyte. This assay evaluates the sperm's ability to undergo capacitation, the acrosome reaction, and fusion with the oocyte. Many feel the SPA is an invaluable test for screening patients before they undergo IVF due to the high cost of this high-technology assisted reproduction procedure. Studies have shown a correlation between positive SPA results and improved IVF outcomes.<sup>25</sup>

#### Postcoital Testing

The postcoital test, also known as the cervical mucous penetration assay, is designed to evaluate impaired male factors such as hyperviscosity, abnormal penile anatomy, decreased semen volume despite good sperm density, and unexplained infertility. The postcoital test is performed by examining the cervical mucus several hours after intercourse, ideally around the periovulatory phase of the female. The cervical mucus is smeared on a slide and examined microscopically for the presence of ferning within the mucus and for the quantitative presence of sperm and forward sperm motility. The role of the postcoital test continues to be a point of debate.

#### Acrosome Reaction Test

For fertilization to occur, the sperm must undergo the acrosome reaction. The acrosome is a membrane-bound organelle covering most of the head of the sperm. On interaction with the zona pellucida of the ova, the sperm releases proteolytic enzymes from the acrosome to penetrate and enter the ova. This acrosome reaction may be insufficient, or absent, in some infertile males. Pampiglione and colleagues showed that an acrosome response of less than 31.3% predicted fertilization failure in 100% of cases.<sup>26</sup> In the laboratory, the acrosome reaction can be induced with a calcium ionophore. The acrosome generally is examined with electron microscopy but can also be evaluated with monoclonal antibodies to the acrosome or by utilizing triple-stain techniques.

#### Additional Semen Tests

##### Leukocyte Testing

Most evidence suggests that leukocytes impair sperm function and motility. Pyospermia has been associated with abnormal results on SPA and the inability to fertilize with IVF. However, it is difficult to differentiate between leukocytes and immature germ cells on a standard semen analysis. To evaluate for pyospermia, the patient's ejaculate is mixed with peroxidase test working solution and placed into a hemocytometer, where it is examined under high magnification. Peroxidase-positive cells will stain brown; this helps differentiate between leukocytes and germ cells. Pyospermia may be indicative of an infection and should be treated with a semen culture and appropriate antibiotics. More commonly pyospermia is due to an inflammatory process causing the release of oxidants (reactive oxygen species, ROS) from the defective sperm. Use of an anti-inflammatory medication is usually curative.

##### Sperm Antibody Testing

Antisperm antibodies have been associated with lower pregnancy rates and are present in nearly 13% of males presenting to an infertility clinic.<sup>27</sup> Clumping of sperm, decreased sperm motility, and a poor postcoital test result may all indicate the presence of antisperm antibodies. A postcoital test will often show immotile sperm with a characteristic shaking motion. Risk factors for antisperm antibodies include vasal obstruction, genital infections, cryptorchidism, and genital trauma. The immunobead test is the most accurate assay in identifying antisperm antibodies. This assay utilizes polyarylamide beads linked to rabbit antihuman antibodies. Immunoglobulin A (IgA) or IgG antibodies can bind freely to the sperm, and a result showing that greater than 20% to 50% of sperm demonstrate immunobead binding is believed to be clinically significant.

#### Hormone Assays

Indications for a hormone evaluation in a subfertile male include signs of decreased sexual function (i.e., decreased libido), low sperm density (<10 million sperm/mL), and suspected endocrinopathies (i.e., hypothyroidism). Serum FSH and testosterone levels can identify up to 99% of all endocrinopathies in men with soft testes and less than 1 million sperm/mL. Standard hormone assays undertaken in completely evaluating the infertile male also should include LH and prolactin levels. Many causes of endocrinopathies can initially be identified by these

<b>Table 54-6 WHO Criteria: Minimal Limits for Adequate Fertilization</b>	
<b>Volume</b>	≥2.0 mL
<b>pH</b>	7.2–7.8
<b>Density</b>	≥20 million/mL
<b>Total sperm count</b>	≥40 million
<b>Motility</b>	≥50% with normal morphology
<b>Morphology</b>	≥30% normal forms

**Table 54-7**  
Hormone Findings in Male Infertility

	FSH	LH	Testosterone	Prolactin
Normal spermatogenesis	Normal	Normal	Normal	Normal
Hyperprolactinemia	Normal/↓	Normal/↓	↓	↑
Hypogonadotropic hypogonadism	↓	↓	↓	Normal
Hypergonadotropic hypogonadism (primary testicular failure)	↑	↑	Normal/↓	Normal
Impaired spermatogenesis	↑/Normal	Normal	Normal	Normal
Exogenous androgens	Normal/↑	↓	↑	Normal

four hormone assays: LH, FSH, prolactin, and testosterone (Table 54-7). Some advocate also checking estradiol levels, because elevated testosterone-to-estradiol ratios (T/E ratios) have been shown to result in decreased spermatogenesis in some infertile males.

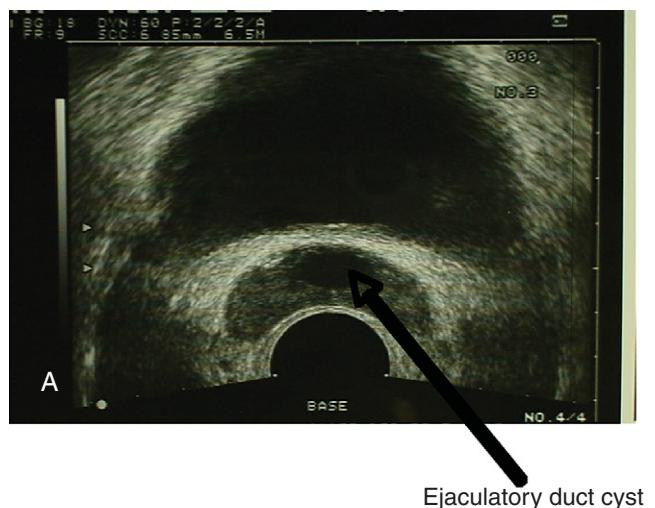

### Radiologic Evaluation

#### Ultrasound

The transrectal ultrasound (TRUS) and the scrotal ultrasound are invaluable tools in helping to diagnose the infertile male. TRUS is particularly useful when evaluating a patient with a low-volume, acidic, fructose-negative ejaculate or when there is a high suspicion for ejaculatory duct obstruction (Fig. 54-4). Seminal vesicles larger than 15 mm in thickness are suggestive of ejaculatory duct obstruction; the seminal vesicles can be aspirated at this time to confirm the diagnosis, which can be done by finding a large number of sperm (Fig. 54-5). TRUS can also be helpful in identifying a unilateral absence of the seminal vesicles, which is frequently associated with absence of the ipsilateral vas deferens and kidney (Fig. 54-6). The scrotal ultrasound is used to evaluate patients with suspected varicoceles as well as to evaluate testicular and epididymal masses. A scrotal Doppler ultrasound showing reversal of blood flow within a spermatic vein greater than 3 mm in diameter is a diagnostic indicator of a varicocele (Fig. 54-7). Finally, patients without vas deferens should have a renal ultrasound because approximately 20% of them will have renal malformations.<sup>28</sup>

#### Vasography

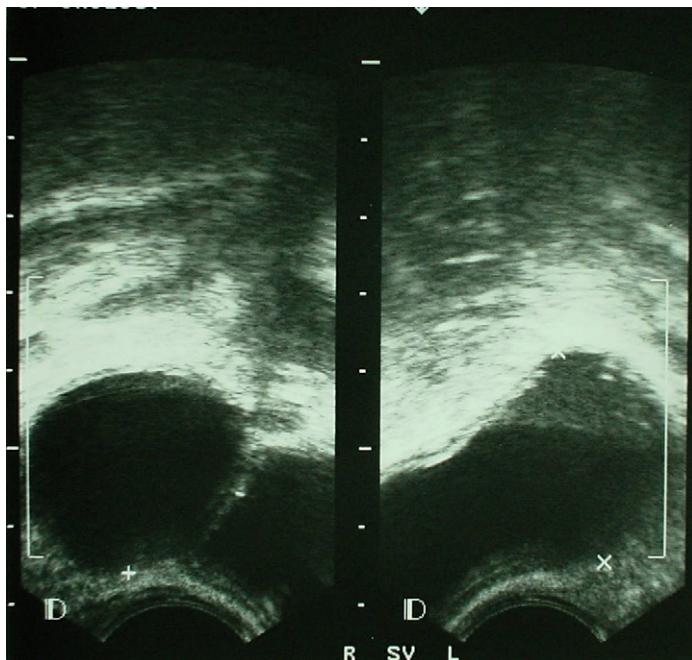

Vasography is a useful tool in diagnosing patients with obstruction. It is indicated in azoospermic patients with the presence of sperm documented on testis biopsy. Vasography should be performed at the time of reconstructive surgery because of the risk of vasal injury. Vasography involves injecting contrast into the proximal vas deferens toward the ejaculatory ducts. Contrast should not be injected in the direction of the epididymis because of the risk of epididymal injury associated with this procedure. Radiographic imaging is then used to delineate the point of vasal obstruction (Fig. 54-8).

**Figure 54-4** Ejaculatory duct cyst extending from distal (A) to proximal (B) prostatic urethra. (Courtesy of Linda Scherefred, Sonographer, Scott Department of Urology, Baylor College of Medicine, Houston.)

### Genetic Evaluation

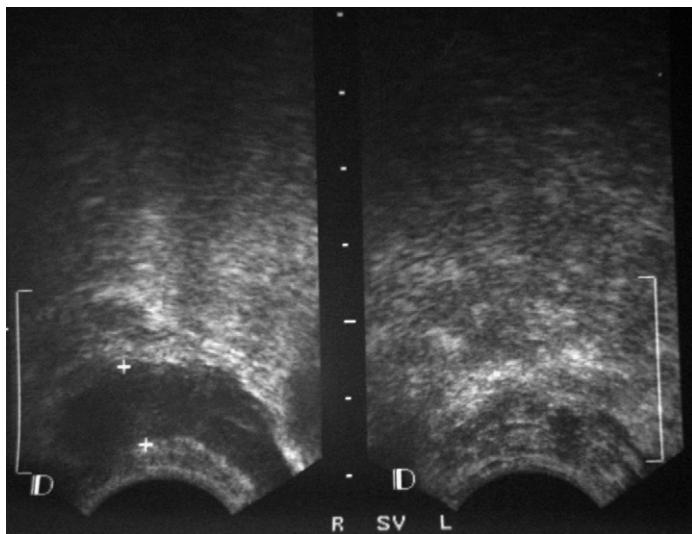

Routine testing for genetic abnormalities is not generally performed. However, patients with severe oligospermia (<10 million sperm/mL) and nonobstructed azoospermia should have a karyotype and determination of Y chromosome microdeletion performed, because 12% of azoospermic and severely oligospermic males are found to have a genetic abnormality.<sup>11</sup> Most laboratories use polymerase chain reaction assays or gel electrophoresis to identify Y chromosome microdeletions. Patients with bilateral and unilateral absence of the vas deferens should be tested for mutations in the *CFTR* gene and for mutations in the 5T allele as well. Up to 86% of patients with CBAVD have an identifiable *CFTR* mutation. Finally, mutations in the *KAL* gene have also been frequently found in patients suspected of having Kallmann syndrome.

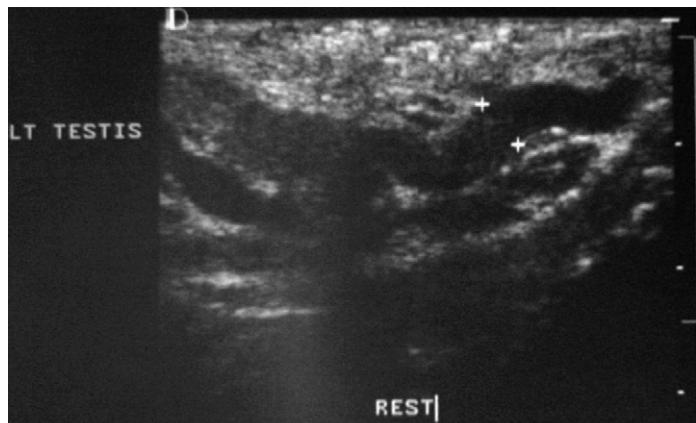

**Figure 54-5** A patient with an ejaculatory duct cyst and bilaterally dilated seminal vesicles, each measuring approximately 22 mm in diameter. (Courtesy of Linda Scherefred, Sonographer, Scott Department of Urology, Baylor College of Medicine, Houston.)

### Testicular Biopsy

A testicular biopsy is indicated in azoospermic patients to differentiate between those with obstructed and nonobstructed azoospermia. Multiple diagnostic biopsies (testicular mapping) should be performed on both testes if present. Patients with suspected nonobstructed azoospermia (small testis and FSH levels 2 times normal) who desire to proceed with ART should not have a testicular biopsy for diagnostic purposes only. These patients should undergo a therapeutic procedure (testicular

**Figure 54-6** Absent left seminal vesicle in a patient also found to have an absent left kidney on abdominal ultrasound.

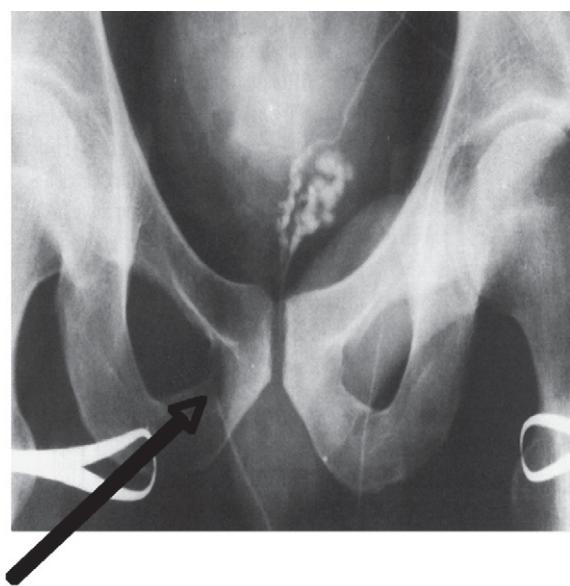

**Figure 54-7** A 32-year-old male with a left-sided varicocele measuring 3.4 mm, noted between + signs. (Courtesy of Linda Scherefred, Sonographer, Scott Department of Urology, Baylor College of Medicine, Houston.)

mapping or micro-testicular sperm extraction [TESE]) for sperm retrieval with subsequent IVF or ICSI.

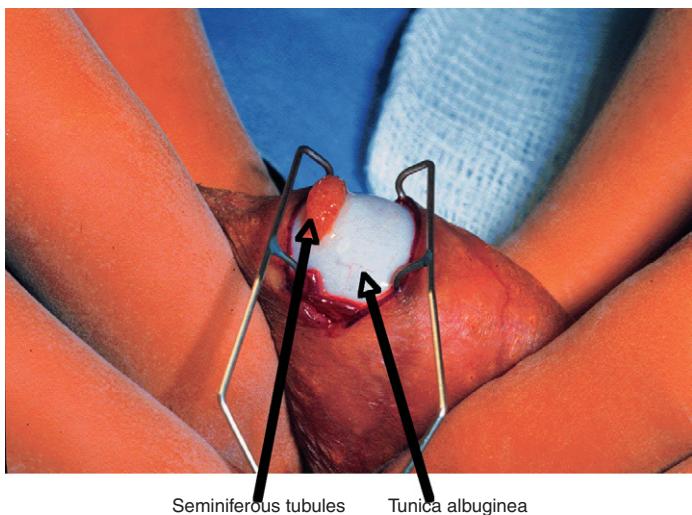

Testicular biopsies can be performed through a percutaneous needle biopsy, fine-needle aspiration for cytology, or through an open surgical approach (Fig. 54-9). With the open surgical approach, the biopsy specimen can be sent for a frozen section or an intraoperative “touch prep” can be made. The touch preparation involves gently moving the specimen across a microscope slide with fine tissue forceps. An intraoperative evaluation can rapidly assess whether sperm are present or if another area of the testis should be biopsied.

There are six main histologic patterns seen on testicular biopsy: normal, hypospermatogenesis, Sertoli-cell-only, maturation arrest, sclerosis, and a mixed type (Fig. 54-10). Up to 40% of patient with Sertoli-cell-only histology have occasional rare foci of spermatogenesis. Other mixed histological findings

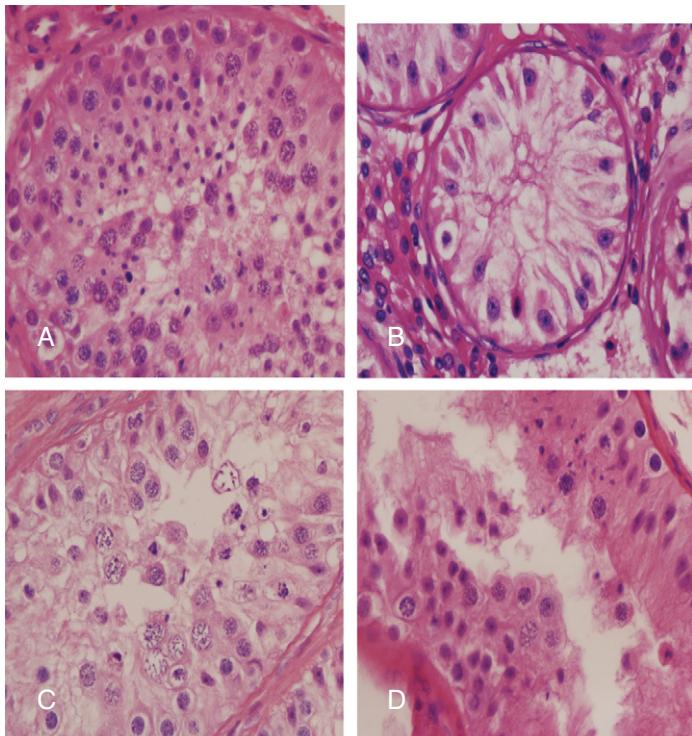

Vasal obstruction

**Figure 54-8** Vasogram showing right-sided vasal obstruction.

can include complex pathologic patterns, with some tubules representing Sertoli-cell-only and others with maturation arrest.

## TREATMENT

### Pretesticular Causes of Infertility

#### *Endocrinopathies*

Most endocrinopathies are treated with hormone replacement, treatment of the underlying disease, or cessation of certain

drugs or gonadotoxins. In the case of pituitary adenomas and prolactinomas, surgery may be required. Recent studies have shown that some men will present with a decreased T/E ratio. Aromatase inhibitors prevent the peripheral conversion of testosterone to estradiol and androstenedione to estrone. Treatment with aromatase inhibitors has been shown to result in significant increases in sperm concentration and motility in some of these oligospermic males.<sup>29</sup> Mainly for this reason, estradiol levels are now included in most infertility hormone assays.

### Testicular Causes of Infertility

#### *Varicoceles*

Indications for varicocele repair include abnormal semen parameters in the subfertile male, persistent testicular pain, and testicular atrophy. Semen parameters most likely to improve after varicocele repair are sperm motility and sperm density. Some studies have shown improvements in sperm morphology and penetration assays as well as return of sperm to the ejaculate of previously azoospermic men.<sup>30</sup> Varicoceles can be repaired surgically or nonsurgically. Nonsurgical repairs consist of radiographic embolization of the spermatic veins using coils, balloons, or sclerotherapy. These percutaneous procedures have a higher recurrence rate than traditional open surgical procedures and are advocated in cases of recurrent varicoceles. Surgical repairs by most urologic reproductive surgeons involve microsurgical techniques that preserve the internal spermatic arteries and lymphatics.

Correction of varicoceles has been shown to improve not only semen motility, density, and morphology, but also serum FSH and testosterone levels.<sup>5</sup> A study by Marks and colleagues showed approximately 41% improvement in sperm motility and morphology and 21% improvement in sperm forward progression.<sup>31</sup> These investigators also found that men who had a varicocele repair had a 45% pregnancy rate in 1 year as opposed to a 26% rate in those treated empirically with clomiphene citrate for idiopathic infertility. In a randomized prospective trial of varicocelectomies, 10% of men randomized to no therapy were able to achieve spontaneous pregnancies in 1 year compared to 60% of men who underwent a varicocele repair.<sup>32</sup>

#### *Genetic Disorders*

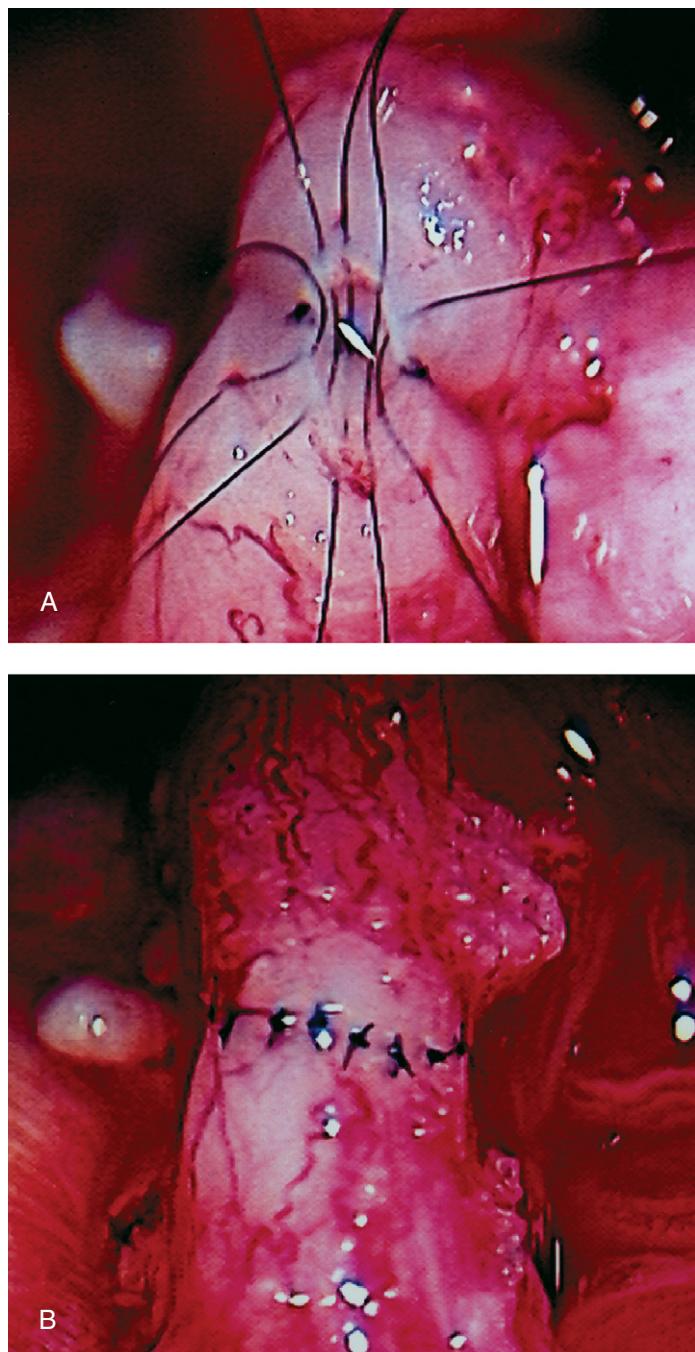

The treatment of genetic causes of infertility varies depending on the type of disorder. Most commonly, patients with genetic disorders have primary testicular failure resulting in azoospermia or severe oligospermia. In some of these patients a combination of TESE with ICSI is successful. However, the patient and his partner must be properly counseled about the risks of passing on the genetic disorder before proceeding with ART. In certain instances, such as with patients with CBAVD and cystic fibrosis, the patient's partner should also undergo genetic testing.

### Post-Testicular Causes of Infertility

#### *Vasal Obstruction*

##### *Microsurgical Reconstruction*

A variety of microsurgical techniques exist to bypass obstructions of the vas deferens or the epididymis. These operations are among the most technically challenging procedures that urologists perform and should be done only by a well-trained and experienced microsurgeon. Vasovasostomy involves reanastomosis

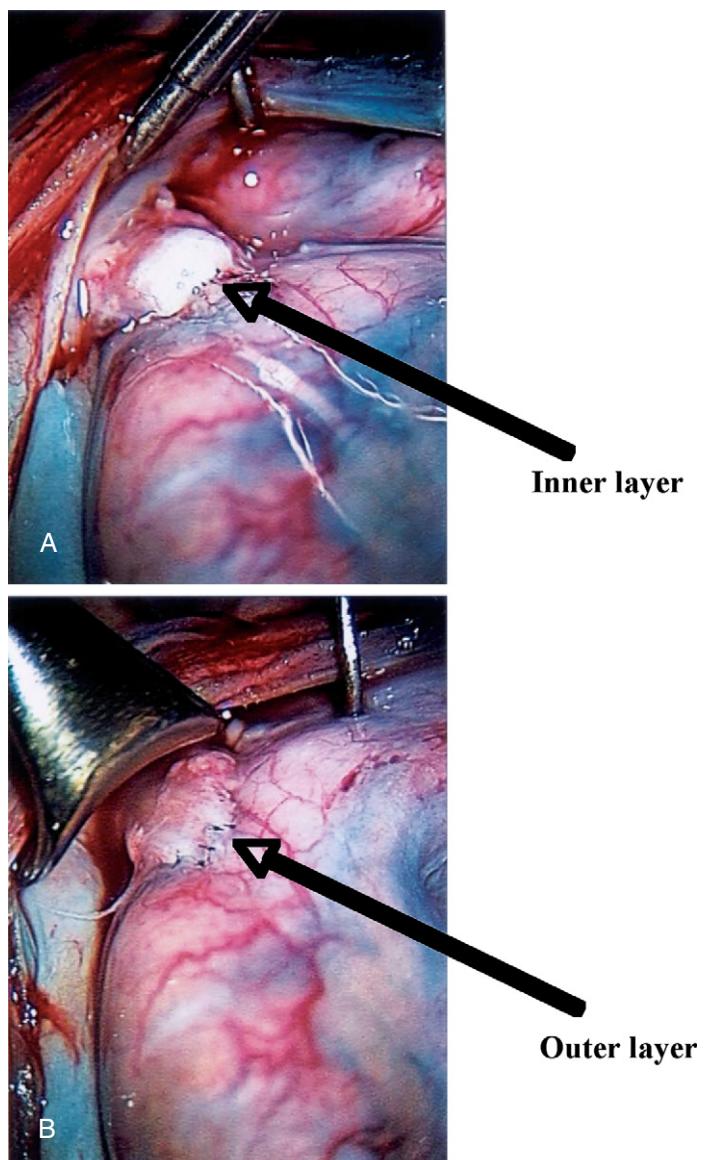

**Figure 54-11** Vasovasostomy performed using the standard two-layer closure. *A*, Inner layer. *B*, Outer layer.

of the vas deferens under high magnification using 9-0 and 10-0 sutures (Fig. 54-11). Most vasovasostomies are performed on patients desiring a vasectomy reversal because of a change in marital status. The success rate of a vasovasostomy depends on the experience of the surgeon and duration of obstruction. One study showed that men with vasal obstruction lasting less than 3 years had a 76% spontaneous pregnancy rate following vasectomy reversal as compared with 30% in men in whom the obstruction lasted longer than 15 years.<sup>33</sup>

Epididymovasostomy is an extremely challenging operation that involves performing an end-to-side anastomosis between the vas deferens and an epididymal tubule (Fig. 54-12). Because sperm maturation and motility occur in the epididymis, some believe that the anastomosis should be performed as low/distal as possible on the epididymis. Spontaneous pregnancy rates after an epididymovasostomy range from 23% to 43% for unilateral and bilateral repair, respectively.<sup>34</sup>

A study from Baylor has shown that the location of a vasectomy can influence the type of microsurgical reconstruction performed later during vasectomy reversal. Patients with vasectomies performed close to the testicle were twice as likely to have an epididymovasostomy as those who had a more distal occlusion site. These findings suggest that vasectomies should be performed as far away from the testicle as possible to improve the success of potential later reversal.

**Figure 54-12** *A* and *B*, Epididymovasostomy repair in a man desiring vasectomy reversal. This patient's contralateral side was able to be repaired through a vasovasostomy.

## Reproductive Endocrinology and Infertility

### Transurethral Resection of the Ejaculatory Duct

Patients with ejaculatory duct obstruction are treated with transurethral resection of the ejaculatory ducts (TURED). This procedure can be made easier with simultaneous TRUS or injection of colored dye into the seminal vesicles or vas deferens. In a series of 24 patients undergoing TURED, 50% had an increase in sperm density and 29% of patients were able to achieve spontaneous pregnancies.<sup>35</sup> Other options in treating ejaculatory duct obstruction are laser drilling and balloon dilation of the ejaculatory ducts, but these procedures are performed much less frequently.

### Epididymal Sperm Aspiration

Microsurgical epididymal sperm aspiration, or MESA, is indicated for sperm retrieval when vasal obstruction cannot be repaired following a previously failed microsurgical reconstruction and in cases of CBAVD. The procedure involves opening the epididymal tubules and aspirating spermatozoa (Fig. 54-13). Percutaneous epididymal sperm aspiration, or PESA, is a fast, inexpensive way to also obtain sperm from the epididymis. However, MESA is the preferred method for obtaining larger numbers of motile sperm for cryopreservation or ICSI. Patients must be willing to undergo IVF or ICSI after MESA or PESA.

### Testicular Sperm Extraction and Aspiration

Testicular sperm extraction is used for therapeutic sperm retrieval. TESE involves open excisional biopsies of the testis and is often used in conjunction with ICSI. The specimen is examined under a microscope; this procedure can be done either in the operating room or the office to make a rapid assessment of the presence of sperm. If no sperm are present, another area of the testis can be biopsied at that time. Su and colleagues demonstrated that nearly 60% of men with nonobstructed azoospermia will have some sperm found in their testicular biopsy.<sup>36</sup> They also showed that when TESE was combined with ICSI they were able to achieve a 55% clinical pregnancy rate.

Another alternative to TESE is testicular sperm aspiration, or TESA. TESA involves percutaneous aspiration of sperm by inserting a needle directly into the testicular parenchyma. Although TESA is faster and less expensive than TESE, it offers

significantly less sperm than TESE. TESA has also been associated with a higher rate of hematoma formation due to the blind passage of the aspiration needle.

### Ejaculatory Disorders

Patients with retrograde ejaculation can be treated with medications or retrieval of their sperm from their postejaculate urine. Sympathomimetics, such as imipramine and pseudoephedrine, are known to close the bladder neck and enhance emission. If these medications fail, sperm can be retrieved from an alkalinized postejaculate urine and used for intrauterine insemination (IUI) or IVF cycles. Postejaculate urine examination should also be performed on males with an ejaculatory volume of less than 1 mL.

Patients with anejaculation can benefit from electroejaculation or vibratory stimulation. Electroejaculation involves inserting a rectal probe and stimulating the sympathetic nerves with an electrical current. Vibratory stimulation involves placing a vibrator on the frenulum of the glans penis. For vibratory stimulation to induce ejaculation, the ejaculatory reflex arc in the thoracolumbar spinal cord must be intact. Therefore, spinal cord-injured patients with lesions above T10 will benefit from vibratory stimulation while those with lesions below T10 will need electroejaculation.<sup>37</sup>

### Idiopathic Infertility

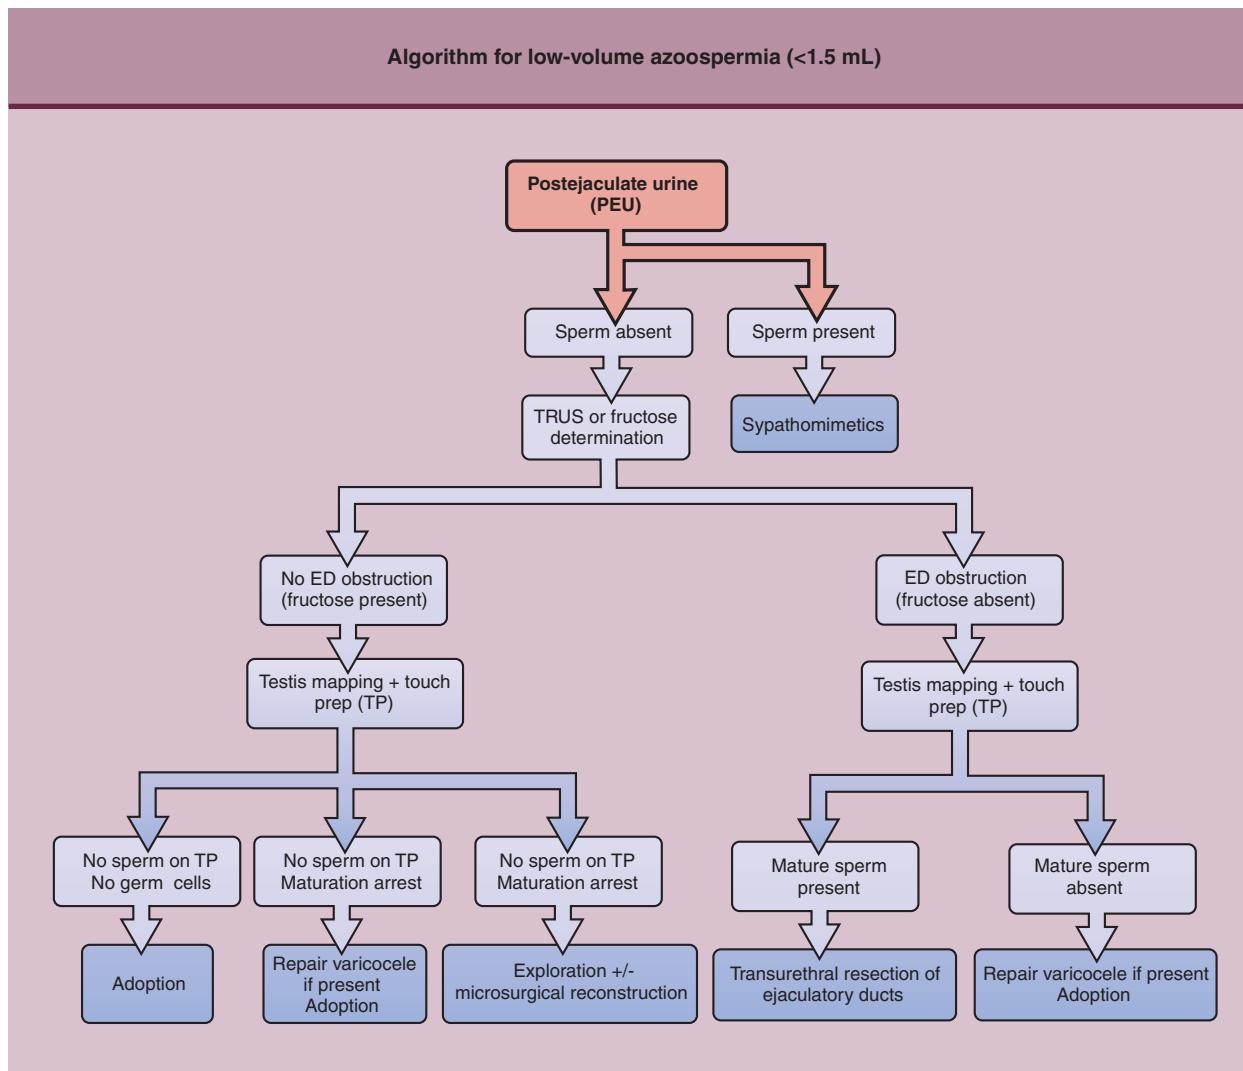

Empiric treatment of idiopathic infertility initially centers around pharmacologic therapy. Clomiphene citrate (Clomid), an estrogen antagonist, is one of the most widely used drugs in treating idiopathic oligospermia. The estrogen antagonist interferes with the negative feedback of estrogen, which causes an increase in gonadotropin secretion. Although some studies have shown improvements in semen parameters after clomiphene citrate treatment, most randomized controlled trials have shown no improved benefit in taking this drug. Exogenous GnRH has also been tried with disappointing results. The medication has to be administered every 2 hours to simulate pulsatile release. High costs and poor efficacy have led many clinicians to abandon this therapy. Finally, mesterolone, a synthetic androgen widely used in Europe, has been used to treat idiopathic male infertility. However, double-blinded controlled trials have failed to show any significant benefit of the drug over placebo.

### Treatment Algorithms

Many treatment algorithms have been designed to help the clinician in evaluating and treating the subfertile male. However, the most common algorithms used are the ones to evaluate and treat low volume ( $<1.5$  mL) and normal volume ( $>1.5$  mL) azoospermia. The initial evaluation of the azoospermic male involves repeating the semen analysis with centrifugation of the specimen. The pellet is then examined under a microscope and if sperm are present, an oligospermia workup is initiated. If sperm are absent and the vas deferens are palpable, the patient is further evaluated for either low-volume or normal-volume azoospermia. If the vas deferens are not palpable and the patient has testes of normal size and normal FSH levels, epididymal aspiration with ART can be performed. However, these patients will need to be tested for CFTR gene and 5T allele mutations before proceeding with ART.

**Figure 54-13** Microscopic epididymal sperm aspiration (MESA).

**Figure 54-14 Algorithm for low-volume azoospermia (<1.5 mL).**

The low-volume azoospermic evaluation involves first checking the patient's postejaculate urine (Fig. 54-14). If spermatozoa are absent, the presence of seminal fructose is assessed or a TRUS is performed to determine the presence of ejaculatory duct obstruction. If no obstruction is found, testicular mapping is performed and further treatment is based on these biopsy results.

When patients have normal-volume azoospermia or abnormal hormone levels, further evaluation by the hormone assay findings is dictated (Fig. 54-15). If the patient is found to have an elevated prolactin level, an MRI or computed tomographic scan of the hypothalamus and pituitary is performed and a tumor evaluation is initiated. If prolactin levels as well as LH and FSH levels are low, an endocrine cause for hypogonadotropic hypogonadism (see Fig. 54-1) is investigated and the patient generally is treated with hormone therapy. When FSH and LH levels are normal or elevated and testosterone levels are normal or decreased, patients will undergo a testicular biopsy and further definitive treatment will be based on these results. Similarly, a normal-volume azoospermic male with normal FSH, LH, and

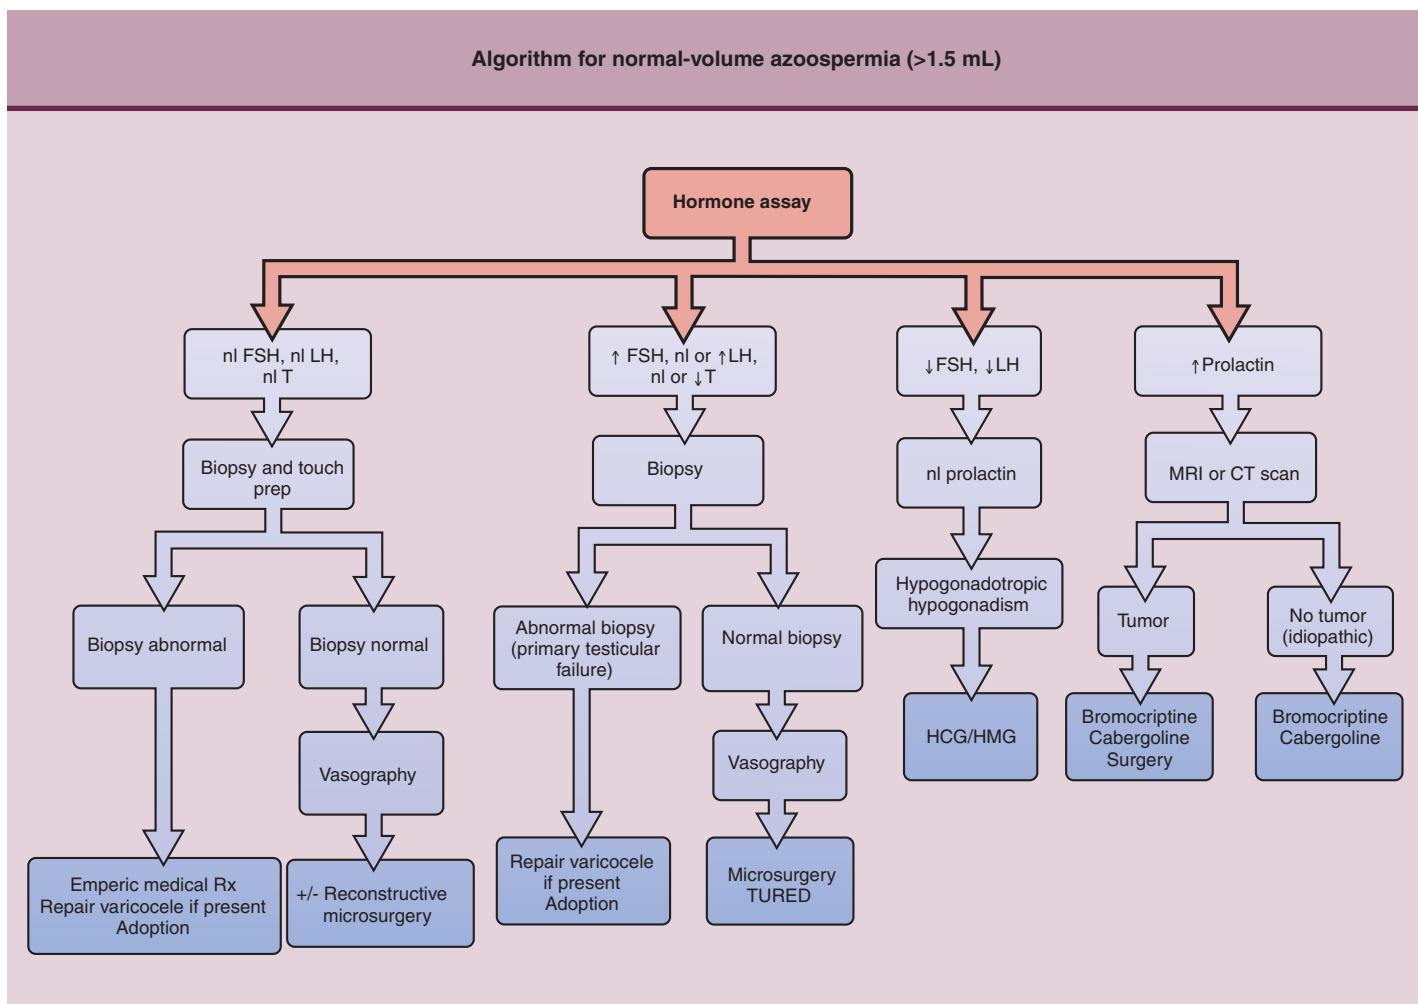

testosterone levels will also be initially evaluated with a biopsy and touch preparation. On the basis of these results, further treatment options can be decided (see Fig. 54-15).

### Assisted Reproductive Technologies

With the advancement of ART, many more reproductive options are now available for the subfertile male. Procedures such as IVF and ICSI have revolutionized the field of male infertility and now offer hope to men who could not have conceived just over 10 years ago. A full description of ART is covered in Chapter 52.

### SUMMARY

Treatment and understanding of male infertility is a rapidly evolving field, with new technologies and procedures constantly being developed. Yet, 25% of males still present with idiopathic infertility. The etiology for male infertility is vast, and the clinician must learn to take a detailed history and perform a thorough physical examination. In addition, the clinician should be familiar with the appropriate radiologic and laboratory tests

**Figure 54-15 Algorithm for normal-volume azoospermia (>1.5 mL).**

needed to make an accurate diagnosis. Surgical treatment of male infertility, especially when it involves microsurgery, should only be performed by highly skilled, experienced surgeons to offer the best outcome to these patients. In half of all infertile couples, male infertility will be a component. Only after the male partner has been completely evaluated can these couples be offered the most cost-effective and productive treatment options.

## KEY POINTS

- A complete evaluation for recurrent pregnancy loss will reveal a possible cause in 70% of cases.
- A complete evaluation (genetic, endocrinologic, anatomic, immunologic, microbiologic, and thrombophilic) should be initiated when the decision to evaluate a couple is made.
- Couples with primary recurrent pregnancy loss have identifiable causes just as frequently as couples with secondary recurrent pregnancy loss; therefore, both types of couples should be evaluated.
- Women with two losses have identifiable problems just as frequently as women with three or more losses; thus, an evaluation for causes can be initiated after two losses.
- If no cause is identified after a complete evaluation, 65% of couples will have a successful subsequent pregnancy.

## EPIDEMIOLOGY, RISK FACTORS, AND PATHOGENESIS

Recurrent pregnancy loss is a devastating problem to couples seeking parenthood and a difficult challenge to their physician. Whereas spontaneous abortion occurs in approximately 15% of clinically diagnosed pregnancies, recurrent pregnancy loss occurs in about 1% to 2% of this same population.<sup>1</sup> Great strides have been made in characterizing the incidence and diversity of this heterogeneous disorder, and a definite cause of pregnancy loss can be established in approximately two thirds of couples after a thorough evaluation.<sup>2</sup> A complete evaluation will include investigations into genetic, endocrinologic, anatomic, immunologic, microbiologic, thrombophilic, and iatrogenic causes. In cases of idiopathic recurrent miscarriage, intense supportive care is indicated and successful outcomes will occur in more than two thirds of all couples.<sup>3</sup>

### Definition of Recurrent Pregnancy Loss

The traditional definition of recurrent pregnancy loss included those couples with three or more consecutive spontaneous miscarriages. However, several studies have indicated that the causes of miscarriage that can be identified after two consecutive pregnancy losses are similar to the causes that can be identified after three consecutive pregnancy losses. Thus, it has been recommended that couples with two or more consecutive spontaneous miscarriages warrant an evaluation to identify any factor that may be associated with their poor reproductive

history.<sup>4,5</sup> Miscarriages are considered to be any loss before 20 gestational weeks and can be further divided into embryonic, defined as a pregnancy that fails before 10 weeks' gestation, and fetal, defined as a pregnancy that fails at or after 10 weeks' gestation. Those couples with primary recurrent miscarriage have never had an ongoing pregnancy beyond 20 weeks' gestation, and those with secondary recurrent miscarriage have previously had a pregnancy that progressed beyond 20 weeks' gestation followed by three or more consecutive spontaneous miscarriages.

### Recurrence Risk

The risk of recurrence depends on several factors, including maternal age, the number of previous miscarriages, and the history of previous term deliveries. Studies that evaluated the frequency of pregnancy loss, based on highly sensitive tests for quantitative human chorionic gonadotropin, indicated that the risk of miscarriage, both clinical and preclinical, in women age 20 to 30 is approximately 25%. The risk of miscarriage in women age 40 or older is at least double that figure.<sup>6,7</sup> Similarly, a greater number of prior miscarriages are associated with a higher risk of subsequent miscarriage in most studies. A patient with two prior losses has a recurrence risk of at least 25%; after four losses, that figure is at least doubled. Most studies have indicated a more favorable prognosis in women with secondary recurrent pregnancy loss.

### Etiology of Miscarriage

Numeric chromosomal abnormalities as a cause of miscarriage have been studied extensively. Based on seven studies, in which 7182 miscarriages were successfully cytogenetically analyzed, it is estimated that nearly 50% of miscarriages in the general population are due to numeric chromosomal abnormalities.<sup>8</sup> Approximately 56% of such abnormalities are trisomies, 20% are polyploidies, 18% are monosomy X, and 6% are other genetic defects. Approximately one third of all trisomies are trisomy 16. All pregnancies with trisomy 16 end in first-trimester miscarriage. Only pregnancies with trisomy 21, 18, and 13 have been reported to survive to birth, although the probability of this is 22%, 5%, and 38%, respectively. Sex chromosome trisomies, including XXY, XXX, and XYY, have a higher likelihood of survival, estimated at 55%, 70%, and 100%, respectively.

The gestational age of demise does have some bearing on the frequency and specificity of chromosomal abnormalities. Approximately 70% of preclinical miscarriages (<6 weeks' gestation) have a numeric chromosomal abnormality.<sup>9</sup> Approximately 46% of clinically recognized miscarriages have a numeric

## Reproductive Endocrinology and Infertility

chromosomal abnormality, whereas only 5% of stillbirths are abnormal.<sup>8,10</sup> Advancing maternal age highly impacts the likelihood of preclinical and clinical miscarriage because of an increased likelihood of errors in maternal meiosis, resulting in trisomic pregnancies.

A numeric chromosomal abnormality in a previous miscarriage does not increase the risk in a subsequent pregnancy. Therefore, such abnormalities are random occurrences, although advancing maternal age is a confounder.

Cytogenetic analysis is an important test to perform in a couple with a history of miscarriage. Conventional chromosome banding does have its limitations, including a failure rate of 10% to 40% because of tissue culture failure and/or maternal contamination. Comparative genomic hybridization supplemented with flow cytometry appears to be a promising alternative for cytogenetic analysis. This technique is more accurate, is less labor intensive, has a lower failure rate because tissue culturing is not required, and has less risk of maternal contamination.

### DIAGNOSIS AND TREATMENT OF RECURRENT PREGNANCY LOSS

In addition to random miscarriage, noncytogenetic factors may be associated with a history of recurrent pregnancy loss. These factors may increase the recurrence risk of miscarriage; therefore, evaluation of couples with recurrent pregnancy loss is warranted. Management based on sound scientific evidence is paramount, with randomized, controlled trials being the gold standard for determining effectiveness of treatment.

#### Structural Genetic Factors

A structural genetic factor is found in either partner in 3% to 5% of couples with recurrent pregnancy loss. The most common structural factor is a balanced reciprocal translocation. In recurrent pregnancy loss, this abnormality is found more frequently in the female partner, at a ratio from 2:1 to 3:1 (female:male). Other structural genetic factors occur less frequently, such as a robertsonian translocation, an inversion, or a supernumerary chromosome. Genetic counseling is key because the impact of such structural genetic factors depends on the chromosomes involved. Prenatal diagnosis by amniocentesis or chorionic villus sampling can identify whether an ongoing pregnancy is affected. Donor gametes or preimplantation genetic diagnosis may be considered, but cytogenetic documentation of miscarriages should be confirmed before proceeding with such advanced reproductive technology.

#### Endocrinologic Factors

##### Luteal Phase Deficiency

Progesterone produced from the corpus luteum is necessary for successful implantation and maintenance of early pregnancy until progesterone production by the placenta takes over. Luteal phase deficiency has been described as a cause of recurrent pregnancy loss. Classically, the definition of a luteal phase deficiency was based on two mid- to late luteal phase endometrial biopsies, which revealed two or more days of histologic delay. More recently, a midluteal progesterone level of less than 10 ng/mL has been suggested to be diagnostic. Women with out-of-phase endometrial biopsies are unable to maintain endo-

metrial progesterone receptors and have abnormal expression of the  $\alpha_v\beta_3$  integrin, a biomarker of uterine receptivity.<sup>11</sup> The  $\alpha_v\beta_3$  integrin normally appears in the endometrium glands on cycle days 20 to 21, during the “window of implantation.” The majority of these patients, when treated with supplemental progesterone or low-dose clomiphene citrate, will have restoration of normal histologic endometrium and normal  $\alpha_v\beta_3$  expression. Late implantation of the embryo has also been associated with an increased miscarriage rate.<sup>12</sup>

##### Untreated Hypothyroidism

Untreated hypothyroidism may increase the risk of miscarriage. A recent study of more than 700 patients with recurrent pregnancy loss identified hypothyroidism in 7.6%.<sup>13</sup> Hypothyroidism is easily diagnosed with a sensitive thyrotropin stimulation test; patients should be treated to become euthyroid before attempting a pregnancy.

##### Insulin Resistance

Patients with poorly controlled diabetes are known to have an increased risk of spontaneous miscarriage. This risk can be reduced to normal if the patient is treated appropriately and becomes euglycemic preconceptually.<sup>6</sup> It is known that women with polycystic ovary syndrome (PCOS) have an increased risk of miscarriage. The high prevalence of insulin resistance in women with PCOS may account for the increased risk of miscarriage in this group.<sup>14</sup> Testing for fasting insulin and glucose is simple, and treatment with insulin-sensitizing agents can reduce the risk of recurrent miscarriage.<sup>15</sup>

##### Elevated Day 3 Follicle-Stimulating Hormone Levels

Elevated day 3 follicle-stimulating hormone (FSH) levels ( $>12$  mIU/mL) have been associated with decreased pregnancy rates in women undergoing in vitro fertilization. Although the frequency of elevated day 3 FSH levels in women with recurrent miscarriage is similar to the frequency in the infertile population, the prognosis for a successful pregnancy outcome in women with recurrent miscarriage and an elevated day 3 FSH is decreased.<sup>16</sup> Some clinicians recommend that testing should be performed in women over age 35 with recurrent pregnancy loss, and that these women may produce embryos with a high rate of aneuploidy.<sup>17</sup> One study identified a higher rate of aneuploidy in women with recurrent miscarriage compared to women undergoing similar analysis for sex-linked disorders (70.7% vs. 45.1%) using preimplantation genetic diagnosis at the time of in vitro fertilization. Women with recurrent miscarriage and elevated day 3 FSH levels should have appropriate counseling.

#### Anatomic Factors

##### Congenital Uterine Anomalies

Congenital uterine anomalies associated with müllerian fusion defects have been associated with an increased risk of pregnancy loss.<sup>18</sup> The most common abnormality associated with pregnancy loss is the septate uterus. Uncontrolled studies suggest that resection of the uterine septum results in higher delivery rates than in women without treatment. Other congenital abnormalities, such as bicornuate and unicornuate uterus, are more frequently associated with later trimester losses or preterm delivery, rather than recurrent miscarriage.

### Acquired Uterine Abnormalities

Intrauterine adhesions or synechiae (Asherman's syndrome) have been associated with recurrent miscarriage. Intrauterine synechiae are most commonly secondary to uterine curettage at the time of abortion or a postpartum curettage. The adhesions are thought to interfere with normal placentation. They can be excised hysteroscopically. Intrauterine cavity abnormalities, such as leiomyomas and polyps, can contribute to pregnancy loss by interfering with implantation. Until recently, it was felt that only submucous leiomyomas should be surgically removed before subsequent attempts at pregnancy. However, several studies investigating the implantation rate in women undergoing in vitro fertilization have clearly demonstrated decreased implantation with intramural myomas in the range of 30 mm.<sup>19</sup> When smaller myomas are identified, it is unclear if myomectomy is beneficial in patients undergoing in vitro fertilization.<sup>20</sup>

### Immunologic Factors

#### Autoimmune Factors

##### Antiphospholipid Antibodies

Autoantibodies to phospholipids, thyroid antigens, nuclear antigens, and other substances have been investigated as possible causes for pregnancy loss.<sup>13</sup> Antiphospholipid antibodies include both the lupus anticoagulant and anticardiolipin antibodies. The occurrence of recurrent pregnancy loss, fetal death, and/or thrombosis in conjunction with antiphospholipid antibodies is termed the *antiphospholipid antibody syndrome*<sup>21</sup> (Table 55-1). Controversy still exists concerning testing for other phospholipids, but an increasing number of studies suggest that antibodies to phosphatidyl serine are also associated with pregnancy loss.<sup>22</sup> In the past, treatment with low-dose steroids was advocated; however, subsequent studies indicate that this treatment significantly increases maternal and fetal complications without enhancing live birth rate.<sup>23,24</sup> Independent, prospective investigations have indicated the efficacy of subcutaneous heparin and low-dose (81 mg/day) aspirin for the treatment of anti-phospholipid antibody syndrome.<sup>25-27</sup>

**Table 55-1**  
**Clinical and Laboratory Characteristics of Antiphospholipid Antibody Syndrome**

Clinical	Laboratory
<b>Pregnancy morbidity</b>	
≥1 unexplained death at ≥10 weeks Delivery at ≤34 weeks with severe PIH 3 or more losses before 10 weeks	IgG aCL (≥20 GPL) IgM aCL (≥20 MPL) Positive lupus anticoagulant test
<b>Thrombosis</b>	
Venous Arterial, including stroke	
GPL, IgG phospholipid units; MPL, IgM phospholipid units; PIH, pregnancy-induced hypertension. Patients should have at least one clinical and one laboratory feature at some time in the course of their disease. Laboratory tests should be positive on at least two occasions more than 6 weeks apart. Modified from Wilson WA, Ghavari AK, Piette JC: International classification criteria for antiphospholipid syndrome: synopsis of a post-conference workshop held at the Ninth International (Tours) APL Symposium. Lupus 2001;10:457-460.	

##### Antithyroid Antibodies

Antithyroid antibodies (antithyroid peroxidase, antithyroglobulin) have been reported in increased frequency in women with recurrent pregnancy loss. However, if the patient is euthyroid, the presence of antithyroid antibodies does not affect pregnancy outcome.<sup>28</sup> Women who have positive antithyroid antibodies and are euthyroid are at an increased risk for hypothyroidism during and after pregnancy. These women should have their thyrotropin levels tested during each trimester and postpartum for thyroiditis.<sup>29</sup>

##### Antinuclear Antibodies

Approximately 10% to 15% of all women will have detectable antinuclear antibodies regardless of their history of pregnancy loss. Their chance of successful pregnancy outcome is not dependent on the presence or absence of antinuclear antibodies. Treatments such as steroids have been shown to increase the maternal and fetal complications without benefiting live births<sup>24</sup>; thus, routine testing and treatment for antinuclear antibodies is not indicated.

##### Alloimmune Factors

###### Human Leukocyte Antigens, Embryotoxic Factors, and Immunophenotypes

Alloimmune factors have been suggested to be associated with recurrent pregnancy loss. Previously, sharing of human leukocyte antigen (HLA) between partners was thought to be associated with recurrent pregnancy loss, based on a decreased maternal immune response to paternal HLA antigens and, thus, decreased production of blocking antibodies. Recent large studies, however, reveal no association between HLA (and HLA-DQ $\alpha$ ), homozygosity, and recurrent pregnancy loss.<sup>30</sup> Other investigators have implicated certain embryotoxic factors, such as tumor necrosis factor- $\alpha$  and interferon- $\delta$ , identified in the supernatants of peripheral blood lymphocytes from women with pregnancy loss; however, this has not been confirmed by independent studies. Immunophenotypes of endometrial cells from women with recurrent pregnancy loss demonstrate altered natural killer cell (CD56+) populations. Some have suggested that increased natural killer cells are associated with pregnancy loss; others have indicated that decreased natural killer cells are associated with pregnancy loss. None of these factors have been clearly associated with pregnancy loss; thus, there are no recommended tests or treatments at this time.<sup>31</sup>

Despite the lack of diagnostic tests to identify an alloimmune factor association with a history of recurrent pregnancy loss, there is abundant evidence that there are immunologic interactions between the mother and her allogeneic pregnancy.<sup>32-34</sup> On the basis of this evidence, active and passive immunotherapies have been offered to many couples with otherwise unexplained recurrent pregnancy loss.

##### Active and Passive Immunotherapy

Active immunotherapy, in the form of either paternal or third-party mononuclear cell immunization, has been extensively evaluated since the initial controlled trial published in 1985.<sup>35</sup> Subsequent trials, all with small numbers of patients enrolled, had inconsistent results.<sup>36,37</sup> In 1999, a multicenter, randomized, double-blind, placebo-controlled trial supported by the National

## Reproductive Endocrinology and Infertility

Institutes of Health showed that paternal mononuclear cell immunization did not improve pregnancy outcome in couples with unexplained recurrent pregnancy loss.<sup>30</sup>

The first randomized, controlled trial assessing the efficacy of passive immunotherapy using intravenous immunoglobulin for treatment of unexplained recurrent miscarriage was published in 1994.<sup>38</sup> Three subsequent trials showed encouraging results for couples with unexplained secondary recurrent pregnancy loss.<sup>39–41</sup> A multicenter, randomized, controlled trial is currently in progress.

### Microbiologic Factors

Certain infectious agents have been identified more frequently in cultures from women who have had sporadic miscarriages.<sup>42</sup> These include *Ureaplasma urealyticum*, *Mycoplasma hominis*, *Chlamydia*, and other less common pathogens. Although no studies have associated any infectious agent with recurrent pregnancy loss, it is unlikely that many clinicians would leave a patient untreated to determine this association. Because of the clear association with sporadic pregnancy losses and the ease of diagnosis, women with recurrent pregnancy loss should be cultured for these organisms and both partners should be treated if positive.

### Thrombophilic Factors

Attention has been focused on certain inherited disorders that may predispose to arterial and/or venous thrombosis and their possible association with pregnancy complications.<sup>43,44</sup> These include the group of mutations leading to a hypercoagulable state, such as factor V Leiden (G1691A), factor II-prothrombin mutation (G20210A), and hyperhomocysteinemia (thermolabile MTHFR C677T). Other possible abnormalities leading to hypercoagulable states that may be associated with recurrent miscarriage include the antithrombin III deficiency, protein C deficiency, protein S deficiency, and elevated factor VIII (Table 55-2).

Although such inherited thrombophilias are established causes of thrombosis, they have only recently been associated with adverse pregnancy outcomes, including fetal demise. Subanalysis of individual inherited thrombophilias has confirmed an association with recurrent pregnancy loss and factor V Leiden.<sup>45</sup> Other associations have been suggested between many inherited

thrombophilias and adverse pregnancy outcomes, including but not limited to recurrent pregnancy loss, fetal demise, fetal growth restriction, gestational hypertension, and abruption. Subanalysis of individual inherited thrombophilias and an individual adverse pregnancy outcome suggests but has not confirmed such associations.

It seems clear that some of these inherited thrombophilias are found more commonly in women with recurrent early pregnancy losses.<sup>43,46</sup> Although outcome studies of patients with recurrent pregnancy loss and a positive test for an inherited thrombophilia are limited and conflicting, a case-control study suggests that the presence of factor V Leiden is significantly associated with a lower live birth rate.<sup>45</sup> Hyperhomocysteinemia has been reported in early pregnancy losses and is treated with 1 to 2 mg/day of folic acid supplementation.<sup>47</sup>

Currently prophylactic or therapeutic heparin has been advocated by some researchers when an inherited thrombophilia is found in association with unexplained recurrent pregnancy loss,<sup>44</sup> although there have been no prospective controlled studies. Ideally, randomized, controlled trials will be performed to determine whether thromboprophylaxis improves the live birth rate in such patients.

### Lifestyle Issues

Tobacco use of more than 15 cigarettes a day has been associated with a 1.5-fold to 2-fold increased risk of pregnancy loss; alcohol consumption of greater than five drinks per week is associated with a similar increased risk.<sup>48</sup> When both personal habits are present in the same individual, the risk of pregnancy loss may increase fourfold. Couples should be counseled appropriately and be strongly encouraged to discontinue such use before attempting another pregnancy.

## CLINICAL COURSE AND PROGRESSION

### Course of Evaluation

When the clinician makes the decision to initiate an evaluation for recurrent pregnancy loss, it is recommended that complete diagnostic testing be performed. This obviously includes a detailed history, including documentation of prior pregnancies, any pathologic tests that were performed on prior miscarriages, any evidence of chronic or acute infections or diseases, any

**Table 55-2**  
Common Thrombophilias Possibly Associated with Recurrent Pregnancy Loss

Thrombophilia	Inheritance	Prevalence*	Risk of DVT
Factor V Leiden G1691A mutation (activated protein C resistance)	Autosomal dominant	2%–15%	3–8x
Factor II G20210A mutation (prothrombin mutation)	Autosomal dominant	2%–3%	3x
MTHFR C677T mutation (hyperhomocysteinemia)	Autosomal recessive	11%	2.5–4x
Antithrombin deficiency	Autosomal dominant	0.02%	25–50x
Protein C deficiency	Autosomal dominant	0.2%–0.3%	10–15x
Protein S deficiency	Autosomal dominant	0.1%–0.2%	2x
Elevated factor VIII	X-linked	5%–15%	5x

DVT, deep vein thrombosis.

\*Prevalence is in the general population; however, significant ethnic differences are known. Risk of DVT in the nonpregnant individual with the listed thrombophilia compared with a nonpregnant individual without the thrombophilia.

**Table 55-3**  
**Standard Evaluation and Management of Recurrent Pregnancy Loss**

Etiology	Diagnostic Evaluation	Abnormal Result	Therapy
Structural genetic	Cytogenetic analysis of both partners	3%–5%	Genetic counseling, donor gametes
Anatomic	Hysterosalpingogram, hysteroscopy, or sonohysterography (saline-infused sonogram)	15%–20%	Hysteroscopic septum resection, myomectomy, lysis of adhesions
Endocrinologic	Midluteal progesterone Thyrotropin Prolactin Fasting insulin:glucose Day 3 FSH, estradiol	8%–12%	Progesterone Levothyroxine Bromocriptine, cabergoline Metformin Counseling
Immunologic	Lupus anticoagulant Anticardiolipin antibodies ?Embryotoxicity assay ?Immunophenotyping	15%–20%	Aspirin Heparin + aspirin ?Intravenous immunoglobulin
Microbiologic	Cervical cultures	5%–10%	Antibiotics
Thrombophilic	?Antithrombin III ?Protein C, Protein S Factor V Leiden mutation ?Factor II (prothrombin) mutation Hyperhomocysteinemia	8%–12%	Heparin Folic acid
Psychological	Interview Questionnaire	Varies	Support groups Counseling
Iatrogenic	Tobacco, alcohol use Exposure to toxins, chemicals	5%	Eliminate consumption Eliminate exposure

recent physical or emotional trauma, a history of cramping or bleeding with a previous miscarriage, any family history of pregnancy loss, and any previous gynecologic surgery or complicating factor. A summary of the diagnosis and management of recurrent pregnancy loss includes an investigation of genetic, endocrinologic, anatomic, immunologic, microbiologic, iatrogenic, and thrombophilic causes (Table 55-3).

### Outcome of Evaluation

In approximately 70% of all cases of recurrent pregnancy loss, a complete evaluation will reveal a possible etiology.<sup>2</sup> If no cause can be found, the majority of couples will eventually have a successful pregnancy outcome with supportive therapy alone.<sup>3</sup> Couples who have experienced recurrent pregnancy loss want to know what caused the miscarriage. Unexplained reproductive failure can lead to anger, guilt, and depression. Anger may be directed toward their physician for not being able to solve their reproductive problems. Feelings of grief and guilt following an early loss are often as intense as those following a stillbirth, and parents experience a grief reaction similar to that associated with the death of an adult. The couple should be assured that exercise, intercourse, and dietary indiscretions do not cause miscarriage. Any questions or concerns that the couple may have about personal habits should be discussed.

Women who suffer recurrent pregnancy loss have already begun to prepare for their baby, both emotionally and physically, as compared to couples with infertility who have never conceived. When a miscarriage occurs, a couple may have great difficulty informing friends or family about the loss. Feelings of

hopelessness may continue long after the loss. Patients may continue to grieve and have episodes of depression on the expected due date or the date of the pregnancy loss. Participation in support groups or referral for grief counseling may be beneficial in many cases.<sup>49</sup>

## KEY POINTS

- Diagnosis of pathologic hyperprolactinemia should be made only after all known causes of physiological or iatrogenic hyperprolactinemia are excluded.
- Management of hyperprolactinemia depends on the presence and size of a prolactinoma and the patient's desire for fertility.
- Dopamine agonists are highly effective for treating microprolactinomas, macroprolactinomas, and idiopathic hyperprolactinemia.
- Although all dopamine agonists are effective, cabergoline is often more effective and better tolerated than bromocriptine.
- Because more data are available for bromocriptine use during pregnancy, bromocriptine should be the drug of choice when pregnancy is desired.
- In general, surgical resection of prolactinomas should be a last resort.

The existence of a human prolactin molecule was proven in 1971.<sup>1</sup> Prior to this discovery it was assumed that biological activities that depended on prolactin in other animals were mediated by growth hormone in the human. Once its existence in the human was established, assays were developed and normal plasma concentrations defined. As a consequence, abnormal concentrations were soon identified and the diagnosis of hyperprolactinemia was made for many patients with previously unexplained amenorrhea or impotence.

Prolactin is a polypeptide hormone secreted primarily by lactotrophs in the anterior pituitary gland. In humans, it has lactogenic, steroidogenic, and immunoregulatory functions. *Hyperprolactinemia*, simply defined as circulating plasma prolactin concentrations exceeding the upper limit of normal, may be caused by a variety of physiological, iatrogenic, or pathologic conditions. An understanding of the physiology and regulation of prolactin is required to distinguish pathologic conditions from physiological responses.

## EPIDEMIOLOGY

The prevalence of hyperprolactinemia ranges from 0.4% in an unselected adult population to 17% of patients with polycystic ovary syndrome (PCOS).<sup>2</sup> An incidence of 5% has been reported among women of reproductive age<sup>3</sup> and 14% among women with secondary amenorrhea.<sup>4</sup> Pituitary microadenomas have been found in 1.5% to 26.7% of autopsies in subjects not known

to have had pituitary lesions while alive.<sup>5</sup> Macroadenomas, on the other hand, are very rarely encountered in postmortem studies.

## PHYSIOLOGY

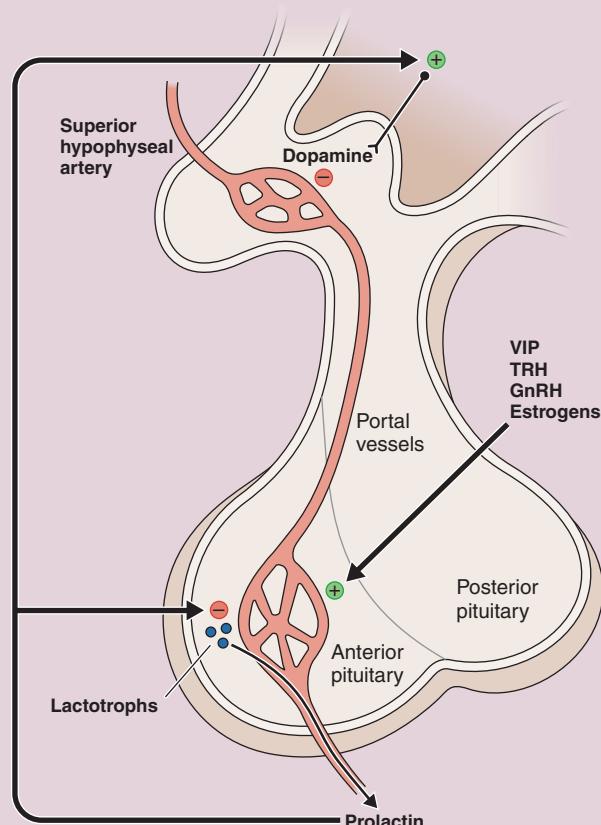

Human prolactin is a 199-amino acid protein with a molecular weight (MW) of 23,000 daltons. Larger prolactin-like molecules can also be found in the circulation. Big prolactin (MW 48,000 to 56,000 daltons) and big, big prolactin (100,000 daltons) are immunologically active but have less biologic activity than the small prolactin monomer. These larger prolactin molecules may represent dimers or tetramers of the native hormone, or may consist of prolactin molecules bound by immunoglobulin G.<sup>6</sup>

The known biologic actions of prolactin in humans are lactogenesis, steroidogenesis, and immunoregulation. The prolactin receptor, encoded by a single gene located on chromosome 5, is expressed in a variety of organ systems. During pregnancy, breast tissue is primed by estrogen and progesterone. The elevated estrogen level during gestation results in proliferation of lactotrophs and increased prolactin production. Prolactin initiates the synthesis of casein, whey, lactoglobulin, and lactalbumin within the breast. However, lactation is not initiated until the high estrogen concentration of pregnancy is reduced postpartum. Breast milk production continues in response to exposure to prolactin secreted as a result of nipple stimulation during breastfeeding.

In the ovary human prolactin has been shown to influence the secretion of progesterone from luteinized human granulosa cells in culture. Conditions of prolactin excess or deficiency in the culture medium are associated with marked decreases in progesterone production. Prolactin receptors and prolactin itself are expressed by luteinized granulosa cells.<sup>7</sup> Prolactin receptors have also been demonstrated within the human adrenal gland. Adrenal stimulation by prolactin affects the secretion of cortisol, aldosterone, and dehydroepiandrosterone from adrenal cell cultures.

Prolactin also appears to play a role in the maintenance of immunocompetence.<sup>8</sup> Receptors for the hormone have been identified on human T and B lymphocytes. The ability of prolactin to stimulate proliferation of lymphoma cells from Nb2 rats provides the basis for current biologic assays. Cyclosporine, an immunosuppressive agent, has been shown to displace prolactin from its receptors. A role for prolactin in the etiology of human autoimmune diseases is currently being investigated.

Regulation of prolactin production and secretion is multifactorial. The primary regulatory mechanism is chronic inhibition by dopamine. Dopamine secreted by neurons in the hypothalamus and the infundibulum of the uterine tube reaches the

**Regulation of prolactin secretion by the anterior pituitary**

**Figure 56-1 Regulation of prolactin secretion by the anterior pituitary.**

anterior pituitary via the portal circulation. Stimulation of D<sub>2</sub> receptors on lactotroph cell membranes results in the lowering of intracellular adenylate cyclase activity. Lower levels of intracellular cyclic adenosine monophosphate result in diminished prolactin release. Prolactin may also inhibit its own release by providing negative feedback at the level of the lactotroph or by stimulating the release of hypothalamic dopamine. Several substances are known to stimulate prolactin secretion. These include epidermal growth factor, vasoactive intestinal peptide, thyrotropin-releasing hormone (TRH), gonadotropin-releasing hormone (GnRH), and estrogens (Fig. 56-1).

There are currently five recognizable dopamine receptors, each of which belongs to the superfamily of G-protein receptors. They are classified into the D<sub>1</sub> group (comprised of the D<sub>1</sub> and D<sub>5</sub> receptors) and the D<sub>2</sub> group (consisting of the D<sub>2</sub>, D<sub>3</sub>, and D<sub>4</sub> receptors). The D<sub>2</sub> receptor is the dopamine receptor displayed by lactotrophs. Not all lactotrophs express equally functioning dopamine receptors. The difference in responsiveness to dopamine is evidence of a phenomenon termed *lactotroph*

*heterogeneity*. This heterogeneity is of clinical importance because a subset of hyperprolactinemic patients is resistant to dopamine agonist therapy.

**CLINICAL FEATURES**

Premenopausal women with hyperprolactinemia may present with menstrual disturbances, infertility, and/or galactorrhea. Table 56-1 lists the most common complaints. Galactorrhea refers to nipple discharge, either spontaneous or expressed, that contains milk. The diagnosis can be made simply by viewing fat globules in a droplet of discharge under light microscopy. When galactorrhea alone is identified, prolactin levels will be normal in up to 85% of cases. However, when both galactorrhea and amenorrhea are experienced, the chance of being hyperprolactinemic is 90%.<sup>9</sup>

Hyperprolactinemia accounts for 10% to 38% of secondary amenorrhea. The cause of gonadal dysfunction is suppression of GnRH release by excess stimulation of prolactin receptors in the hypothalamus. The hypogonadism associated with hyperprolactinemia can result in hot flushes, vaginal dryness, and decreased bone density due to subnormal levels of circulating estradiol.

Diminished bone mineral density associated with hyperprolactinemia has been described in multiple studies. One study of premenopausal women with prolactinomas found a relative risk for osteoporosis of 4.5 compared to healthy controls.<sup>10</sup> Up to 80% of women will have osteoporosis or osteopenia of the lumbar spine, femoral neck, or both at the time of diagnosis.<sup>11</sup> Bone mineral density is significantly decreased in hyperprolactinemic women with amenorrhea but not in those with normal menstruation.<sup>12,13</sup> Bone loss is greater in women with amenorrhea associated with hyperprolactinemia than in those with amenorrhea and normal prolactin levels.<sup>14,15</sup> Bone mineral loss may be reversed after successful treatment of hyperprolactinemia, but bone density does not return to baseline levels.<sup>11,12,15</sup> Hyperprolactinemia in adolescents with menstrual disturbances warrants prompt attention because virtually all of these young women will demonstrate osteopenia or osteoporosis at the time of diagnosis.<sup>11</sup>

**CAUSES OF HYPERPROLACTINEMIA**

Hyperprolactinemia is defined simply as the elevation of circulating prolactin hormone above the normal level (usually 20 ng/mL in women). Diagnosis of “pathologic” hyperprolactinemia requires exclusion of other physiologic or iatrogenic causes of excess

**Table 56-1**  
**Most Common Symptoms of Hyperprolactinemia**

Oligomenorrhea
Amenorrhea
Galactorrhea

Hypopituitarism

**Table 56-2**  
**Causes of Hyperprolactinemia**

Physiologic	Pharmacologic	Pathologic
Stress	Neuroleptics	Prolactinoma
Sleep	SSRIs	Nonfunctioning pituitary tumors
Lunch or dinner	H <sub>2</sub> -receptor blockers	Empty sella syndrome
Chest wall stimulation	Methyldopa	Infiltrative disorders or CNS masses
Pregnancy	Verapamil	Hypothyroidism
	Reserpine	Renal failure
	Metoclopramide	Idiopathic
	Protease inhibitors	

prolactin secretion. Table 56-2 lists many of the causes of hyperprolactinemia.

### Physiologic Variation

The level of circulating prolactin is subject to a variety of physiologic influences, which must be considered. Acute physical or emotional stress will cause transient hyperprolactinemia. Sleep causes prolactin levels to rise. Food ingestion at lunch or dinner (but not breakfast) will also cause a transient elevation of prolactin values.

Stimulation or irritation of the chest wall by suckling, breast implants, herpes zoster, or local trauma can cause prolactin to increase. Conflicting data are available regarding the impact of a clinical breast examination on prolactin secretion. Pregnancy can cause an elevation of prolactin levels to as high as 600 ng/mL. This elevation is believed to result from increased serum estrogen stimulation of the hypothalamus and pituitary.

### Pharmacologic Hyperprolactinemia

Medications that prevent the release of, or block the action of, dopamine are common causes of hyperprolactinemia. All conventional antipsychotics block D<sub>2</sub> receptors and can elevate prolactin levels up to tenfold.<sup>16</sup> Overall, 65% of reproductive-age women taking antipsychotics experience hyperprolactinemia (mean value of 69 ng/mL).<sup>17</sup> Newer “prolactin-sparing” antipsychotics such as clozapine, quetiapine, and olanzapine may cause no change or even a small decrease in prolactin levels.<sup>18,19</sup> Selective serotonin reuptake inhibitors, tricyclic antidepressants, H<sub>2</sub> receptor blockers, methyldopa, verapamil, reserpine, metoclopramide, and protease inhibitors can all cause elevations of prolactin.

### Pathologic Hyperprolactinemia

Pathologic hyperprolactinemia can be caused by lactotroph adenomas, decreased inhibition of prolactin secretion, or underlying medical conditions. Any process involving the hypothalamus and/or pituitary that interrupts the normal secretion of dopamine in the portal circulation can cause hyperprolactinemia. Examples include nonfunctioning pituitary tumors, craniopharyngiomas, sarcoidosis, trauma, or seizures. Other endocrine conditions such as acromegaly or primary hypothyroidism are associated with hyperprolactinemia. TRH can stimulate prolactin release. Renal failure is frequently associated with hyperprolactinemia, but any degree of chronic

renal insufficiency may also cause elevated prolactin levels due to impaired clearance of the hormone or of a prolactin-stimulating factor.<sup>20,21</sup>

Prolactin-secreting pituitary lesions are not true adenomas and are thus most appropriately termed *prolactinomas*. Such lesions are found in at least 40% of hyperprolactinemic patients. Over 90% are confined to the sella and rarely increase in size over time.<sup>22,23</sup> They are almost always benign.

## EVALUATION

Diagnosis of pathologic hyperprolactinemia is made only after other causes have been ruled out. More than one blood sample should be used to verify the diagnosis. Collection is ideally performed in the fully awake, fasting state and in the follicular phase of the menstrual cycle (if ovulatory). Occasionally levels of prolactin that are normal or only moderately elevated are reported when high levels are suspected clinically. This can be caused by the *hook effect*, a falsely low reading due to oversaturation of some immunoradiometric or chemiluminometric assays.<sup>24</sup> If such an effect is suspected, a sample should be reevaluated with serial dilutions.

In other cases prolactin concentrations that are several times normal may be found in patients without any symptoms of hyperprolactinemia. This may occur when the majority of excess circulating hormone is in the form of big, big prolactin. This condition is termed *macroprolactinemia*. Approximately 25% of hyperprolactinemic serum samples are accounted for by the presence of macroprolactin (big, big prolactin).<sup>6,25</sup> Although some macroprolactinemic patients present with amenorrhea, galactorrhea, or infertility, macroprolactin is less biologically active than the prolactin monomer and the majority of patients are asymptomatic. Many asymptomatic women with hyperprolactinemia due to macroprolactin have undergone costly and unnecessary evaluations and treatments.

Most commercial assays do not differentiate between macroprolactin and the prolactin monomer. Polyethylene glycol (PEG) precipitation can be used to identify macroprolactin when this condition is suspected.<sup>6,26</sup> Figure 56-2 demonstrates the difference in serum prolactin concentrations after PEG treatment of samples with and without macroprolactin. For the asymptomatic patient with macroprolactinemia, neither pituitary imaging nor treatment is required. A complete evaluation, however, is indicated if symptoms are present.

When an elevation of serum prolactin levels has been confirmed and careful history has excluded other known causes, laboratory evaluation consists of measurement of serum thyrotropin, human chorionic gonadotropin, blood urea nitrogen, and creatinine. When such testing fails to identify a cause for confirmed hyperprolactinemia, a central lesion should be sought (Fig. 56-3).

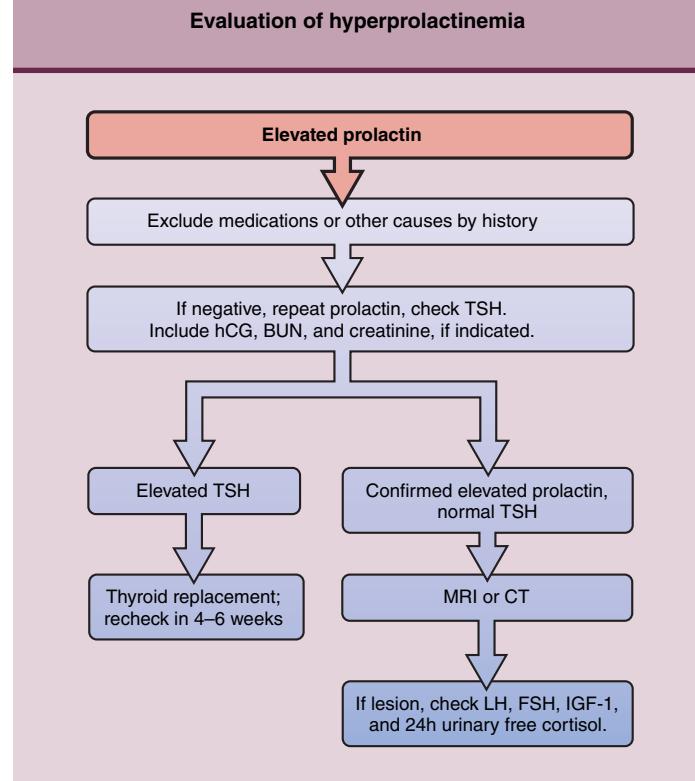

Imaging of the pituitary is indicated at any degree of unexplained hyperprolactinemia (as opposed to waiting until the serum level exceeds a given cutoff value). Some 40% of hyperprolactinemic patients will have a detectable pituitary abnormality even when prolactin levels are only mildly elevated.<sup>27</sup> As demonstrated in Figure 56-4, prolactin levels tend to correlate with prolactinoma size,<sup>28</sup> although exceptions do occur. Nonfunctioning adenomas or other lesions may be large despite

Rights were not granted to include this figure in electronic media.  
Please refer to the printed publication.

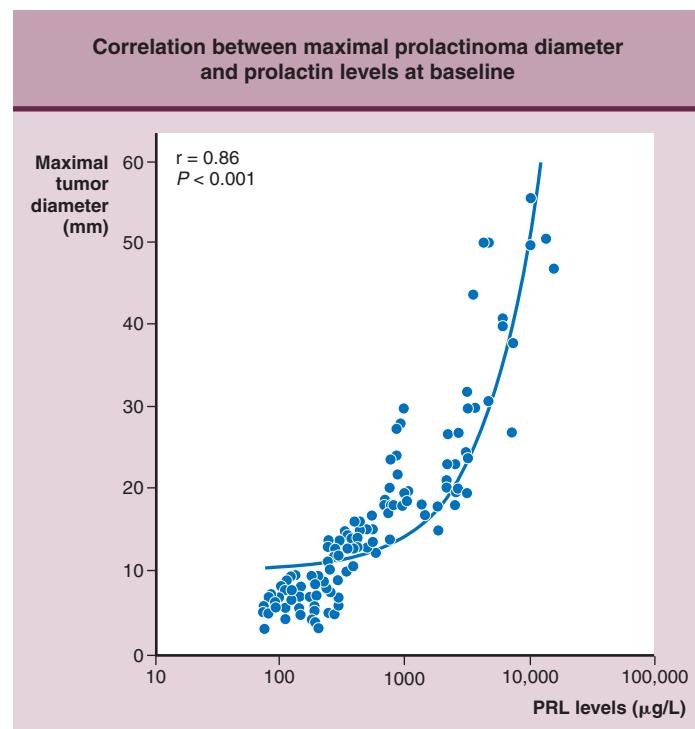

**Figure 56-2 Serum prolactin concentrations before and after treatment with polyethylene glycol (PEG) in patient with either macroprolactinemia or true hyperprolactinemia.** (From Suliman AM, Smith TP, Gibney J, McKenna TJ: Frequent misdiagnosis and mismanagement of hyperprolactinemic patients before the introduction of macroprolactin screening: application of a new strict laboratory definition of macroprolactinemia. Clin Chem 2003;49:1504–1509.)

relatively low levels of excess prolactin secretion. If a suspected explanation for hyperprolactinemia exists, such as the administration of neuroleptics, but prolactin levels are very elevated ( $>200$  ng/mL), imaging should be performed because such levels may be associated with a prolactinoma. Magnetic resonance imaging (MRI) is the most sensitive diagnostic modality, although contrast-enhanced computed tomography scanning may also be employed.<sup>29</sup> If a lesion within the pituitary gland measures less than 10 mm in diameter, it is termed a *microadenoma*. Lesions 1 cm or larger are *macroadenomas*. If the tumor extends beyond the sella turcica or is adjacent to the optic chiasm, ophthalmologic referral should be made for visual field testing.

Almost half of all pituitary lesions secrete prolactin. However, pituitary lesions are capable of secreting any pituitary hormone. At times nonprolactin-secreting lesions may cause hyperprolactinemia secondarily by blocking the inhibitory influence of the hypothalamus on pituitary lactotrophs. Therefore, when lesions are identified, screening tests should be performed to rule out the secretion of other hormones. A 24-hour urine free cortisol level and a serum insulin-like growth factor 1 (IGF-1) will exclude a corticotropin-secreting lesion and a somatotropin-secreting lesion, respectively. Follicle-stimulating hormone, luteinizing hormone, and thyrotropin levels should also be evaluated to exclude gonadotrophic or thyrotrophic adenomas. If

**Figure 56-3 Evaluation of hyperprolactinemia.**

**Figure 56-4 Correlation between maximal prolactinoma diameter and prolactin levels at baseline.** (From Colao A, Sarno AD, Cappabianca P, et al: Gender differences in the prevalence, clinical features and response to cabergoline in hyperprolactinemia. Eur J Endocrinol 2003;148:325–331.)

the pituitary lesion is shown to secrete prolactin only, further management will depend on the size of the lesion, the patient's desire to conceive, and concern about hypoestrogenism.

Women with galactorrhea who have a normal serum prolactin level do not require pituitary gland imaging. However, these women should be screened for somatotropin disturbances because elevated somatotropin levels may stimulate milk secretion. Hyperhidrosis, glucose intolerance, arthritis, neuropathy, hypertension, heart disease, and acral and soft tissue overgrowth may be signs and symptoms of acromegaly in addition to galactorrhea.

## MANAGEMENT

Management options include observation, medication, and surgery. The goals of management depend on the degree of clinical symptoms, the presence and size of a pituitary adenoma, the patient's fertility desires, and concern about bone density.

### Observation

Observation is a valid option in the patient with nontumoral hyperprolactinemia or a microprolactinoma not causing neurologic signs or symptoms. It has been reported that 90% to 95% of microadenomas remain stable or shrink over time.<sup>23,30</sup> In approximately 34% of cases an elevated prolactin concentration will spontaneously normalize within 5 years.<sup>22,31,32</sup> It is unlikely that a prolactinoma will grow significantly without an associated increase in serum prolactin levels. Most patients can be safely monitored with serial prolactin levels, with repeat imaging reserved for cases of significant serum elevations or development of neurologic symptoms.

When observation is selected it is important to advise the patient that osteopenia or osteoporosis may result from

prolonged hypoestrogenism and hyperprolactinemia. Estrogen therapy or an estrogen-containing contraceptive should be considered.

### Medical Therapy

The goals of treatment are suppression of excess prolactin secretion, elimination of clinical symptoms, reduction in tumor size, and preservation of normal pituitary function. Medical therapy is directed at stimulating dopamine receptors, which inhibit prolactin production and secretion and lactotroph mitosis. Options include the ergot-derived bromocriptine, cabergoline, and pergolide and the apomorphine-derived quinagolide. Table 56-3 outlines current preparations. Bromocriptine and cabergoline are the only medications currently approved by the Food and Drug Administration (FDA) for the treatment of primary hyperprolactinemia. Bromocriptine carries the additional indication of ovulation induction.

### Bromocriptine

Bromocriptine mesylate (Parlodel) was the first dopamine agonist used with widespread success. If taken as directed, bromocriptine allows resumption of regular ovulation and cyclic menses in over 90% of women with gonadal dysfunction.<sup>33,34</sup> Prolactin levels will become normal in 70% to 90% of treated women, depending on lesion size.<sup>33-35</sup> After the start of therapy 70% of macroadenomas begin to shrink within 6 weeks and up to 100% within 6 months.<sup>35</sup> Approximately half of macroadenomas shrink at least 50% in size. Tumor shrinkage may continue for several years.<sup>34</sup> If present, visual changes often resolve within days of initiating treatment.<sup>35</sup>

Bromocriptine reaches peak serum levels within 3 hours of oral administration. It has a half-life of 3.3 hours and is capable of lowering prolactin concentrations for 9 hours. Oral dosing is

**Table 56-3**  
Medications Used to Treat Hyperprolactinemia

Medication	Recommended Dosage	Common Side Effects
Bromocriptine (Parlodel)	2.5–10 mg/day, divided PO, 2.5 mg/day PV	Nausea, dizziness, headache, syncope, nasal congestion, orthostatic hypotension, (fewer GI effects when given vaginally)
Bromocriptine (Parlodel SRO)*	2.5–15 mg/day	Similar to bromocriptine
Bromocriptine (Parlodel LA)*	50–100 mg q month IM	Similar to bromocriptine; milder or more transient
Cabergoline (Dostinex)	0.25–1 mg q week or twice weekly	Similar to bromocriptine Hypotension more common
Quinagolide (Norprolac)*	0.025–0.15 mg/day	Similar to bromocriptine, but less common, milder, and more transient
Pergolide (Permax)	0.025–0.5 mg/day	Similar to bromocriptine Fever, nasal congestion, hypotension more common
Hydergine	6–12 mg/day, divided	Similar to bromocriptine
Pramipexole (Mirapex)	0.125–0.3 mg/day	Nausea, postural hypotension
Ropinirole (Requip)	0.08–2.5 mg/day, divided	Nausea, postural hypotension
Lisuride (Dopergin)	0.1–1.2 mg/day, divided	Similar to bromocriptine Nausea, dizziness, drowsiness more common
Terguride	0.25–1.5 mg/day, divided	Similar to bromocriptine Transient CNS effects more common

\*Not available in the United States.

Adapted from Bankowski BJ, Zucar HA: Dopamine agonist therapy for hyperprolactinemia. Clin Obstet Gynecol 2003;46:349–362.

thus required two to three times a day. A long-acting injectable form and a slow-release oral form of bromocriptine are available outside the United States. The slow-release oral form is administered daily, and the injectable is given every 28 days. The side effect profiles of all forms of bromocriptine are similar.

Bromocriptine stimulates D<sub>2</sub> receptors but binds to D<sub>1</sub> receptors as well, which results in adrenergic side effects such as nausea, vomiting, postural hypotension, dizziness, syncope, headache, constipation, and nasal congestion. Approximately half of all patients experience at least one adverse effect, and up to 12% of patients will not tolerate the drug.<sup>36</sup> A low starting dose with gradual dosage increases may help prevent many adverse effects. Treatment is usually initiated with one half of a 2.5 mg bromocriptine tablet taken with food at night. The dose is then increased by one half to one tablet every few days as needed. Dosages greater than 2.5 mg three times a day are rarely required. Response to bromocriptine is assessed by checking the level of circulating prolactin several days after initiating therapy and after each dose adjustment. Vaginal administration of 2.5 to 5 mg daily is also effective and may be used to reduce side effects.<sup>37,38</sup>

When used for ovulation induction, an alternative to daily dosing is intermittent bromocriptine administration. Taking bromocriptine only during the follicular phase results in ovulation and pregnancy rates similar to continuous administration while resulting in decreased cost and improved compliance.<sup>39</sup>

### Cabergoline

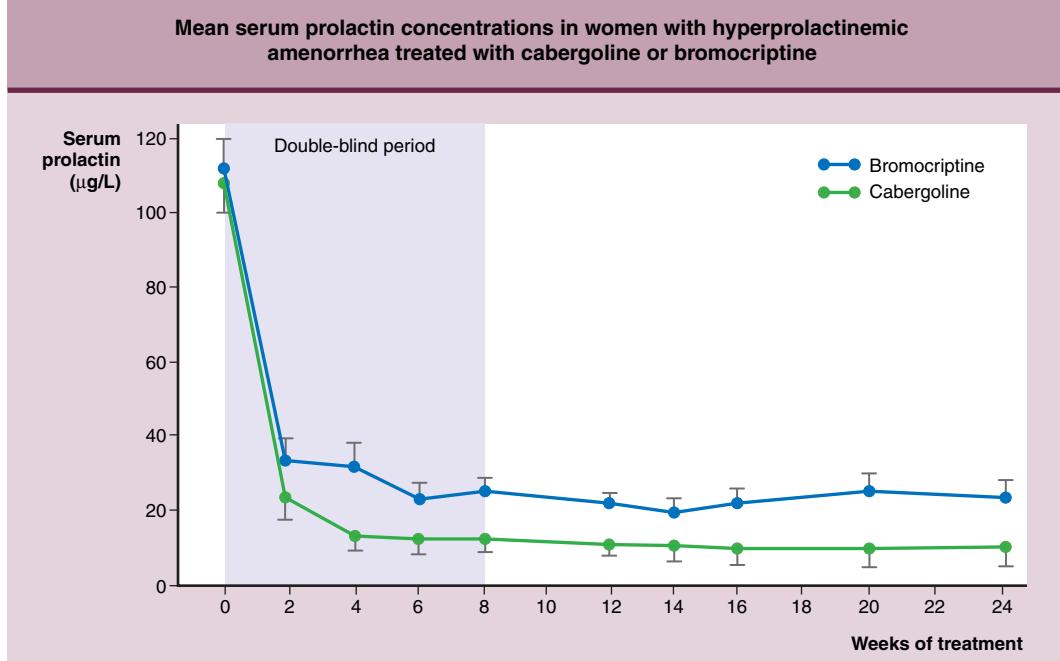

Cabergoline (Dostinex) was approved by the FDA for the treatment of hyperprolactinemia in 1996. It is effective in normalizing prolactin levels and restoring ovulation in over 85% and 90% of women, respectively. It has a high affinity and selectivity for D<sub>2</sub> receptors, allowing for once- or twice-weekly dosing and decreased side effects compared to bromocriptine. Dopaminergic

side effects are similar to those observed with bromocriptine, but overall tolerability with cabergoline is superior.<sup>40</sup>

Cabergoline suppresses prolactin levels in a dose-dependent fashion. In a placebo-controlled, multicenter study 74% of hyperprolactinemic patients had normal prolactin levels within 4 weeks of therapy with 0.5 mg twice weekly. A dosage of 1 mg twice weekly resulted in normalization in 95% of subjects. All dosages ranging from 0.125 mg to 1 mg twice weekly were successful at restoring menses in 82% of amenorrheic women.<sup>41</sup> Cabergoline and bromocriptine were compared in a large, multicenter, double-blind trial for the treatment of hyperprolactinemic, amenorrheic women.<sup>36</sup> A dosage of 0.5 to 1 mg of cabergoline twice a week was more effective than 2.5 to 5 mg of bromocriptine twice a day at restoring ovulatory cycles (72% vs. 52%). Stable normoprolactinemia was achieved in 83% and 58% in the cabergoline and bromocriptine groups, respectively. Figure 56-5 shows the mean prolactin concentrations in both groups. Cabergoline was also better tolerated, with only 3% discontinuing therapy versus 12% of the bromocriptine group (Fig. 56-6). Another trial, by Di Sarno and colleagues, showed that serum prolactin concentration was normalized and tumor size reduced in 82% of macroadenomas and 90% of microadenomas (compared to 46% and 57%, respectively, in a cohort of subjects treated with bromocriptine).<sup>42</sup>

Cabergoline is often effective treatment for patients who are intolerant or resistant to bromocriptine. Verhelst showed a normalization of prolactin concentration in 86% and 70% of patients with bromocriptine intolerance or resistance, respectively.<sup>43</sup> Colao and colleagues found that cabergoline is effective in treating many patients with macroadenomas who received previous treatment with other dopamine agonists but that it is most effective in agonist-naïve patients.<sup>44</sup> They prospectively evaluated 110 patients with macroadenomas treated with cabergoline; 26 patients had not had any prior therapy, and the

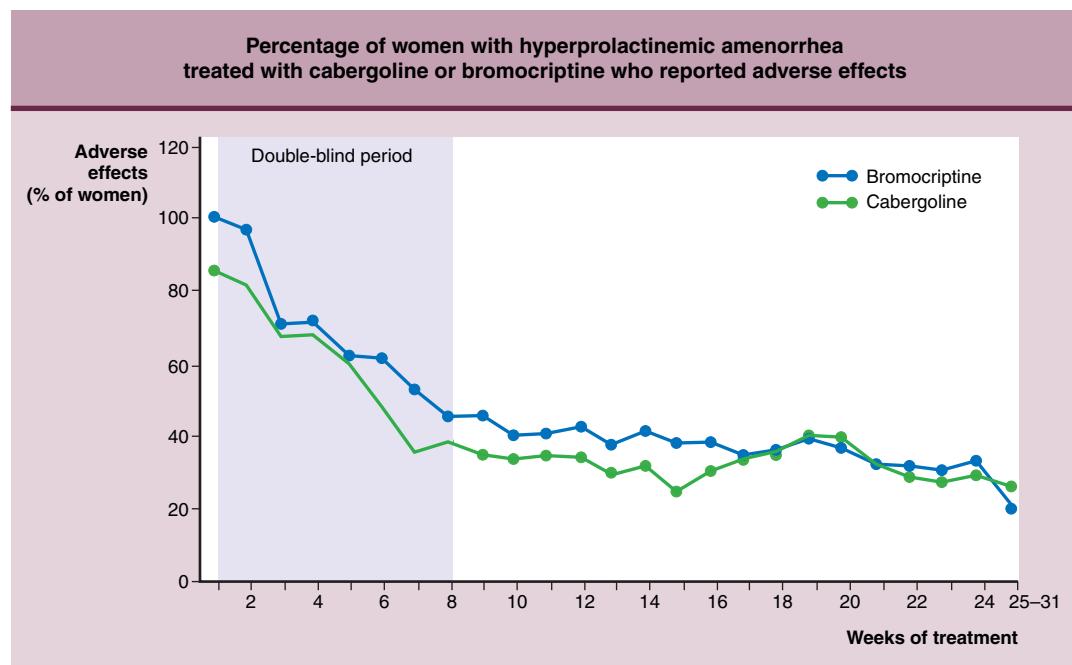

**Mean serum prolactin concentrations in women with hyperprolactinemic amenorrhea treated with cabergoline or bromocriptine**

**Figure 56-5 Mean (+/- SE) serum prolactin concentrations in women with hyperprolactinemic amenorrhea treated with cabergoline or bromocriptine.** (From Webster J, Piscitelli G, Polli A, et al: A comparison of cabergoline and bromocriptine in the treatment of hyperprolactinemic amenorrhea. Cabergoline Comparative Study Group: N Engl J Med 1994;331:904-909.)

**Figure 56-6 Percentage of women with hyperprolactinemic amenorrhea treated with cabergoline or bromocriptine who reported adverse effects.**

(From Webster J, Piscitelli G, Polli A, et al: A comparison of cabergoline and bromocriptine in the treatment of hyperprolactinemic amenorrhea. Cabergoline Comparative Study Group: N Engl J Med 1994;331:904–909.)

rest had been treated previously with bromocriptine or other dopamine agonists. Nineteen were intolerant, 37 resistant, and 28 responsive (but had discontinued therapy for various reasons). Normal prolactin levels were achieved in virtually all patients (109/110), but higher doses and a longer treatment time were required to achieve normalization in the resistant group. In addition, 30% of the resistant patients went on to experience recurrent mild hyperprolactinemia. Figure 56-7 shows that

shrinkage was greatest among the agonist-naïve group, with an average reduction of 92%. Average shrinkage was 66%, 58%, and 59% in the intolerant, resistant, and responsive groups, respectively.

Cabergoline is a long-acting agonist capable of inhibiting pituitary prolactin secretion for more than 7 days after a single dose.<sup>45</sup> Oral dosing is started at 0.25 mg twice a week or 0.5 mg weekly. This dosage is often sufficient to normalize prolactin

**Figure 56-7 Tumor volume before and after 1, 2, and 3 years of cabergoline treatment in patients with no prior treatment, history of dopamine agonist intolerance, resistance, or responsiveness.** (From Colao A, DiSarno A, Landi ML, et al: Macroadenoma shrinkage during cabergoline treatment is greater in naïve patients than in patients pretreated with other dopamine agonists: a prospective study in 110 patients: J Clin Endocrinol Metab 2000;85:2247–2252.)

## Reproductive Endocrinology and Infertility

levels.<sup>43</sup> If nausea or vomiting are significant, vaginal administration of 0.5 mg twice weekly is safe and effective.<sup>46</sup>

Data on safety of cabergoline in pregnancy is limited. Reports are available for more than 300 conceptions occurring concomitant with cabergoline administration without evidence of teratogenic risk.<sup>47</sup> Small series suggest that the rate of pregnancy loss is equal to that of the general population.<sup>40,48</sup> However, because data are limited, it is currently recommended that cabergoline be discontinued at least 1 month before attempting conception.

### **Pergolide**

Pergolide (Permax) is a synthetic ergot derivative currently approved by the FDA for the treatment of parkinsonism but has been used successfully to treat hyperprolactinemia. It is the least expensive dopamine agonist available. Pergolide requires only once-daily dosing. Administration is generally begun at 25 µg orally in the evening. The dose can be increased every 3 to 4 days by 25 µg increments as needed up to 500 µg.

Randomized, controlled trials have shown pergolide to be as effective as bromocriptine at lowering prolactin levels, reducing galactorrhea, and restoring normal menstruation.<sup>49,50</sup> Two recent series of patients with macroadenomas showed an average reduction of 88% to 97% in serum prolactin levels.<sup>51,52</sup> The combined results of these series showed shrinkage of 50% or more in 36 of 44 cases, and 75% or more in 19 of 44. Visual field defects were completely restored in 15 of 18 subjects. The incidence of adverse dopaminergic effects is similar to bromocriptine, although patients taking pergolide experience more flulike symptoms, fever, and vasodilation.

### **Other Agents**

Quinagolide (Norprolac, CV 205-502) is a D<sub>2</sub> agonist derived from apomorphine. It is currently available only in Europe. With a half-life of 22 hours, it is given once daily. Oral dosing is begun at 25 µg. Quinagolide returns prolactin to normal levels in 82% of hyperprolactinemic subjects.<sup>53</sup> Patients who are unable to tolerate bromocriptine are better able to tolerate quinagolide.<sup>54,55</sup> When compared in clinical trials quinagolide is similar to cabergoline in its ability to reduce prolactin concentration.<sup>56,57</sup> However, cabergoline is better tolerated and induces greater tumor suppression than quinagolide.<sup>57</sup>

Hydergine, another ergot derivative, is approved by the FDA for treatment of dementia. It has been used to lower prolactin levels and induce ovulation in hyperprolactinemic women with oral doses of 2 mg three times a day.<sup>58</sup> It has not been compared directly to other dopamine agonists.

Pramipexole (Mirapex) and ropinirole (Requip) are nonergot dopamine agonists that are approved by the FDA for the treatment of Parkinson's disease. Both have been shown in small studies to lower prolactin levels.<sup>59,60</sup> Dopaminergic side effects are common and are similar to those for other dopamine agonists. Other similar agents have been found to treat hyperprolactinemia in a limited number of studies and are included in Table 56-3.

### **Surgery**

Prior to the availability of dopamine agonists, surgical resection of prolactinomas was the mainstay of therapy. It is most often accomplished as a transsphenoidal partial hypophysectomy.

Neurosurgeons have recommended surgical resection in the presence of pituitary apoplexy, macroadenoma, intolerance or resistance to medication, patient preference, or risk of enlargement during pregnancy.<sup>61,62</sup> Because long-term cure rates are highest and complication rates lowest after resection of microadenomas, others have suggested that primary surgery be considered as an alternative to medical therapy for patients with small lesions.<sup>63-65</sup>

Complication rates of transsphenoidal pituitary surgery can be high. These include pituitary insufficiency (19%), diabetes insipidus (18%), cerebrospinal fluid fistulas (4%), carotid artery injury, loss of vision, and meningitis (1% to 2%).<sup>66</sup> Morbidity for prolactinoma resection is often lower than for other pituitary lesions, especially when lesions are small. In recent years an endonasal approach using a rigid endoscope has been used successfully while incurring less morbidity.<sup>67,68</sup> A randomized trial comparing endonasal endoscopy with sublabial transsphenoidal microsurgery reported similar cure rates (normoprolactinemia in 66% and 75% of patients, respectively) with a mean follow-up of 3.5 years. The complication rate was only 4.5% among the endoscopic group, versus 27% in the open group.<sup>69</sup>

Surgical therapy frequently fails to cure hyperprolactinemia. A recent review of 120 microadenomas and macroadenomas treated surgically reported an initial cure rate (postoperative prolactin of <20 ng/mL) of 64%. However, there was a 16.9% recurrence of hyperprolactinemia within 50 months. High pre-operative prolactin levels were most predictive of recurrence.<sup>65</sup> These results are similar to other studies. A summary of 34 published series, including a total of 2600 surgical resections showed that 73.7% of microadenomas and 32.4% of macroadenomas had normal prolactin levels within 1 to 12 weeks of surgery. Recurrence rates were 21% for microadenomas and 19.8% for macroadenomas.<sup>30</sup>

The incidence of malignancy in prolactinomas is rare.<sup>70</sup> Current data do not support surgery for the purpose of excluding malignancy. It therefore appears that, in general, surgery should be considered only as a last resort for treatment of prolactinomas. Clear indications include pituitary apoplexy and lesions that grow despite dopamine agonist therapy. Patients with prolactinomas who are undergoing concurrent treatment with neuroleptics or those who are intolerant of or unwilling to undergo chronic medical therapy may also be offered surgery.

### **Irradiation**

Irradiation of the pituitary has been used in various forms to treat prolactinomas, but cure rates are inconsistent. Irradiation achieves reduction and control of prolactin secretion in 44% to 70% of patients.<sup>71</sup> Side effects include hypopituitarism, increased risk of cerebrovascular accident, and vision loss. Furthermore, if subsequent surgery becomes necessary it is often complicated by radiation-induced fibrosis. Currently gamma knife radiotherapy is employed on a limited basis to treat residual lesions.<sup>72</sup>

## **INDIVIDUALIZING MANAGEMENT RECOMMENDATIONS**

There are no official guidelines for treatment of hyperprolactinemia. Proper management is guided by the findings on pituitary imaging and the patient's desire for fertility.

### No Prolactinoma—Pregnancy Not Desired

Two therapeutic choices are available for the patient without a detectable pituitary abnormality who does not desire pregnancy. These are observation and dopamine agonist therapy. If observation is selected the patient should be informed of the potential for negative impact on bone density. Oral contraceptives (OCs) can usually be safely taken. However, estrogen is known to stimulate pituitary prolactin secretion. Estrogen in combination OCs has been implicated in the formation or expansion of pituitary adenomas in some individuals. Some early reports suggested a relationship between OC use and development of prolactinomas. However, more recent attempts to link OCs to elevated prolactin levels and adenoma growth have not supported a correlation.<sup>73</sup> A prospective study of 16 patients (8 with idiopathic hyperprolactinemia and 8 with microprolactinomas) failed to show any increase in prolactin levels or growth of adenomas after 2 years of combination OC use.<sup>74</sup> Corenblum and Donovan reported on 38 women with hyperprolactinemia and amenorrhea with and without prolactinomas who were taking either combination OCs for up to 2.8 years or conjugated estrogens and medroxyprogesterone acetate for up to 4 years. Prolactin levels and adenoma size remained unchanged or decreased in all groups.<sup>75</sup>

Prolactin levels should be checked yearly after normalization has been achieved. If normal prolactin levels are not attained or dopamine agonist therapy is not tolerated, changing to another agonist may be effective.

### Prolactinoma Present—Pregnancy Not Desired

Other hormone-producing adenomas should be excluded when a pituitary lesion is visualized. In most cases microadenomas do not enlarge over time. Patients should be offered medical therapy or observation. Either dopamine agonist is appropriate, but cabergoline is often better tolerated and may be more effective. Periodic monitoring by MRI is recommended, with more frequent assessment if a macroprolactinoma is present. Combination OCs can generally be taken safely in the presence of microprolactinomas and may protect against bone loss. Women with prolactinomas should be counseled about the risks of OCs and other estrogen-containing products. In addition to pituitary imaging, patients not receiving medical therapy should undergo periodic bone density monitoring. Because macroadenomas have a higher incidence of expansion, medical therapy is indicated. Dopamine agonists are effective at normalizing prolactin levels and reducing macroprolactinoma volume. Prolactin levels drop dramatically within days to weeks of therapy, but tumor shrinkage may take weeks to years.<sup>44</sup> A repeat MRI 6 months after initiating therapy is appropriate.

If a macroprolactinoma threatens to compromise the optic nerve and does not respond to medical therapy, surgical resection should be considered. External radiation may be a necessary adjunct to surgery if substantial tumor bulk remains.

### No Prolactinoma—Pregnancy Desired

When pregnancy is desired by the hyperprolactinemic patient, bromocriptine is the first line of therapy. Normalization of prolactin levels and resumption of menses typically occur within 8 weeks of therapy. The drug is discontinued when pregnancy is diagnosed. Discontinuation does not increase the chance of

pregnancy loss. Children conceived during bromocriptine administration are not at increased risk for congenital malformation.<sup>76</sup> Due to the normal elevation and variation of prolactin levels in pregnancy there is no clinical utility in measuring serum values.

Some hyperprolactinemic, anovulatory patients fail to respond to dopamine agonists or cannot tolerate the side effects. In such cases clomiphene citrate or gonadotropins may be used for ovulation induction. Although cabergoline is also effective at restoring normal gonadotropin activity, there are only limited data about the impact of the medication on early pregnancy.<sup>48,77</sup>

### Prolactinoma Present—Pregnancy Desired

Identification of pituitary hormone secretion other than prolactin from pituitary lesions is essential. After this has been accomplished, the patient is managed in a manner similar to that described for the hyperprolactinemic patient who does not have a lesion. Dopamine agonists or ovulation induction agents may be used. Patients should be counseled about the risks of pregnancy. Gland and adenoma enlargement may occur under the influence of elevated estrogen levels. The chance of developing neurologic symptoms such as headache or visual changes is only 1% to 5% for women with microadenomas but as high as 36% when a macroadenoma is present. When suprasellar extension of a macroadenoma is present, there is a 15% to 35% chance of tumor enlargement during pregnancy.<sup>35</sup>

When pregnancy is achieved, dopamine agonists are discontinued by tapering the daily dose to avoid adenoma infarction. A baseline neuro-ophthalmologic examination is recommended. When a macroprolactinoma is present, visual field testing is performed each trimester to detect gland or lesion enlargement. Measurement of prolactin levels during pregnancy is not useful for predicting prolactinoma growth. Any suggestion of optic nerve compression should prompt MRI evaluation. Dopamine agonist therapy may be restarted if optic nerve compromise is confirmed.

Breastfeeding is not contraindicated. Dopamine agonists can be administered during lactation if neurological symptoms occur. Occasionally spontaneous infarction of an adenoma occurs postpartum. This can result in lowered prolactin levels and resumption of normal menses. If breastfeeding does not occur following delivery, prolactin levels rapidly fall to normal at the end of the first postpartum week. If breastfeeding occurs, prolactin concentrations may remain elevated for a prolonged time, depending on the frequency, duration, and intensity of the suckling stimulus.

## CONTROVERSIES

### Duration of Medical Therapy

Lifelong dopamine agonist therapy may not be necessary for all hyperprolactinemic patients. Early investigations of the effect of agonist withdrawal found that hyperprolactinemia recurred in 70% to 90% of patients. A shortcoming of these studies was a lack of criteria for determining when to attempt withdrawal. Another factor contributing to the poor withdrawal results was the limited duration of therapy in some studies. Regrowth of prolactinomas was particularly likely if therapy was limited to 1 year or less. However, more recent evidence suggests that

## Reproductive Endocrinology and Infertility

withdrawal of medications in properly selected patients can be successful. This may be due to morphologic changes of the lesion, such as fibrosis, cellular atrophy, and necrosis, that occur after long-term dopamine agonist therapy.<sup>78,79</sup>

In the largest study of bromocriptine withdrawal to date Passos and colleagues studied 62 patients with microprolactinomas and 69 with macroprolactinomas who had achieved normoprolactinemia prior to withdrawal. Normal prolactin levels persisted in 20.6% for a median of 44 months of follow-up (range, 3 to 240 months). There was no tumor regrowth observed. The authors attempted to identify variables that could predict successful withdrawal; however, none of the variables studied, including gender, age, tumor size, pretreatment prolactin levels, treatment duration, or initial dose, was predictive of stable normoprolactinemia.<sup>80</sup>

Patients treated with cabergoline may be especially amenable to withdrawal. In a prospective study of 39 patients taking cabergoline for just 1 year, 17% remained euprolactinemic for 12 months of follow-up.<sup>57</sup> In the same study, none of the 39 subjects withdrawn from quinagolide maintained normoprolactinemia.

Colao and colleagues prospectively observed more than 300 patients taking cabergoline as primary therapy for at least 2 years (median, 3 years). Criteria used to consider withdrawal were a normal prolactin concentration, MRI showing no tumor or at least 50% reduction of an existing tumor, and availability for follow-up. In this group, 200 patients discontinued therapy and were followed for 2 to 5 years. Elevated prolactin levels recurred in only 24% of nontumoral patients, 31% of those with microprolactinomas, and 38% of those with macroprolactinomas. None of the 175 patients with lesions before starting therapy experienced tumor regrowth. The risk of recurrent hyperprolactinemia increased 19% for each millimeter increment in diameter of the residual tumor.<sup>81</sup>

It therefore appears safe to consider medication withdrawal in patients with or without prolactinomas who have achieved normal prolactin levels. Ideally patients should be asymptomatic for 2 years and have demonstrated a reduction in tumor size, if present. Patients should be monitored for recurrence of hyperprolactinemia or corresponding symptoms. An appropriate schedule for checking serum prolactin is 3, 6, and 12 months after cessation. An MRI should be repeated every 6 months for the first year, then annually thereafter (or sooner if clinically indicated).

## KEY POINTS

- Pregnancy is the most common cause of secondary amenorrhea in reproductive age women.
- After pregnancy, the next five most common causes are polycystic ovary syndrome (PCOS), hypothalamic amenorrhea, thyroid dysfunction, hyperprolactinemia, and ovarian failure.
- Chronic anovulation is a risk factor for endometrial hyperplasia and carcinoma without treatment.
- PCOS patients are at additional increased risk for type 2 diabetes, hypertension, and myocardial infarction.
- Mild elevation in prolactin may occur with hypothyroidism, and the thyroid-stimulating hormone (TSH) level should be measured to rule out thyroid disease. Treating the thyroid disease is likely to normalize the prolactin level.
- Prolactin normally increases with pregnancy.
- Hyperprolactinemia can lead to hypoestrogenism and osteopenia/osteoporosis.
- Forty percent of pituitary adenomas are prolactinomas, and 90% of prolactinomas are microadenomas.
- Hypoestrogenism from hypogonadotropic hypogonadism or hypergonadotropic hypogonadism left untreated increases the likelihood of low peak bone mass/osteopenia/osteoporosis.
- Differentiating hypoestrogenism from hypogonadotropic (hypothalamic) amenorrhea or hypergonadotropic hypoestrogenism is best achieved by the measurement of follicle-stimulating hormone (FSH). In the former case, FSH is normal or low, and in the latter case, FSH is high (>40 mIU/mL).
- Premature ovarian failure deserves rapid and full evaluation and treatment; psychological counseling is also important.
- Up to 25% of hypergonadotropic hypogonadal women with a karyotype containing an intact (or a portion of the) Y chromosome may have a propensity for a gonadal tumor, and the gonad should be removed.
- The most common cause of intrauterine adhesions is uterine curettage performed during or shortly after a pregnancy.

Secondary amenorrhea is a common problem of reproductive age women. It is defined as the cessation of menses, after at least one or more menstrual cycles, for a minimum of three cycles or 6 months<sup>1,2</sup> (Table 57-1). By the presence of at least one menses the reproductive organs must be initially intact, effectively ruling out congenital urogenital anomalies (e.g., imperforate hymen, transverse vaginal septum, cervical agenesis, uterine agenesis).

Additionally, the hypothalamic-pituitary-ovarian (HPO) axis must be intact to allow for normal pubertal milestones to be met and result in the initial menses prior to the onset of secondary amenorrhea, effectively ruling out primary causes of hypogonadotropic hypogonadism. The pathologic conditions resulting in secondary amenorrhea cover a broad list of etiologies: anatomic, endocrine, genetic, systemic disease, exogenous factors, and iatrogenic causes (see Table 57-3). Some etiologies for amenorrhea such as pregnancy, lactation, and menopause are normal, while others are pathologic and can have a significant impact on overall health. It is best to use a systematic approach to identify the etiology of secondary amenorrhea. One such approach is the World Health Organization (WHO) classification system of amenorrhea<sup>3</sup> (Table 57-2).

Alternatively, a review of the menstruation process and the hypothalamic-pituitary-ovarian-uterine axis is helpful in determining a logical physiologic approach to the etiology of secondary amenorrhea; it is easy to remember and assists in directing an evaluation.

A brief review of the normal menstruation process is important to identify when abnormal cycles or amenorrhea deserve evaluation. The normal menstrual cycle is orchestrated by a complex array of signals involving the hypothalamic-pituitary-ovarian-uterine axis. These signals consist of endocrine, paracrine, and autocrine mechanisms. The brief review will address only some of the endocrine signals. The hypothalamus contains an area within the medial basal portion called the arcuate nucleus, and this area consists of specialized neurosecretory cells that produce gonadotropin-releasing hormone (GnRH) in a pulsatile fashion. These GnRH signals are released at 60- to 90-minute intervals into a portal connection with the anterior pituitary.<sup>4</sup> The pituitary gonadotroph cells synthesize gonadotropins in response to the GnRH signals.<sup>5</sup> Gonadotropins consist of follicle-stimulating hormone (FSH) and luteinizing hormone (LH). The amplitude and frequency of the GnRH signals regulates the type and amount of gonadotropins synthesized. These gonadotropins are released into the bloodstream and are detected by FSH receptors and LH receptors in the ovarian follicles. The ovarian follicles initially respond to FSH by producing estrogen, which is released into the bloodstream where the uterus has receptors and responds by proliferating the endometrial lining. The estrogen also feeds back to the hypothalamus and the pituitary. When a sufficient amount of estrogen is made for an appropriate amount of time, the pituitary responds with a spike in LH secretion, called the LH surge. Approximately 24 hours after the peak LH surge, ovulation occurs. The ovarian follicle releases the oocyte and the follicle converts into a corpus luteum and produces progesterone. The uterus responds to the progesterone secretion by decidualizing the endometrium in preparation for

**Table 57-1**  
**Diagnostic Criteria for Secondary Amenorrhea**

- Normal pubertal milestones
- Initial onset of menses
- Cessation of menses for 3 cycles (if regular cycles) or 6 months (if irregular cycles are present)

an embryo to implant. If no embryo is formed, the corpus luteum stops producing progesterone about 14 days later ( $\pm 2$  days). The waning progesterone levels result in sloughing of the endometrium to the basal layer of the uterus. The sloughing endometrium exits the uterus via its three openings (two fallopian tube ostia and cervical canal) with the assistance of uterine contractions. Since the cervical canal is generally larger and more distensible, most endometrial tissue and blood exit via the vagina in the form of a menstrual period. A majority of women are believed to normally have some retrograde blood flow into the abdominal cavity at the time of menstruation that is later absorbed.<sup>6</sup> Although this physiologic explanation is grossly oversimplified, it helps in addressing issues and approaches in secondary amenorrhea.

The first portion of the menstrual cycle, the follicular phase, begins at the onset of menstruation and continues until ovulation. The duration of the follicular phase varies among women and between cycles in the same woman, and may range from 8 to 21 days. As a woman ages, this phase of the menstrual cycle may shorten. This fact may lead to a shortening of the entire menstrual cycle (e.g., from 29 to 22 days, or a similar shortening when there is a shorter follicular phase and an unchanged luteal phase). The next portion of the menstrual cycle, which describes the time period after ovulation until the onset of the next menses, is called the luteal phase. The luteal phase is fairly consistent from cycle to cycle within women and between women; the duration is usually 12 to 14 days. Consequently, adding the duration of the two phases yields the length of the entire normal menstrual cycle; normal menstrual cycle lengths may vary from 21 to 35 days. When cycle durations are shorter than 21 days or longer than 35 days, it is likely that the patient is not ovulating. Longer cycles may also occur naturally when a pregnancy occurs and the corpus luteum persists in response to the hCG signal.

Secondary amenorrhea is defined as no menstruation for three cycles or 6 months.<sup>1,2</sup> Three cycles may be as short as 63 days to as long as 105 days or longer according to the information stated above. In women with irregular or erratic cycles, 6 months is the arbitrary cutoff when an evaluation should be initiated.

## EPIDEMIOLOGY

Secondary amenorrhea, not including pregnancy or other normal physiologic causes, affects an estimated 3% to 4% of women from the general population.<sup>7-10</sup> During the first few years after menarche (the first period), it is not uncommon for girls to have anovulatory cycles that later become regular cycles. Close monitoring is warranted but intervention at this point is not required. Once beyond these first few years, oligomenorrhea and secondary amenorrhea should be evaluated. Prior texts have recommended that an evaluation begin at age 16 when other secondary sexual characteristics are present. However, recent published reports of pubertal data on U.S. girls suggest that this evaluation should begin earlier, at about 14 years of age in developed countries, since 90% of U.S. girls menstruate by age 13.75; in less well developed countries the age may be lowered only to 15 or left at 16.<sup>11-15</sup> For the time being, the standard of care for the United States is dictated by the American Society for Reproductive Medicine (ASRM) Practice Committee, which recommends that this evaluation occur at 15 years of age with secondary sexual characteristics and 13 years of age without breast development, or within 5 years after breast development if that occurs before age 10.<sup>2</sup>

Etiologies for secondary amenorrhea are listed in Table 57-3.<sup>9,10,16</sup> Pregnancy should always be ruled out first. Even patients who have a history of amenorrhea may ovulate unexpectedly and conceive. Either a urine or a serum  $\beta$ -human chorionic gonadotropin (hCG) concentration is an adequate test. Most over-the-counter urine kits measure an hCG level over 50 mIU/mL as positive and some go as low as 25 mIU/mL. Serum  $\beta$ -hCG can be measured down to less than 5 mIU/mL. By the time of a missed period, the hCG level should be about 100 mIU/mL and will double every 2 days in 66% of cases.<sup>17</sup> Adolescents, in general, may not be forthcoming regarding sexual activity and should be offered pregnancy testing.<sup>13</sup> Amenorrhea due to pregnancy (normal or not) is not the focus of this chapter. Besides pregnancy, cases of secondary amenorrhea will likely be due to one of five etiologies: polycystic ovary syndrome (PCOS), thyroid dysfunction, hyperprolactinemia, hypothalamic amenorrhea, and ovarian failure. The remaining etiologies are much less common.

## CLINICAL FEATURES

Any patient with secondary amenorrhea or even oligomenorrhea deserves a diagnostic evaluation. Initially, a thorough history and physical examination should be performed. In secondary amenorrhea, developmental milestones for growth and secondary sexual characteristics (breast and pubic hair development)

**Table 57-2**  
**World Health Organization (WHO) Classification of Secondary Amenorrhea**

WHO Class	Estradiol	Follicle-stimulating Hormone (FSH)	Prolactin	Other	Diagnosis
WHO 1	Low	Normal or low	Normal	No hypothalamic or pituitary mass	Functional hypothalamic amenorrhea
WHO 2	Normal	Normal	Normal	—	Eugonadal
WHO 3	Low	High	Normal	—	Ovarian failure

**Table 57-3**  
**Etiologies of Secondary Amenorrhea**

Anatomic Site	Etiologies of Amenorrhea
Hypothalamus (hypogonadotropic hypogonadism)	Stress (physical or emotional) Eating disorder Excessive exercise Obesity Excessive weight loss Chronic systemic disease Idiopathic hypogonadotropic hypogonadism (IHH) CNS tumor
Pituitary	Thyroid disease (hyper- or hypo-) Pituitary adenoma Hyperprolactinemia (drug-induced, physiologic, idiopathic, etc) Craniopharyngioma Other pituitary tumors Hypopituitarism Empty sella Pituitary infarct
Ovary	Polycystic ovary syndrome Premature ovarian failure Ovarian neoplasm
Uterus	Pregnancy Endometrial atrophy (drug-induced) Endometrial damage (infection) Asherman's syndrome (intrauterine adhesions)
Cervix	Cervical stenosis or obstruction
Adrenal	Cushing's syndrome Adrenal adenoma Late-onset congenital adrenal hyperplasia
Systemic	Chronic systemic disease
Exogenous	Contraceptives, depot leuprorelin

should be reviewed and most likely will be normal, unlike the case in some patients with primary amenorrhea. Occasionally, a patient may have what initially sounds like secondary amenorrhea, but upon review of developmental milestones, may reveal that puberty did not occur normally but was induced by hormonal therapy and amenorrhea occurred when she stopped the cyclic hormonal therapy. This type of case should be classified as primary and not secondary amenorrhea (see Chapter 31).

A detailed history should review the patient's general health looking for chronic diseases such as diabetes, renal failure, seizures, inflammatory bowel disease, hypertension, depression, or any form of malabsorption or nutritional deficiency.<sup>2,18</sup> Any chronic illness that is not diagnosed or is not well controlled may affect the menstrual cycle.<sup>19</sup> In some circumstances the medical therapy for a chronic illness may be the cause of the menstrual irregularity (e.g., antidepressant, dopamine antagonist, phenothiazines, reserpine derivative).<sup>20</sup> Use of illicit drugs, such as opiates or amphetamines, may affect the menstrual cycle. Trauma to the head, breast, or pelvis may affect the HPO axis and subsequently the menstrual cycle. Similarly, tumors of the central nervous system (CNS) may cause an HPO axis disturbance and result in amenorrhea. Additionally, significant weight changes (gain or loss) often impacts the menstrual cycle. Significant weight gain and obesity have been associated with anovulation and amenorrhea.<sup>21,22</sup> Significant weight loss, either

voluntary or iatrogenic (e.g., gastric bypass surgery), has also been associated with secondary amenorrhea. It is important to consider anorexia nervosa in the differential diagnosis. Anorexia nervosa criteria include onset before 25 years of age, loss of at least 25% of original body weight, distorted attitude toward eating (weight overrides hunger, admonitions, reassurance, and threats), denial of illness, enjoyment in losing weight, desired body image of extreme thinness, unusual handling of food, no known medical cause to account for the weight loss, no other psychiatric diagnosis, and at least two of the following: amenorrhea, lanugo, persistent bradycardia ( $\leq 60$  beats per minute), periods of overactivity, episodes of bulimia, and vomiting.<sup>23</sup> A few questions regarding diet, exercise (frequency and intensity), and stress are warranted.<sup>24-26</sup>

A clinical history of change in hair quality (coarser or finer; increased loss) may point to an endocrine disturbance. Increased hair growth may be associated with hypothyroidism, hirsutism, PCOS, Cushing's syndrome, and late-onset congenital adrenal hyperplasia. Rapid increases in terminal hair growth or the onset of virilization should raise suspicion of an androgen-secreting tumor, most likely of ovarian or adrenal origin.<sup>27</sup> The clinical history and physical examination are often sufficient to suspect the diagnosis. The measurement of serum androgens can help clinch the diagnosis and identify the likely source of the tumor. Occasionally, a patient comes in with secondary amenorrhea and a new diagnosis of Cushing's syndrome is made; most have additional symptoms such as hypertension, central obesity, and purplish striae.<sup>28</sup>

A detailed review of the patient's gynecologic history is important. Irregular periods since the onset of menarche are more common in PCOS syndrome and late-onset congenital adrenal hyperplasia, whereas a later onset after menarche may indicate new-onset thyroid disease, a PCOS variant, or other cause. Secondary amenorrhea associated with a history of hot flashes suggests the presence of ovarian failure, which occurs in 1% to 5% of women under 40 years of age.<sup>29,30</sup> Abnormal Papanicolaou (Pap) smears, sexually transmitted diseases, pelvic infections, and gynecologic procedures (either cervical or uterine) may be of consequence. Infrequently, secondary amenorrhea results after surgical procedures, such as cryosurgery, cone biopsy, dilation and curettage (D&C; particularly D&C associated with pregnancy, as in missed abortion, elective termination, or postpartum hemorrhage), or hysteroscopic procedures (e.g., myoma resection, intrauterine adhesiolysis). These procedures may result in cervical stenosis, which blocks the outflow of menstruation and is often associated with significant dysmenorrhea, or may result in lack of endometrial development due to intrauterine adhesions, causing hypomenorrhea or amenorrhea without other symptoms.<sup>31</sup> Secondary amenorrhea is uncommon after uterine artery embolization; however, there have been two such case reports.<sup>32,33</sup> In these cases, the amenorrhea occurs immediately after the surgical procedure and the time course is evident. Rarely, after an obstetric delivery associated with significant bleeding, the patient may note no lactation and later amenorrhea resulting from an insult to the pituitary, causing Sheehan's syndrome (hypopituitarism). Intentional (iatrogenic) secondary amenorrhea may follow endometrial ablation.

Occasionally, secondary amenorrhea occurs after stopping the birth control pill (postpill amenorrhea) or after stopping depot

## Reproductive Endocrinology Infertility

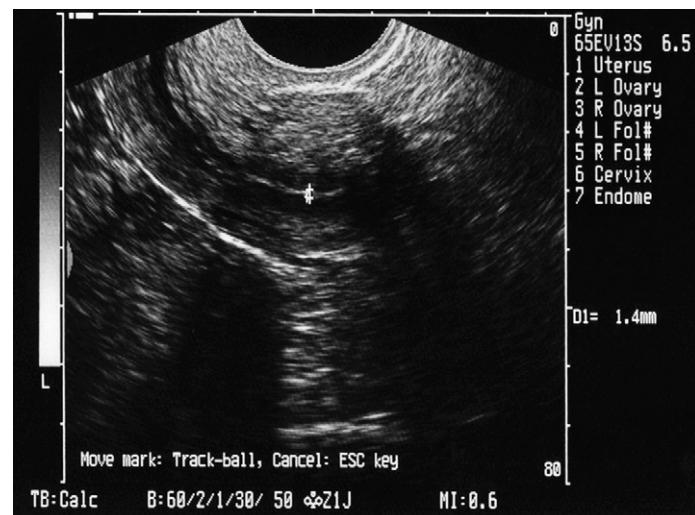

medroxyprogesterone acetate. Patients with postcontraceptive amenorrhea deserve an evaluation if amenorrhea persists beyond 6 months after the last birth control pill or 12 months after the last medroxyprogesterone injection. The incidence of postpill amenorrhea is 0.7% to 0.8%<sup>7</sup> and is a diagnosis of exclusion. The past menstrual history prior to contraceptive therapy alerts the physician as to whether amenorrhea is a new, progressive, or recurring problem (such as may occur in PCOS).

Additionally, progestational agents, hormonal contraceptives, and GnRH agonists may be used to induce a medical secondary amenorrhea to treat significant endometriosis symptoms or other causes of dysmenorrhea. One case report exists of two individuals with secondary amenorrhea as a result of occupational exposure to microparticles of estrogens/progestins while working in an oral contraceptive manufacturing plant.<sup>34</sup>

Close attention during the physical examination can help elucidate some of these etiologies and narrow the differential diagnosis. The vital signs may reveal the bounding and rapid pulse of hyperthyroidism, the slow pulse associated with hypothyroidism, or the hypertension of Cushing's syndrome. The body habitus and body mass index ( $>25$  = overweight,  $>30$  = obesity, and  $<21$  = underweight) may yield extremes of weight. Skin color and consistency can also be indicators of appropriate nutrition or other endocrine etiologies (such findings as soft, moist skin with a rapid, bounding pulse may suggest hyperthyroidism, whereas dry skin with mild hirsutism may suggest hypothyroidism or hypoestrogenism). Skin lesions such as acanthosis nigricans may indicate insulin resistance, or striae may indicate the presence of Cushing's syndrome. Hair type and distribution may indicate hirsutism (associated with PCOS syndrome) or lanugo (suggestive of a nutritional disorder). The breast examination may reveal a bilateral, cloudy white nipple discharge, which appears as multiple fat cells on microscopy and is consistent with galactorrhea. Frequently, galactorrhea is associated with hyperprolactinemia. The abdominal and pelvic examinations serve to rule out a mass or infection. Ovarian masses or a hematometra may be present. In the latter case, the patient usually has a tender mass on pelvic examination and possibly on abdominal examination. If a hematometra results from cervical stenosis, then probing the cervical canal with a uterine sound during the physical examination may both diagnose and cure the problem; more commonly cervical dilation is needed or an ultrasound-guided D&C in severe cases. Decreased pubic hair and decreased vaginal rugae with pinkish-red shiny mucosa suggests hypoestrogenism. The patient may also note decreasing breast size, hot flashes, and vaginal dryness when asked. A swab of the vaginal side wall rolled on a microscope slide and stained with a nuclear stain can reveal a maturation index consistent with a higher percentage of parabasal cells than intermediate or superficial cells, which also indicates hypoestrogenism.

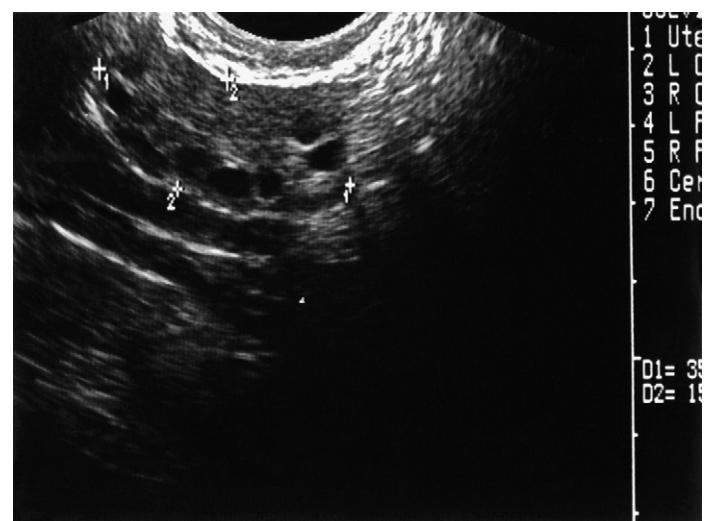

**DIAGNOSIS**

During the initial visit for secondary amenorrhea, it is important to reassure the patient that the etiology will likely be determined by a thorough history, physical examination, ultrasound examination, and a few blood tests.<sup>35</sup> The history and physical and ultrasound examinations may guide the diagnostic testing so that

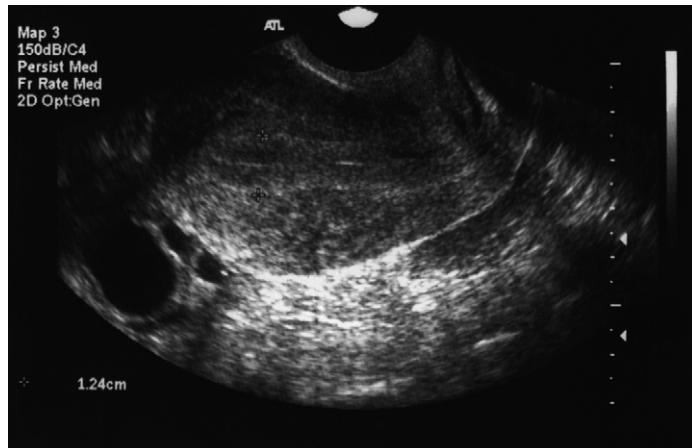

**Figure 57-1 Transvaginal ultrasonogram of the uterus.** The endometrial stripe (≠) is very thin, consistent with hypoestrogenism.

fewer tests are needed. If an ultrasound machine is available in the office, a quick assessment at the time of the physical examination may indicate whether estrogen is being produced, by the thickness of the endometrium and the size of the uterus. Transvaginal ultrasound can be quite helpful during this initial assessment.<sup>36</sup> Ovaries with rare follicles and a uterus with a thin endometrial stripe (Fig. 57-1) on ultrasound suggest ovarian failure. Ovaries with several small follicles and a thin endometrial stripe also indicate a hypoestrogenic state. Ovaries with many ( $>10$ ) small follicles each (Fig. 57-2) and an endometrium with a trilaminar pattern (Fig. 57-3) suggest chronic anovulation and possibly PCOS.<sup>37</sup> Overly thickened endometrium ( $>14$  mm) may be associated with early pregnancy or may suggest endometrial hyperplasia or worse; nonpregnant individuals in this

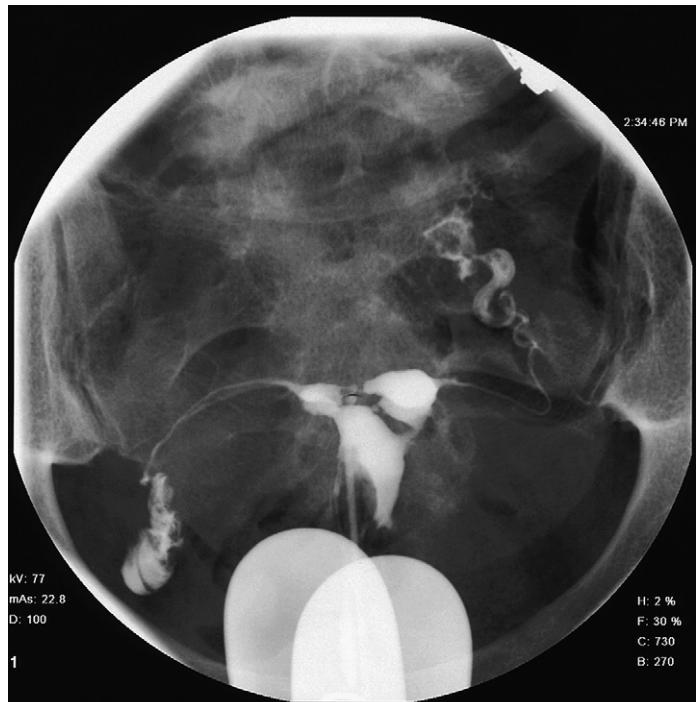

**Figure 57-2 Transvaginal ultrasonogram of an ovary.** This ovary has multiple small follicles that can be normal in the early part of the menstrual cycle or consistent with polycystic ovary syndrome (PCOS). In addition, the small follicles are displaced to the periphery, which is consistent with the "pearl necklace" sign commonly seen in PCOS.

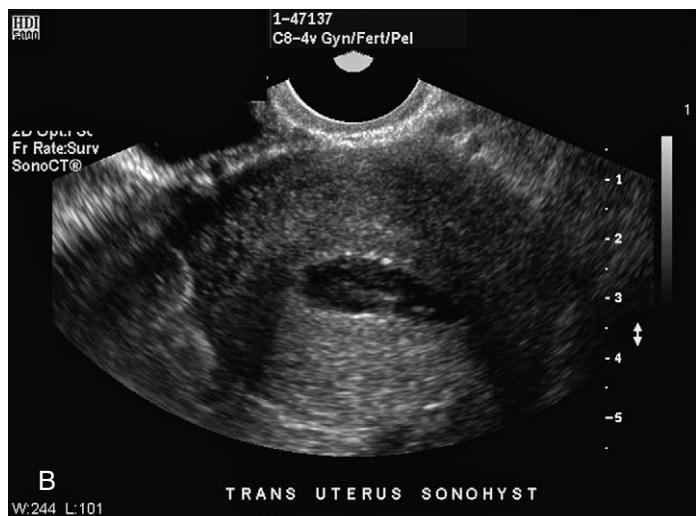

**Figure 57-3 Transvaginal ultrasonogram of the uterus.** The endometrial stripe is thickened and has a trilaminar appearance. This finding is normal in the proliferative phase, and this image also shows an enlarged ovarian follicle, consistent with the proliferative phase. Chronic anovulation can also present with a trilaminar, thickened endometrial stripe because of the unopposed estrogen effect.

situation deserve an endometrial biopsy. Secondary amenorrhea with unopposed endogenous estrogen may have an increased risk for progression to complex hyperplasia with atypia or endometrial cancer. Lastly, irregular areas of thin endometrium within thicker endometrium may suggest intrauterine adhesions or Asherman's syndrome.<sup>38</sup> Transvaginal ultrasound is only about 52% accurate in making the diagnosis of intrauterine adhesions alone.<sup>39</sup> Saline infusion sonohysterography is a technique by which saline is injected into the uterine cavity through a catheter with a balloon or acorn plug to block backflow through the cervix (Fig. 57-4). This technique allows for improvement in the diagnosis of intrauterine synechiae to about 90% to 100%.<sup>39</sup> A hysterosalpingogram (HSG) may also reveal the diagnosis of

**Figure 57-5 Hysterosalpingogram of the uterus.** An intrauterine adhesion or synechia is noted by the displaced contrast material.

**Figure 57-4 Saline infusion sonohysterogram (SIS) of the uterus.** A, The transvaginal ultrasonogram of the uterus in the longitudinal position is shown. The hypoechoic area within the uterine cavity is saline, which was injected during the SIS procedure. B, The transvaginal ultrasonogram of the transverse uterus near the fundus is shown with saline within the uterine cavity.

**Figure 57-6 CT scan of the uterus.** This sagittal CT scan with contrast is notable for a uterus that is distended with blood, also known as hematometra, due to cervical stenosis. The arrows demonstrate the position of the uterocervical junction. Both the uterus and the cervical canal were distended after a prior loop electrical excision procedure. The bladder contains contrast material and is anterior to the uterus.

reproductive-aged woman. If there are concerns about hypoestrogenism, then FSH and estradiol measurements are warranted. An elevated FSH with a low estradiol suggests ovarian failure. This test should be repeated a month later to confirm this diagnosis. Most of these women will have hot flashes if they have been exposed to endogenous estrogen previously (as is presumed in secondary amenorrhea). A normal or low FSH with a low estradiol suggests hypothalamic amenorrhea; this group of patients rarely complain of other symptoms besides secondary amenorrhea.

The third-generation TSH test is a highly sensitive test that can detect hyper- or hypothyroidism. In the case of hypothyroidism there may be a concurrent elevation in prolactin levels in 0% to 40% of cases, and 85% of hypothyroid patients with hyperprolactinemia normalize the prolactin levels with thyroid therapy.<sup>40</sup> A case of pituitary gland hyperplasia in primary hypothyroidism regressed with aggressive thyroid hormone therapy.<sup>41</sup> Control of thyroid disease can result in resolution of anovulation and resumption of normal menstrual cycling.

Hyperprolactinemia deserves further evaluation. Multiple causes need to be considered. A mild elevation in prolactin maybe due to hypothyroidism, pregnancy, or a poorly timed test. Certain medications (e.g., antidepressants) may elevate the prolactin level and make the laboratory interpretation difficult. First, the prolactin level should be retested in the ideal setting: fasting, morning, follicular phase, and prior to any exercise, sex, or breast manipulation.<sup>42</sup> If the prolactin level is still elevated, even mildly, then MRI of the head is recommended to determine the presence or absence of a pituitary tumor. Fifty to sixty

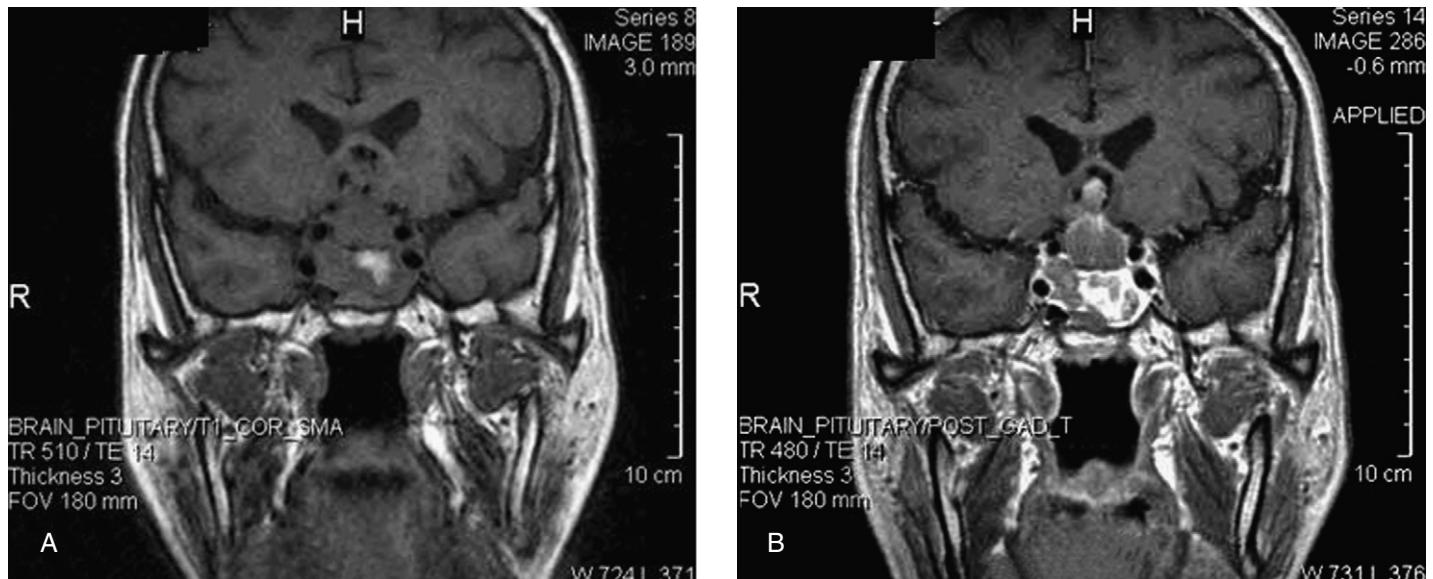

percent of women with hyperprolactinemia, regardless of level, have a pituitary tumor. MRI can also determine whether there is extension of a pituitary tumor into the bony structures above the sella turcica to rule out potential compression of the optic nerve or, conversely, another CNS lesion may be compressing the pituitary stalk and indirectly cause hyperprolactinemia.

Pituitary tumors are designated as microadenomas when their size is less than 10 mm and as macroadenomas when their size is greater than 10 mm (Fig. 57-7). Approximately 90% of prolactinomas are small.<sup>43</sup> It is rare for a microadenoma to progress to a macroadenoma even without treatment.<sup>44</sup> On the other hand, all macroadenomas must have been microadenomas at one point in time, though macroadenomas are much rarer.<sup>45</sup> Macroadenomas increase in size about 20% to 33% of the time.<sup>46</sup>

The most common pituitary tumor is the prolactin-secreting pituitary adenoma or prolactinoma, and it makes up about 40% of all pituitary tumors.<sup>43</sup> Nonsecreting pituitary tumors make up another 30% to 40%, followed by ACTH-secreting tumors and GH-secreting tumors at 2% to 10% each, and lastly by TSH-secreting tumors at 1%.<sup>45,47</sup> Nonsecreting pituitary tumor patients may secrete excess  $\alpha$ - or  $\beta$ -subunit FSH as measured by radioimmunoassays.<sup>48</sup> Occasionally, a nonpituitary tumor or mass compressing the pituitary stalk or distorting the pituitary anatomy may result in hyperprolactinemia without a prolactinoma being present. In autopsy reports, 3% to 27% of asymptomatic patients were found to have occult pituitary tumors and about 10% of normal live human volunteers had pituitary tumors of 3 to 6 mm size on MRI of the pituitary<sup>49</sup>—these asymptomatic tumors are referred to as incidentalomas. Another study showed that 88% of asymptomatic individuals with “incidentalomas”

**Table 57-4**

ranging in size between 5 and 25 mm could be followed without surgery and that these tumors are benign.<sup>50</sup> Other etiologies in this differential diagnosis include craniopharyngiomas, meningiomas, arachnoid cysts, granulomatous diseases, gliomas, metastatic tumors, chordomas, germ cell tumors, and other cell rest tumors and benign lesions.<sup>27,45,47</sup> Most hormone over-secreting tumors have few clinical symptoms and typically are subtle and slowly progressive clinically.<sup>45</sup> In addition to the above screening, clinical screening for hormone oversecretion is indicated and should include insulin-like growth factor 1 (most sensitive for acromegaly) or growth hormone (GH) level after an oral glucose load (normal GH level <2 ng/L) and a test for Cushing's disease (24-hour urinary free cortisol or an overnight dexamethasone suppression test).

#### Polycystic Ovary Syndrome, Nonclassical Adrenal Hyperplasia, and Hyperandrogenism

The diagnosis of PCOS is a clinical diagnosis after exclusion of other etiologies with similar symptoms of anovulation, hyperandrogenism, and possibly obesity (e.g., hypothyroidism, late-onset or nonclassical congenital adrenal hyperplasia, and hyperprolactinemia). Nonclassical congenital adrenal hyperplasia can be screened for via a basal 17-hydroxyprogesterone level; elevation over 200 ng/dL requires further testing with an ACTH stimulation test.<sup>51</sup> The clinical diagnosis of PCOS is based on a triad of symptoms and signs: oligomenorrhea/amenorrhea, hyperandrogenism (by clinical examination or laboratory values), and polycystic-appearing ovaries on ultrasound, according to the last consensus statement.<sup>52</sup> Hyperandrogenism may consist of hirsutism and acne or may have no external symptoms, just elevated androgens in reproductive-aged women (elevated or high normal total testosterone or free testosterone or other androgen).<sup>53</sup> Asians are more likely to have elevated androgen levels than hirsutism or acne when the diagnosis is PCOS syndrome. Other groups may be similar. Polycystic-appearing ovaries on ultrasound (see Fig. 57-2) consists of multiple small

follicles (>10 follicles per ovary that are less than 10 mm in size). These small preantral follicles may be aligned along the cortical border of the ovary, called the "pearl necklace" sign. The diagnosis of PCOS does not rely on the LH:FSH ratio, although this ratio may be elevated at or over 2:1. Some PCOS patients have normal LH:FSH ratios. A subset of patients with PCOS syndrome has insulin resistance, and this should be evaluated. Skin findings of acanthosis nigricans suggest the presence of insulin resistance.<sup>53</sup> There are several ways to diagnose insulin resistance: an elevated fasting insulin level, an increased ratio of insulin to glucose, or increased levels of insulin during a glucose challenge test. These patients are at increased risk for type 2 diabetes and should be screened with a fasting glucose level regularly. Two fasting glucose levels on separate occasions that are greater than 126 mg/dL indicate the presence of type 2 diabetes, according to the American Diabetes Society.

Highly elevated androgens (total testosterone >200 ng/dL or dehydroepiandrosterone sulfate [DHEA-S] >700 µg/dL) with rapidly worsening hirsutism or virilization may be indicators of a tumor in the ovary or adrenal gland. Elevated total testosterone with normal DHEA-S suggests that the tumor likely originates in the ovary and not the adrenal gland. Occasionally, PCOS presents with a high testosterone and a pelvic ultrasound is indicated to evaluate the ovaries for the presence of a neoplasm. If both the total testosterone and the DHEA-S levels are elevated, the tumor is more likely to be in the adrenal gland. MRI of the abdomen/pelvis and possibly the head is warranted to confirm the diagnosis. MRI is preferred over CT because it can visualize soft tissue structures better (pituitary, ovaries, etc.) without artifacts from bony structures.

If symptoms of Cushing's syndrome are present, a 24-hour urine free cortisol test or a dexamethasone suppression test is indicated to make the diagnosis. A dexamethasone suppression test is performed by giving 1 mg dexamethasone at about 10 or 11 PM and then measuring the fasting morning cortisol level the next morning at 8 AM, which should be suppressed (<5 mg/dL).

## Reproductive Endocrinology Infertility

An elevated cortisol deserves further evaluation for Cushing's syndrome or other sources of cortisol production with either a long dexamethasone suppression test or MRI.

### TREATMENT BY DIAGNOSIS AND OUTCOME

The treatment for secondary amenorrhea depends on the etiology.

#### Hypothalamic Amenorrhea

In hypothalamic amenorrhea, the patient is not making much estrogen or progesterone because there is no stimulus from the hypothalamus and thus the rest of the HPO axis is not activated. It is important to identify and treat the cause whenever possible. Ninety-four percent of these patients have reversible causes, and only 6% have irreversible conditions.<sup>16</sup> Causes may be stress, eating disorders, excessive exercise, or organic disease, such as CNS tumors.<sup>25,26,54</sup> MRI should be performed to rule out a CNS lesion prior to any medical therapy. CNS lesions causing hypothalamic amenorrhea may need surgical intervention and deserve referral to a neurosurgeon for assessment. Once a CNS tumor is ruled out, it is important to treat any identified causes (e.g., reduce stress, deal with eating disorders, meet nutritional needs, and reduce excessive exercise). Treating the cause leads to ovulatory cycles within 12 months, but as many as 30% remain amenorrheic.<sup>5</sup> Despite therapy, patients with eating disorders often replace their eating problem with excessive exercise, which continues the hypothalamic amenorrhea. Amenorrhea due to excessive exercise may be, in part, due to inadequate nutritional replacement. Increased exercise increases the nutritional requirements. Yet, protein, fat, and total caloric intake are often lower than needed in relation to the increased energy demands of exercise in amenorrheic athletes.<sup>24</sup> Body composition and psychological stress may also be playing a role. The initial therapy for excessive exercise is to reduce the amount of exercise and to modify dietary intake appropriately; this is usually sufficient for resumption of menstrual cycles. In addition, patients with anorexia nervosa benefit from participation of a team of experts in their therapy. This team may consist of a medical physician or gynecologist, nutritionist, and psychiatrist.

Hypothalamic amenorrhea has the greatest detrimental impact on bone when it occurs during adolescence. These individuals are at increased risk of not achieving their normal peak bone mass. With a lower peak bone mass, they will be at increased risk of osteopenia and osteoporosis later in adult life.<sup>55,56</sup> The amount of bone loss is directly proportional to the duration of hypoestrogenism.<sup>55</sup> The minimum level of estradiol to maintain bone mineral density is estimated to be 60 pg/mL.<sup>24</sup>

Concurrent hormonal supplementation and calcium and vitamin supplements are warranted in patients with hypothalamic amenorrhea to protect against rapid bone loss. Hormonal supplementation may be given in a variety of ways: cyclically to mimic a menstrual cycle or continuously to maintain the amenorrhea, yet treat the bone loss issue. Cyclically, a conjugated estrogen (0.625 mg/day) or ethinyl estradiol (1–2 mg/day) is given daily and a progestin (5–10 mg) or progesterone (100–200 mg) is given for 12 to 14 days per month. It is usually easiest to pick an easy-to-remember day like the first of each month to start

the progestin or progesterone therapy. Continuously, hormones may be given with the same dose of estrogenic compound but a lower dose of progestin (e.g., 2.5 mg) per day. Alternatively, higher dose hormones, such as birth control pills or the contraceptive vaginal ring or patch may be administered to achieve the same purpose.<sup>57</sup> In the reproductive-age group, some women prefer one of the hormonal contraceptive methods, whether or not they are sexually active, since their peers may be using contraceptive therapy and the patients may perceive it as more acceptable. In situations such as amenorrhea due to anorexia nervosa or excessive exercise the patient may prefer a continuous regimen of hormonal contraceptives without using the placebo pills and without breaks in treatment in the hope of maintaining the amenorrhea (iatrogenically) but lessening the adverse sequelae of hypoestrogenism. Prolonged therapy with a progestin-dominant drug as in hormonal contraceptive therapy leads to endometrial atrophy and amenorrhea. Over time some of these individuals may have breakthrough bleeding, which responds to a short course of supplemental estrogen. Beside the possible minor side effect if breakthrough bleeding, there is no known medical contraindication to continuous use of oral contraceptives, vaginal rings, or patches, even for years at a time. This regimen has been a common practice for women with pelvic pain and endometriosis.<sup>58</sup> A number of athletes and dancers (e.g., ballerinas) appreciate the medically induced amenorrhea. It is a wonderful approach in the right patient.

#### Fertility with Hypothalamic Amenorrhea

Women with persistent hypogonadotropic hypogonadism (i.e., hypothalamic amenorrhea) who wish to conceive usually receive pretreatment with estradiol and progesterone cyclically for at least 1 month (1–2 mg ethinyl estradiol or 0.625–2.5 mg conjugated estrogen daily overlapping the last 10–14 days with 5–10 mg medroxyprogesterone or 100–200 mg progesterone). This hormonal pretreatment up-regulates the gonadotropin receptors, and then these patients are given gonadotropin therapy. It is possible to override most causes of hypothalamic amenorrhea with gonadotropin therapy, but it is better to address the underlying cause of the hypothalamic amenorrhea first. For these patients, pharmacologic doses of gonadotropins (a combination of FSH and LH) are used as injectable therapy to directly stimulate the ovaries. Since the ovaries and uterus are physiologically normal, the ovaries respond with follicular growth and the uterine lining proliferates in response to the ovarian follicular estradiol production. These patients will rarely respond to the milder oral fertility drug clomiphene citrate. Clomiphene citrate requires an intact and functioning HPO axis, since it works like an antiestrogen and indirectly stimulates the hypothalamus to stimulate the pituitary to secrete FSH and LH, which then stimulate the ovaries. Once these patients ovulate, they have similar pregnancy rates as their age-matched cohorts,<sup>59</sup> and they will need luteal progesterone support to maintain the pregnancy. They are still at increased risk for multiple gestation and ovarian hyperstimulation with gonadotropin therapy.

Alternatively, these patients could be treated with GnRH therapy with 90% success for ovulation.<sup>5</sup> GnRH therapy is administered with an intravenous or subcutaneous pulsatile pump, which allows only one or two follicles to mature and ovulate. Again, the luteal phase after ovulation needs to be

supplemented, either with the GnRH pump or with progesterone supplementation. These GnRH pump–treated patients have a lower risk of multiple gestation. This treatment can be effective in the compliant and dedicated patient with a closely monitoring physician. However, it is cumbersome in the daily life of the patient and is prone to difficulties (e.g., clotting of the catheter, catheter falling out, infection, moving the site every few days). Due to its low level of use in the United States, the pharmaceutical company that made the GnRH pump voluntarily took it off the market, and therefore it is difficult to find. Research is currently under way to consider alternative routes of administration. Perhaps there may be a GnRH patch in the near future that will be easier to use and this therapy will become more popular. Psychological support in the form of counseling may also benefit these patients.

### **Hypergonadotropic Hypoestrogenism**

Hypergonadotropic hypoestrogenism specifically describes patients with amenorrhea due to elevated gonadotropins (FSH >30 or 40 mIU/mL, depending on the laboratory, and performed on at least two occasions separated by 1 month or more) and low estrogen (<50 pg/mL). In patients with amenorrhea due to hypergonadotropic hypoestrogenism and under 40 years of age, the diagnosis is premature ovarian failure (POF). The incidence is approximately 1%.<sup>30</sup> This disorder can occur in patients with primary or secondary amenorrhea. It is more common for patients with secondary amenorrhea to have the associated hot flashes than for those with primary amenorrhea (85.6% vs 22.2%).<sup>60</sup>

Chromosomal abnormalities occurred in 13.3% of women with secondary amenorrhea due to premature ovarian failure.<sup>16</sup> Trisomy, mosaicism, balanced translocations, and monosomy have all been reported.<sup>60</sup> Individuals with an abnormal karyotype and the presence of a Y chromosome or a portion of the Y chromosome may be at increased risk of a gonadal tumor formation (most often a gonadoblastoma), and the gonads should be excised.<sup>61,62</sup> To date, there are no reported cases of secondary amenorrhea in patients with POF and a karyotype containing a Y chromosome. In the case of Turner's mosaic (45,X; 46,XY), the gonads may be difficult to completely identify either by laparoscopy or laparotomy, since these gonads are streaks (unless a tumor is present). These streaks may extend anywhere along the ovarian suspensory ligament to the upper infundibular pelvic ligament, at or above the pelvic brim. If the karyotype does not include a portion of the Y chromosome, then the gonads do not need to be extirpated. Occasionally, a true Turner's syndrome patient has secondary amenorrhea<sup>63</sup>; the majority have primary amenorrhea, delayed puberty, and other stigmata (e.g., short stature, webbed neck, increased carrying angle, low hairline).

Immune disturbances are fairly common in this POF group (17.4%) and consist of a majority of thyroid disorders and rarely vitiligo, hypoparathyroidism, Addison's disease, insulin-dependent diabetes mellitus, and polymyositis. Other common causes of POF are iatrogenic: chemotherapy, radiation therapy (even if irradiation is not to the pelvis but focused above the diaphragm), or ovarian surgery. Approximately 3.5% of patients developed POF after infection with chickenpox, shigellosis, malaria, or an undefined viral syndrome.<sup>60</sup> POF may also occur

with a systemic disease (e.g., galactosemia). About 28% of POF patients have a familial history of POF.<sup>29</sup> There have been isolated reports of resumption of menses, some with reported pregnancies, in patients with POF; however, there are no tests to predict who will have resumption of menses. Resumption of menses is estimated to occur in 10% of cases and less than 1% of these patients have conceived. Withdrawal bleeding in response to progestin occurred in about 50% of these patients, again indicating that progestin withdrawal is not an accurate test. Laparoscopic ovarian biopsies are also unreliable; Rebar and Connolly<sup>60</sup> reported on three patients with no ovarian follicles on biopsy specimens who later resumed menses and ovulated. There is no medical reason to perform a biopsy on these ovaries, and laparoscopy should not be part of this workup. These patients are also at risk for accelerated bone loss and osteopenia.

The initial evaluation should include a full workup for any of the potentially serious disorders associated with hypergonadotropic hypoestrogenic amenorrhea, including complete blood count with differential, sedimentation rate, total serum protein, albumin/globulin ratio, rheumatoid factor, antinuclear antibody, fasting blood sugar, morning fasting cortisol, serum calcium and phosphorus, free thyroxine, TSH, antithyroglobulin antibodies, antimicrosomal antibodies, thyroid-stimulating immunoglobulins, and karyotype. There is no reason to look for ovarian antibodies, except on a research protocol. A baseline dual-energy X-ray absorption (DEXA) test of the hip and lumbar spine can be considered, particularly if the patient has been hypoestrogenic for a long period of time.

The treatment for patients with POF is to alleviate the hypoestrogenic symptoms (hot flashes, vaginal dryness, etc.) and to decrease bone loss. Therapy can be given as hormone replacement therapy or contraceptive hormones, similar to the treatment for hypothalamic amenorrhea described above. Some patients require a higher dose of estrogen to relieve their menopausal symptoms (particularly hot flashes). The dose may range from 0.625 to 2.5 mg/day of conjugated estrogens or from 1 to 2 mg/day of ethinyl estradiol. Typically, it takes approximately a month to reach a steady state. Progestins, as noted above, should be given to anyone who still has an intact uterus to avoid the increased risk of endometrial hyperplasia or carcinoma. The progestins may be given cyclically, continuously, or every 3 months. Contraceptive hormones are also effective in reducing menopausal symptoms and protecting against bone loss.<sup>57</sup> Either therapy is acceptable. POF is often an emotional situation for patients. Counseling should be recommended. A small percentage of these patients develop "polyglandular syndrome type II." In this syndrome, other endocrine glands may become hypo-functioning over time. Consequently, these individuals should be tested every 1 to 2 years for endocrinopathies and immune disorders. Any identified abnormalities should be further assessed and treated.

Since it is unpredictable who will and who will not ovulate in POF, hormone replacement therapy given in a cyclic fashion will mimic a natural cycle and will not suppress any natural ovulations, should they occur. Some patients like to have this opportunity. Obviously, if ovulation occurs, there will likely be bleeding at an unexpected time, or less likely, persistent amenorrhea during an expected withdrawal bleed owing to conception.<sup>64</sup> One retrospective study noted that patients with

## Reproductive Endocrinology Infertility

secondary ovarian failure had an 11.1% chance of ovulating on estradiol replacement and a 4.8% chance of conception.<sup>65</sup> There is really no treatment that predictably reverses this ovarian failure process or induces ovulation effectively and reliably. A few prospective randomized studies investigated the down-regulation of FSH and LH levels by use of a GnRH agonist for endogenous gonadotropin suppression followed by treatment with gonadotropins to stimulate ovulation without significant success.<sup>66,67</sup> These findings offer little hope for conception with a patient's oocytes. However, these patients are excellent candidates to be egg donor recipients, once the endometrium is adequately prepared. Pregnancy rates in these patients with donor oocytes are high (currently ranging from 40% to 70% per cycle, depending on the center). However, the decision to use donor oocytes may be a difficult hurdle to overcome. A special note regarding Turner's syndrome patients: donor egg programs have been successful at getting Turner's syndrome patients pregnant but there is an increased risk of aortic dissection and a half-dozen Turner's syndrome patients have died as a result.<sup>68</sup> There is controversy over whether Turner's syndrome patients should proceed with donor oocyte programs. Certainly, an echocardiogram and aortic assessment are indicated prior to conception and possibly periodically during the pregnancy.

When hypergonadotropic hypogonadism occurs at 40 years of age or older, it is referred to as early menopause. Again, hormone therapy is indicated to treat symptoms and to protect against accelerated bone loss. These individuals are less likely to have as high a risk for immunologic or endocrine disorders than younger patients; routine general health screening is indicated. Again, these patients are good candidates for donor oocyte programs but have a low likelihood of conception with their own oocytes.

### Pituitary Causes: Hyperprolactinemia

Hyperprolactinemia that results in secondary amenorrhea also is associated with hypoestrogenism. It is important to correct the hyperprolactinemia and thus reverse the hypoestrogenism and stop the accelerated bone loss. Prolactin-secreting micro- and macroadenomas both are initially treated medically with a dopamine agonist, such as bromocriptine or cabergoline. This medication is slowly titrated upward until it brings the prolactin level into the normal range. Slow titration of oral doses or vaginal placement of oral tablets may help reduce side effects. The side effects of bromocriptine are often more prevalent than of cabergoline. The types of side effect are similar for the two medications and include nausea, headache, and dizziness; other side effects have less than 10% incidence. Within a few months after the prolactin level is under control, menstrual cycling often recurs. If a couple is interested in conceiving, they can then try. In the event that conception occurs, medical therapy is discontinued in the case of microadenomas, since microadenomas are rarely aggressive. In the case of macroadenomas, the medication is continued throughout pregnancy. Bromocriptine and cabergoline are Pregnancy Category B drugs. The surgical approach for macroadenomas is reserved for those tumors which are resistant to medical therapy and for those patients who cannot tolerate the side effects of the medication. Medical therapy can reduce the size of macroadenomas by 10%, but close followup with radiologic evaluation every 6 to 12 months

is required. Observation is another alternative for macroadenomas without visual field defects, since only about 33% increase in size; again close observation with frequent MRI is indicated. If tumor growth occurs or if there are visual field defects, surgery is indicated. Surgical treatment may not totally remove the tumor, and medical therapy may be needed postsurgically.

If the patient is not interested in conceiving and has a microadenoma, it is likely that she will decrease her dose of dopamine agonist (bromocriptine or cabergoline) after a year or two of therapy. When she is tapered off the therapy, she may continue menstrual cycling and the prolactin level may remain normal.

Alternatively, a patient with a prolactin-secreting macroadenoma may choose not to use dopamine agonist therapy to control her hyperprolactinemia, but to use only hormone therapy (estradiol and progestin) to treat the hypoestrogenism resulting from the hyperprolactinemia. Hormonal therapy alone is perfectly acceptable when a patient has a macroadenoma because it rarely progresses in size. Bone mineral density loss is a significant medical concern in these patients, so they should be treated with either hormonal replacement or reversal of the hyperprolactinemia to avoid significant bone loss. Bone mineral density monitoring is indicated.

### Thyroid Disease: Either Primary Hypothyroidism or Hyperthyroidism

The initial screening test for thyroid disease is a serum TSH measurement. Most laboratories measure a highly sensitive or third-generation TSH level, which can detect both hypothyroidism (elevated TSH) and hyperthyroidism (low TSH). If serum TSH is abnormal, it should be repeated and a free thyroxine (tetraiodothyronine or T<sub>4</sub>) level added. Hypothyroidism is much more common than hyperthyroidism. Primary hypothyroidism or hypothyroidism originating in the thyroid gland is diagnosed by an elevated TSH and a low free thyroxine (T<sub>4</sub>) level. It is treated with daily oral levothyroxine therapy that is started at 0.05 mg/day and increased slowly over 6- to 8-week intervals to bring the serum levels into the normal range; typically the replacement dose is 0.1 to 0.2 mg/day (or 100 to 200 µg/day). This medication is usually well tolerated. Jitteriness, sweats, and palpitations may occur if the dose is started too high or moved up too quickly. These patients should be followed every 6 to 8 weeks until the thyroid function tests normalize and are stable, and then every 6 to 12 months with laboratory evaluations.

Subclinical hypothyroidism is diagnosed by an elevated TSH and a normal free T<sub>4</sub> concentration. In patients who desire to conceive soon, it is reasonable to treat subclinical hypothyroidism with low doses of levothyroxine (usually <100 µg/day is needed to control TSH level). If fertility is not a present concern, no treatment is necessary; the patient is followed up with repeat laboratory assessment in 6 to 12 months and treated when clinically significant hypothyroidism occurs.

Other thyroid disorders may figure in the etiology of secondary amenorrhea (see Chapter 63). Again briefly, if both TSH and free T<sub>4</sub> levels are low, secondary hypothyroidism or hypothyroidism due to a pituitary origin may be present and further evaluation with MRI and other pituitary function testing are indicated.

Hyperthyroidism deserves further evaluation with laboratory tests for antithyroid antibodies, possibly thyroid ultrasound, and radioiodine uptake screening. Thyroid nodules may require fine needle aspiration or biopsy. Medical therapy for hyperthyroidism consists of methimazole or propylthiouracil (PTU). Radioactive iodine therapy is often the procedure of choice for hyperthyroidism but may leave the patient hypothyroid and then thyroid replacement therapy is indicated. There is also a role for surgical therapy in some cases of hyperthyroidism and thyroid carcinoma. Occasionally, hyperthyroidism results from over-treatment of hypothyroidism. Whatever the cause of hyperthyroidism, it will have a significant negative impact on bone metabolism, resulting in increased bone loss, if it is not corrected.

### **Polycystic Ovary Syndrome**

PCOS is a common disorder that is diagnosed clinically by the triad of oligomenorrhea/amenorrhea, hyperandrogenism, and polycystic-appearing ovaries. Treatment is directed at either inducing ovulation or giving a progestational agent. Prolonged time periods without progestin treatment expose the patient to unopposed estrogen, which can eventually cause endometrial carcinoma. In patients with a history of chronic anovulation without treatment, an endometrial biopsy is warranted, prior to initiating therapy, to rule out endometrial carcinoma or pre-cancer (e.g., complex hyperplasia with atypia). Once this is ruled out, a patient may be treated monthly (or at least every 3 months) with progestin or progesterone. The progestin regimen may consist of medroxyprogesterone at 5 to 10 mg/day for 7 to 14 days. This therapy will induce a withdrawal bleed within 2 weeks of the completion of therapy, when endogenous estrogen production has been present to develop an endometrial lining. Alternative therapies to medroxyprogesterone include progesterone vaginal cream or progesterone 100 to 200 mg/day for 10 to 14 days, vaginal micronized progesterone gel 4% to 8% every other day for 6 doses, or a 100-mg injection of progesterone in oil. Some practitioners use this progesterone withdrawal therapy to confirm the presence of estrogen production in lieu of measuring estradiol and FSH levels, but this test is less reliable. Alternatively, patients may choose oral contraceptives or contraceptive rings or patches for treatment. The latter two treatments are also progestin-dominant therapies that cause the endometrium to atrophy and additionally offer contraceptive benefits. For couples trying to conceive, a mild oral fertility therapy may be used. The traditional therapy is clomiphene citrate at 50 to 150 mg/day for 5 days (cycle days 3–7 or 5–9) to induce ovulation. It is effective for ovulation induction in about 60% to 80% of these patients.<sup>69</sup> Patients typically ovulate about 7 days after the last pill. However, there is enough variability in women that instruction in the use of an ovulation predictor kit (OPK) is helpful, and OPKs should be used on cycle days 10 to 20. A positive OPK measures the presence of urinary LH metabolites and indicates when an LH surge is present. Ovulation typically occurs 10 to 48 hours after an LH surge is detected by an OPK. The oocyte has about 12 to 24 hours after ovulation to be fertilized, and sperm survive about 2 days, on average, in the human body after ejaculation. Timing intercourse for the day before and/or the day of ovulation offers the best pregnancy rates.<sup>70</sup> Counseling the patient to have intercourse the day of the surge and daily (or at least every other

day) for 3 days should be sufficient exposure to allow optimal opportunities for conception.

In PCOS patients with insulin resistance, an insulin sensitizer may be used. Several reports note the resumption of menstrual cycles and ovulation while this therapy is being used.<sup>71</sup> In the United States, metformin is the current drug of choice. This medication is started at 500 mg/day, or every other day if the gastrointestinal side effects are bothersome. The dose is increased every few weeks to a treatment range of 1500 to 2000 mg/day in divided doses (500 mg three times a day, 875 or 1000 mg twice a day). A typical mistake is to undertreat this disorder. Once the patient is in the treatment range, cycles tend to resume within a few months if they are going to resume at all. Carmina and Lobo gave metformin in a randomized placebo-controlled trial to nonandrogenic, anovulatory women at a dose of 1500 mg daily for 3 months, and the study resulted in ovulatory cycles in 58% of patients randomized to the treatment arm.<sup>72</sup> Clomiphene citrate can be given in addition to metformin, and ovulation results in 90% of cases, even in patients previously resistant to clomiphene citrate alone.<sup>73,74</sup> The main side effects are gastrointestinal disturbances (gas, diarrhea, etc.). Liver function tests (LFTs) should be monitored prior to therapy and periodically after therapy. Liver dysfunction as a result of this medication is rare; however, if LFTs increase to two times the normal limit, the medication should be discontinued.

An alternative, off-label-use, oral fertility therapy is aromatase inhibitors. Aromatase inhibitors, such as letrozole and anastrozole, have been studied in a limited number of patients in non-randomized prospective trials that report improved ovulation rates. In patients who had inadequate response to clomiphene citrate, letrozole 2.5 mg for 5 days (cycle days 3 to 7) resulted in 75% ovulation and 25% pregnancy rates.<sup>75</sup> Anastrozole 1 mg/day on cycle days 3 to 7 may also be used for ovulation induction, and if not successful, the dose is doubled.<sup>76</sup> A randomized, double-blind comparison study using letrozole and anastrozole showed improved ovulation rates (84.4% vs 60%, respectively) and improved pregnancy rates (18.8% per cycle vs 9.7% per cycle, respectively).<sup>76</sup> The side effects of these medications are better tolerated than those of clomiphene citrate. Only one or two follicles mature and ovulate (average, 1.5), resulting in similar pregnancy rates to clomiphene citrate but lower multiple gestation rates.

Lastly, if the PCOS patient is resistant to oral therapy, gonadotropin therapy is the next step. Over 90% of PCOS patients respond to gonadotropin therapy with ovulation. Typically, the starting dose for PCOS patients is lower than that given to patients with other diagnoses because of the increased risk of overstimulation and potential cancellation. These patients need to be closely monitored and counseled. After ovulation, these patients are also at increased risk for multiple gestation and ovarian hyperstimulation syndrome. Ovarian hyperstimulation syndrome (OHSS) is a phenomenon that occurs after ovulation induction. The syndrome is described in mild to severe levels. The main characteristics are weight gain, abdominal distention, enlarged multicystic ovaries, abdominal discomfort, hemoconcentration, hyponatremia, and hyperkalemia. As the syndrome worsens, the patient may have shortness of breath, ascites, pleural effusions, elevated liver function tests, worsening electrolytes, and dehydration. This syndrome resolves

## Reproductive Endocrinology Infertility

within 2 to 4 weeks with treatment consisting of aggressive hydration, bed rest with deep venous thrombosis (DVT) prophylaxis, protein supplementation, and possible paracentesis or culdocentesis. Rarely thoracentesis is necessary. Pregnancy may exacerbate OHSS and prolong its duration.

Owing to the risks of multiple gestation and particularly high-order multiple gestation, the PCOS patient may opt for in vitro fertilization (IVF). In this process the ovaries are stimulated with gonadotropin therapy, the LH surge is suppressed with either a GnRH agonist or a GnRH antagonist, and hCG is usually used to mature the follicles. The oocytes are removed just prior to ovulation by ultrasound-guided transvaginal needle aspiration. After insemination with sperm and incubation, one to three cleaved embryos (or four to five embryos in older patients) are transferred into the endometrial cavity depending on the patient's age, clinical situation, and national recommendations. Controlling the number of embryos being transferred decreases the risk of high-order multiple gestation.

Another alternative treatment for PCOS is surgical therapy with ovarian drilling. This technique consists of making small (2–3 mm) holes in the ovarian cortex with laser or electrocautery. Ovarian drilling technique is based on the historical wedge resection, which resulted in spontaneous ovulation for a limited time period. Approximately one third of patients from Stein's original report<sup>77</sup> continued to have regular periods for more than 6 years.<sup>78</sup> A randomized controlled trial comparing the effectiveness of laparoscopic electrocautery drilling of the ovaries to ovulation induction protocols<sup>79</sup> showed a cumulative pregnancy rate with electrocautery alone at 34%, whereas the cumulative pregnancy rates with clomiphene citrate and gonadotropins were 49% and 67%, respectively. The latter two ovulation induction treatments did not vary whether they were given alone or after electrocautery drilling. Multiple gestations are reduced if gonadotropin therapy is avoided, but the risks of surgery must be considered.

After delivery of a baby, most PCOS patients resume their anovulatory pattern and require long-term progestational therapy. Additionally, PCOS patients are at increased risk for hypertension and type 2 diabetes mellitus (non-IDDM) and should be screened regularly.<sup>78,80</sup>

### Late-onset or Nonclassical Congenital Adrenal Hyperplasia

Patients with late-onset or nonclassical congenital adrenal hyperplasia (CAH) typically have premature adrenarche or with a polycystic ovary-like syndrome. The clinical findings consist of oligomenorrhea or amenorrhea, hirsutism, and no virilization (classical CAH presents as ambiguous genitalia). On laboratory evaluation the 17-hydroxyprogesterone level is definitely elevated or is just over 200 ng/dL. In the latter case, an ACTH stimulation test should be performed. A baseline 17-hydroxyprogesterone level is drawn, 100 µg of ACTH (cosyntropin) is given, and a repeat 17-hydroxyprogesterone is drawn 1 hour after the ACTH is given. The baseline and stimulated results are compared with the reference normograms.<sup>81</sup> Typically, the 1-hour 17-hydroxyprogesterone level is in the thousands and the diagnosis of nonclassical CAH is made. Heterozygotes may not have as high a level of 17-hydroxyprogesterone. This disorder is caused by partial or complete enzyme deficiency, and 21-hydroxylase

deficiency is the most common cause. Treatment is merely to replace the deficiency in the end product—cortisol—usually using the oral form: prednisone, dexamethasone, or other equivalent. Occasionally, the patient may need a mineralocorticoid such as fluorocortisone; this is more common in the early-onset or classic form of CAH. All these patients need genetic counseling and should be offered genetic testing prior to conceiving to determine their risk for transmitting this disorder to future offspring and to discuss their need for future prenatal testing and therapy.

### Cushing's Syndrome

Cushing's syndrome may have many features that overlap with PCOS: anovulation, hirsutism, and obesity. In addition, Cushing's patients may have a "buffalo hump," striae, and hypertension. The standard diagnostic tests include the 24-hour urine free cortisol and the dexamethasone suppression test. An elevated 24-hour urine free cortisol level is abnormal, and further evaluation for a source of excess cortisol production is indicated. In the dexamethasone suppression test, 1 mg of dexamethasone is given at 10 or 11 PM and the fasting cortisol level is drawn the next morning at 8 AM. The normal response is suppression of the morning fasting cortisol level (<5 ng/dL). If the cortisol is elevated, the diagnosis is made. Further evaluation prior to therapy is indicated and may consist of a prolonged dexamethasone suppression test and MRI to localize the source of steroid production.

### Ovarian and Adrenal Neoplasms

Ovarian or adrenal neoplasms that are producing androgens are often suspected by the clinical history of rapid progression of hirsutism and virilization. Elevated total testosterone (>200 ng/dL) and DHEA-S (>700 ng/dL) levels may indicate the presence of an ovarian or an adrenal secreting tumor. Since similar amounts of testosterone are produced in the ovary and the adrenal gland, this test alone cannot specify an ovarian tumor. Both test results are needed. Since 99% of DHEA-S is produced in the adrenal, if both laboratory tests are elevated, an adrenal tumor is likely. If only the testosterone level is elevated, then the ovary is the likely culprit for an androgen-producing tumor. Ovarian neoplasms are typically best detected by ultrasound and adrenal tumors by MRI. However, very small ovarian tumors may not be detected by ultrasound, and MRI may be helpful. MRI of the abdomen and pelvis may be needed to determine whether an ovarian or adrenal neoplasm is present. If neither technique is helpful, selective catheterization may help locate the source. These neoplasms are typically treated surgically.

## OUTFLOW CAUSES OF SECONDARY AMENORRHEA AND TREATMENT

### Uterus

Pregnancy is the most common cause of amenorrhea and is normal. It is treated expectantly.

Endometrial atrophy due to progestational agents can be easily corrected by estradiol supplementation, in the form of oral, patch, gel, or vaginal ring preparations. The estradiol enables a small amount of endometrium to proliferate and stop the bleeding due to atrophy. Alternatively, the progestational agent

may be stopped for a period of time to allow natural estradiol to be produced.

Endometritis (particularly pelvic tuberculosis) may cause abnormal bleeding and may result in adhesions with hypomenorrhea or amenorrhea over time. Acute endometritis needs to be treated with antibiotics—usually broad spectrum.

Asherman's syndrome results from intrauterine adhesions or synechiae due to a prior intrauterine procedure (e.g., D&C, hysteroscopic myomectomy) or infection (e.g., endometritis). It may be diagnosed on transvaginal ultrasound, saline infusion sonohysterogram, or hysterosalpingogram, as noted above. The standard approach to remove intrauterine adhesions, if the patient is interested in conceiving, is hysteroscopic adhesiolysis under direct vision and posttreatment with an intrauterine balloon for a few days, with estrogen therapy to proliferate the endometrium over previously scarred areas, followed by progesterone or a progestin for a withdrawal bleed. If the patient is not interested in conceiving, no therapy is necessary. She may remain hypomenorrheic or amenorrheic once a diagnosis is established. Since these patients are euestrogenic, there is no risk for accelerated bone loss.

### Cervix

Cervical stenosis is an uncommon cause of secondary amenorrhea. It typically results from a prior cervical procedure, such as cryosurgery or a cervical cone biopsy. It is a rare result of a loop excision electrocautery procedure (LEEP). Patients typically have amenorrhea and pelvic/abdominal pain. Ultrasonography, CT, or MRI reveals a hematometra (see Fig. 57-6). Cervical dilatation is all that is needed for menstruation to resume. This treatment may be performed in some cases with a uterine sound alone, while in others, full cervical dilation is needed. In difficult situations, the cervix does not have an identifiable cervical os or the canal is irregular. Intraoperative ultrasound guidance can be helpful. Rarely, the cervical stenosis is so severe that it cannot be corrected despite the above measures. In cases with evidence of infection or cases of prolonged hematometra, pretreatment with antibiotics before surgical correction of the cervical stenosis is indicated.

Once the cervical stenosis is corrected, these patients may still need assistance in conceiving because the cervical canal glands are likely to be scarred and not produce sufficient mucus for the sperm to swim through to the uterus. These patients tend to respond well to timed intrauterine inseminations with or without superovulation therapy.

Some patients with cervical stenosis also have a very short cervix, particularly after an aggressive cone biopsy, which may have been necessary because of an abnormal Pap smear but is problematic for maintaining a pregnancy. In such cases, the obstetrician would like to be aware of the problem early so that cerclage therapy may be considered.

### BONE HEALTH

In most situations where hypoestrogenism exists for prolonged time periods, there is significant risk for bone loss. Whether the hypoestrogenism is due to hypogonadotropism (hypothalamic amenorrhea) or to hypergonadotropism (premature ovarian failure), the impact on bone is similar. If the hypoestrogenism occurs during adolescence, the peak bone mass may not be

attained. The duration of hypoestrogenism directly correlates with the amount of bone loss. Consequently, there should be a low threshold for starting hormone (replacement) therapy. Estrogen therapy has a direct impact on bone metabolism and on absorption of calcium through the gastrointestinal system.

In addition to appropriate replacement of estrogen, sufficient dietary intake of calcium and vitamin D is important. Calcium supplementation should be on the order of 1200 to 1500 mg/day in divided doses. For bone health, vitamin D intake should be higher than currently supplied in multivitamins; vitamin D supplements should total 400 to 800 IU/day or greater.

### SUMMARY

In general, patients with secondary amenorrhea should be evaluated by a thorough history, physical examination, and ultrasound examination to narrow the differential diagnosis and to direct the laboratory and radiologic evaluations to help identify the etiology. The hypothalamic-pituitary-ovarian-uterine axis approach as outlined above is a logical approach to assessing and treating secondary amenorrhea. The WHO classification system is another usable approach. Once a diagnosis is identified, it is important to treat the cause (e.g., hypothyroidism, pituitary adenoma, infection, stress, outflow tract scarring, or obstruction).

If the patient has persistent anovulation, treatment with a progestational agent is indicated to reduce the risk for endometrial hyperplasia. If there has been a prolonged time period of unopposed estrogen exposure, an endometrial biopsy is warranted before therapy. If the patient desires conception, begin treatment with ovulation induction. The progesterone that is produced during pregnancy as well as the pregnancy itself will prevent endometrial hyperplasia. If the patient is not interested in pregnancy at this time, treatment with hormonal contraceptives or cyclic progestins is the therapy of choice.

In patients with hypoestrogenic amenorrhea (i.e., hypothalamic amenorrhea or hypergonadotropic hypogonadism), estrogen production needs to be induced by treatment of the cause or to be replaced by estrogen supplementation. The estrogen therapy along with calcium and vitamin D supplementation are needed to prevent bone loss. Patients will also need progesterone therapy to avoid the “unopposed estrogen” situation that predisposes to endometrial hyperplasia or carcinoma. Hormonal replacement therapy or oral contraceptive therapy is recommended. When patients with hypothalamic amenorrhea wish to conceive and have not resumed menstrual cycling, they will need either gonadotropin therapy or pulsatile GnRH therapy for ovulation and then luteal support to allow for conception. In patients with hypergonadotropic hypogonadism (premature ovarian failure), the only method to reliably achieve pregnancy is with an oocyte donation program.

In patients with hypoestrogenic amenorrhea due to ovarian failure, estrogen supplementation is important to relieve hot flashes and vaginal dryness and maintain bone mineral density among other benefits. Again, hormone replacement therapy or hormonal contraception is appropriate. It is only this group of patients with POF who are unlikely to be fertile in the future despite any therapy. Luckily, less than 1% of women under age 40 have premature ovarian failure. Unfortunately, less than 10% of these women will ovulate again in their lifetime.<sup>60</sup>

## KEY POINTS

- Approximately 50% of pregnancies in the United States are unintended or unplanned.
- Contraceptive methods with the highest typical use failure (pregnancy) rates require either daily use or use at the time of intercourse.
- Most hormonal methods, including the levonorgestrel-releasing intrauterine contraceptive system, have noncontraceptive health benefits.
- Barrier methods, particularly condoms, protect against some sexually transmitted infections.
- Successful use of a contraceptive method requires counseling on proper use, risks, and side effects.

The introduction of oral contraceptives (OCs) in 1960 defines the major starting point for today's contraceptive methods. Although some methods clearly preceded the "Pill," such as barrier methods and early forms of the intrauterine contraceptive devices (IUDs), the publicity around the availability of OCs increased awareness about contraception both for potential users and the health care profession. Yet, despite the introduction of OCs and the development of many new or improved methods of contraception, unintended or unplanned pregnancies continue to be a major problem in the United States. According to the 1995 National Survey of Family Growth, there were a total of 6.3 million pregnancies in the United States, with 49.2% unintended.<sup>1,2</sup> Among the unintended pregnancies, nearly one half result in a pregnancy termination and more than 10% in spontaneous abortion. Approximately 40% of unintended pregnancies occur among women who do not desire pregnancy yet do not use a method of contraception. About 60% of unintended pregnancies occur among women using some form of birth control, with about 1 million of these pregnancies occurring in OC users. Thus, despite more than 40 years' experience with modern contraceptives, substantial challenges still remain relative to identifying women or couples who can be successful with a given method as well as assisting them in proper use of the method.

When evaluating contraceptive methods, efficacy is narrowly defined as the frequency of pregnancy prevention while a method is being used correctly and consistently. Effectiveness of a contraceptive method usually reflects typical use rates of unintended pregnancy, which would include method or perfect use failures as well as user failure (e.g., not using the method

correctly or consistently).<sup>3</sup> Most method or typical use rates are calculated using either the Pearl Index or a life-table analysis. The Pearl Index is calculated by dividing the number of unintended pregnancies by the total months or menstrual cycles of exposure; the result is multiplied by 1200 if months are used and 1300 if menstrual cycles are used. The result is expressed in number of pregnancies per 100 women-years of exposure. The majority of the efficacy rates expressed in this chapter are calculated by the Pearl Index and express rates occurring during the first year of use. The major problem with this index is that it does not account for duration of exposure; the Pearl Index is reasonably reflective of contraceptive failure if duration of use is short (i.e., 6 to 12 months) and most users use the method for about the same period of time. In a life-table analysis, a separate failure rate is calculated for each month of use such that varying durations of use are not problematic. However, the life-table calculations are often more tedious than those for the Pearl Index, leading to less use of this approach except among researchers. Factors that affect efficacy results in clinical trials include not only methodological issues such as choice of method to calculate efficacy, but also subject characteristics such as frequency of intercourse and motivation.

## CONTRACEPTIVE METHODS

### Barrier Methods and Spermicides

Barrier methods are designed to either block the introduction of spermatozoa into the vagina or their ascent from the vagina into the uterine cavity.<sup>4</sup> Among the contraceptive methods available, they also have the benefit of providing some protection against some sexually transmitted infections (STIs). Because barrier methods require motivation at the time of intercourse and given erratic contraceptive compliance (correct use of a method) in the United States, one can understand why barrier methods have higher typical use pregnancy rates than other contraceptive methods.

#### Condoms

The most common material used for male condom manufacture is latex, although there are also condoms available made from polyurethane material and lamb cecums.

Most condoms are lubricated with silicone or a water-soluble lubricant; some also use a spermicide as a lubricant. In addition to male condoms, there are female condoms, which consist of a rim that holds the condom against the vulva, a sheath of polyurethane material, and a ring that helps anchor the vaginal portion.

## Reproductive Endocrinology and Infertility

The primary mechanism of action of the condom is to capture seminal fluid and sperm within the device at the time of ejaculation. Condoms lubricated with a spermicide can also inactivate or destroy sperm. Use of petroleum jelly (Vaseline) as a lubricant should be avoided because it may destroy the latex. Successful use of male condoms requires that they not be stored at high temperature; that they be handled gently to avoid damage; that they be rolled down the length of the penis before use, leaving a reservoir at the tip of the penis; that users withdraw the penis immediately after intercourse when the penis is still erect while holding the condom; and that the condom be carefully inspected to ensure there is no leakage. Similarly, female condoms should be inspected for leakage after intercourse. If leakage is discovered or the condom breaks during intercourse, spermicide should be inserted into the vagina immediately and emergency contraception started as soon as possible.

In well-motivated couples, pregnancy rates as low as 3 to 5 pregnancies per 100 women-years can be achieved. However, typical use rates are substantially higher, at 10 to 30 pregnancies per 100 women-years.<sup>5</sup>

The primary risk with condom use is hypersensitivity of the skin or vagina to the material or lubricants. Individuals with known latex allergy should use polyurethane condoms.

The major noncontraceptive benefit of condoms is protection against STIs, such as gonorrhea, syphilis, herpes, and human immunodeficiency virus (HIV). In addition, condoms reduce the risk of acute salpingitis or pelvic inflammatory disease (PID).

### **Female Diaphragm**

The diaphragm is circular with a rim that can be compressed along its length (coiled spring version) or compressed at specific sites (arcing spring); diaphragms are also made with a flat spring design, which is similar to the coiled spring diaphragm except the rim is thinner. After fitting by a health care professional, when inserted into the vagina the diaphragm should fit under the symphysis pubis and cover the uterine cervix. Before insertion, spermicide is placed on the side that opposes the cervix and along the rim. Thus, the diaphragm both acts as a barrier to ascent of sperm and provides spermicidal activity. Potential users should be instructed that the device can be inserted up to 6 hours before intercourse and should be left in place for at least 6 hours after intercourse. If intercourse occurs more than once, the device should not be removed but rather more spermicide should be inserted into the vagina. Because successful use requires the device to be held in place by the woman's bony pelvis, cervix, and pelvic musculature, conditions such as pelvic relaxation with uterine prolapse and cystocele and/or rectocele, sharply anteverted or retroverted uterus, shortened vagina, poor muscle tone, or prior vaginal injury are potential contraindications to the use of a diaphragm. Fitting is essentially done by trial and error. One inserts the index and middle fingers of the examining hand into the vagina, then estimates the distance from the inferior margin of the symphysis pubis to the posterior cul-de-sac behind the uterine cervix. This distance is used to size a diaphragm. After showing the user how to compress the diaphragm's rim and insert the device into the vagina, one lets the user practice until she is comfortable with both inserting and removing the device.

The perfect use failure rates are about 6 pregnancies per 100 women-years; typical use rates climb to about 15 to 20 pregnancies per 100 women-years.<sup>5</sup>

A potential noncontraceptive benefit is reduced risk of some STIs. The most commonly reported risk is cystitis; voiding after intercourse may reduce its frequency of occurrence. In addition, a few cases of toxic shock syndrome have been reported among users of diaphragms. Sensitivity to the diaphragm's material or spermicide may also occur.

### **Cervical Cap**

The Prentif cervical cap, the only cap currently distributed in the United States, is made of latex rubber and is shaped like a thimble. It comes in four sizes, with internal diameters ranging from 2.2 to 3.1 cm. Held in place against the cervix by suction, its mode of action is as a barrier to the ascent of sperm. A health care professional must fit the cap and teach the user how to attach it to the cervix. In general, it requires somewhat more skill to successfully place compared to a diaphragm, such that it has been estimated that only about 50% to 80% of potential users feel they can use it successfully or be properly fitted. It should be left in place for at least 6 hours after the last act of intercourse. However, unlike the diaphragm, it does not require a spermicide and can be left in place for 24 to 48 hours.

It has been estimated that perfect use failure rates range from about 9 pregnancies per 100 women-years in nulliparous users to 26 pregnancies per 100 women-years in multiparas. Typical use rates are about 16 per 100 women-years and 32 per 100 women-years for nulliparas and multiparas, respectively.<sup>5</sup>

As with other barrier methods, users of a cervical cap may have a reduced risk of some STIs. Cervical erosion leading to spotting may occur if the device is left in place too long or if it is ill fitting. Although toxic shock syndrome is theoretically possible, no cases have been reported in association with use of cervical caps. Some women may note a vaginal discharge with prolonged use; some may also experience an allergic reaction to the latex.

### **Spermicides**

The only spermicide available in the United States is nonoxynol-9, which is a long-chain surfactant with the chemical name nonylphenoxypolyethoxy ethanol. Its mode of action is to penetrate the cell membranes of spermatozoa to produce sperm death or loss of motility. Similar activity may occur with vaginal epithelial cells, leading to irritation. If used alone, spermicide is inserted high into the vagina no sooner than 30 minutes before intercourse. One should not use other lubricants in conjunction with a spermicide. Douching should be avoided for at least 8 hours after intercourse.

The perfect use failure rate is about 15 pregnancies per 100 women-years; typical use rate is about 30 pregnancies per 100 women-years.<sup>5,6</sup>

An advantage of spermicides is that they may reduce the risk of some STIs, although they do not prevent the transmission of HIV infections.<sup>7</sup> In fact, due to the action of nonoxynol-9 on epithelial cells, women with HIV infection or at risk for such infection should not use spermicides containing nonoxynol-9. In addition, condoms lubricated with this spermicide should not be

used by such at-risk women. The only other risks relative to spermicide use are possible hypersensitivity and an increased risk of urinary tract infections.

### Intrauterine Contraceptive Device

Although only about 1% of U.S. women using contraception use IUDs, among all users of contraception, IUD users are perhaps the happiest with their method.<sup>8</sup> Further, the efficacy rate is better than many methods, including OCs, barrier methods, and even tubal ligation. In countries such as Sweden and Germany, 15% to 20% of married women use the IUD as their contraceptive method. The reasons women in the United States use this method less frequently relates to misperceptions about mechanism of action (e.g., acts as an abortifacient), infection risk, ectopic pregnancy risk, and the whole litigious atmosphere associated with the Dalkon Shield. However, with the introduction of new IUDs such as the Copper T 380 A and the levonorgestrel-releasing system, it is anticipated that the frequency of use of this method in the United States may increase.

#### Copper Device

The Copper T 380 A is a T-shaped device about 36 mm in length and 32 mm in diameter. It is wound with fine copper wire, 300 mm<sup>2</sup> on its vertical arm and 40 mm<sup>2</sup> on each side arm. Attached to the base of the vertical arm are two monofilament strings. This IUD has a useful life span of at least 10 years. Although IUDs have been used for many decades, little scientific evidence documents an exact mechanism of action. A few small studies suggest that this IUD may be spermicidal and that all IUDs interfere with either normal development of ova or the fertilization of ova. Also, this IUD has activity on the endometrium that leads to leukocyte infiltration, a circumstance that leads to phagocytosis of sperm and may impede sperm migration or capacitance. It has been suggested that by making the endometrium a "hostile" environment, the IUD interferes with implantation and thus may act as an abortifacient. However, studies have failed to document rises in human chorionic gonadotropin levels in the second half of menstrual cycles when implantation would occur among IUD users. In the past, IUDs were associated with an increased risk for PID around the time of insertion. However, by restricting use to mutually monogamous couples and couples currently at low risk of STIs, the absolute risk of PID in association with IUD use is almost negligible. Women at risk for HIV infection or who are already infected are still candidates for use of this device. Because this IUD has a duration of action of at least 10 years, it is intended for couples who want long-term contraception. Other ideal candidates are women in whom combination hormonal contraception is contraindicated, such as women with prior thrombosis, smokers older than age 35, and lactating women. As is true of any contraceptive method, symptoms such as abnormal bleeding or discharge should be evaluated before initiating the method. One should document the informed consent process using the materials provided by the manufacturer. Included in the discussion are the risks and benefits of the method as well as how to feel for the strings once insertion has occurred. To ensure successful placement and reduce risk of expulsion, the uterine

cavity should not be distorted and be between 6 and 9 cm in depth. Currently, IUDs available in the United States are inserted under aseptic conditions using a modification of the withdrawal technique, which reduces the risk of uterine perforation. Training is required from a skilled practitioner to learn the proper technique and avoid complications. After insertion, users should be instructed to contact their provider if they miss a menstrual period, experience an abnormal discharge or bleeding, experience pelvic pain or fever, have an exposure to STIs, or cannot feel the string.

The perfect use failure rate with the Copper T380 A is 0.6 pregnancies per 100 women-years; typical use failure rate is approximately 0.8 per 100 women-years.<sup>5</sup> The obvious reason for the two rates being similar is that the IUD does not require motivation either at intercourse or on a frequent basis to use it effectively. However, unlike other methods, such as barriers and most forms of hormonal contraception, users have less individual control relative to stopping use. Over a 10-year period, failure rates range between 2 and 3 pregnancies per 100 women-years, roughly equivalent to the rates achieved by tubal sterilization.

The major risks that have been reported in association with use of this IUD include ectopic pregnancy, spontaneous abortion, uterine perforation, expulsion, and PID. Although 5% to 8% of pregnancies that occur with use of this IUD are ectopic, overall, because of the high effectiveness of this device, the absolute risk of ectopic pregnancy in users is substantially less than that experienced by nonusers of contraception. In addition, if a user becomes pregnant with a device in place, the risk of a spontaneous abortion is about 50%. Removing the device when the strings can be readily identified will reduce this risk by about one half. If an intrauterine pregnancy is confirmed but strings are not seen and the IUD is identified in the uterus (usually by ultrasound), users should be apprised that there is an increased risk of premature rupture of the membranes and preterm delivery. Uterine perforation, which occurs at the time of insertion, has been reported at a rate of 1 to 2 events per 1000 insertions. This risk is minimized by a careful preinsertion pelvic examination to determine the position of the uterus and by use of a tenaculum to straighten the uterine axis during insertion. Expulsion of the device is more common in the first few weeks of use, with rates of about 5%. Improper placement of the device may contribute to expulsion. Over a 5-year time span of use, cumulative expulsion rates are approximately 11%. PID appears to be associated primarily with the insertion of the device, not with its duration of use. Currently, with appropriately selected users, the rate of infection is about 1 case per 1000 insertions. Minor side effects include abnormal bleeding and cramping. Women using this particular device tend to have regular menstrual periods, but the amount of flow is increased by about one third. Use of nonsteroidal anti-inflammatory agents often will reduce the overall amount of flow. In addition, some women experience increased dysmenorrhea, particularly in the first few months of use. Overall, complaints related to bleeding and pain result in about 12% of women discontinuing use in the first year.

A not-infrequent issue with IUD use is the management of missing strings. First, the patient should be encouraged to use a backup contraceptive method until the patient is evaluated. If the IUD strings cannot be seen even with gentle probing of the

## Reproductive Endocrinology and Infertility

endocervical canal, one should perform a pregnancy test, if indicated, and consider ordering a transvaginal ultrasound to determine if the IUD is intrauterine, intraperitoneal, or has been expelled (most likely). If the patient is pregnant, an ectopic pregnancy must be excluded. If the IUD is determined to be in an intraperitoneal location, removal is usually indicated due to likely peritoneal irritation by the device.

### **Levonorgestrel-releasing System**

Although technically considered a hormonal contraceptive, the levonorgestrel-releasing IUD or system (LNG-20 IUS) is discussed here. The LNG-20 IUS, a more recently developed IUD, also uses a T-shaped frame but has a reservoir on the vertical arm that releases 20 µg of the progestin levonorgestrel daily. A single string attached to the vertical arm differentiates it from the T 380 A, which has two strings. Blood levels of levonorgestrel among users are about 25% of that seen among users of oral contraceptives containing this progestin and about one half the levels seen among users of Norplant, the implanted contraceptive that releases levonorgestrel. In contrast to the Copper T 380 A device, the LNG-20 has a life span of 5 years in clinical trials. The LNG-20 IUS's primary mechanisms of action are to thicken cervical mucus to impede ascent of sperm and to alter uterotubal fluid to interfere with sperm migration. Some available data indicate that this IUS causes anovulation in about 10% to 15% of cycles. It also changes the characteristics of the endometrium to reduce the likelihood of implantation. Candidates for use of this IUS fit the same profile as those who would consider use of the Copper T 380 A. The insertion technique also uses a modified withdrawal approach. However, because the technique used differs from that used with the Copper T 380 A, training is required to ensure appropriate placement. Overall, the counseling is similar except for additional information about bleeding.

The LNG-20 IUS has been shown to be highly effective in clinical trials, with both perfect use and typical use pregnancy rates being 0.1 pregnancies per 100 women-years after 1 year of use.<sup>5</sup> Further, the cumulative pregnancy rate over 5 years is 0.7 pregnancies per 100 women-years. Approximately 50% of the pregnancies that occur are ectopic, but, as with the Copper T 380 A device, the absolute risk of ectopic pregnancy is still substantially lower than that experienced by nonusers of contraception.<sup>9</sup>

Because this device releases a potent progestin at the endometrial level, the bleeding pattern is substantially different from that seen with the Copper T 380 A. During the initial 3 to 4 months of use, some women will experience irregular bleeding, which at times may be heavy. However, after a few months of use, most women experience a significant decrease in menstrual flow—by as much as 70%. In some studies, 20% to 25% of users become amenorrheic in the second year of use. In addition, dysmenorrhea tends to improve with use of this device. Because of the effectiveness of the LNG-20 IUS in reducing menstrual blood flow, it has been used as a treatment for menorrhagia. Results in clinical trials to date indicate that it is an effective treatment modality which even approaches the results achieved with endometrial ablation.<sup>10</sup> Thus, this is the first IUS to have significant noncontraceptive benefits. Major risks with this IUS are similar to those noted for the Copper T 380 A. The one

exception is PID. Because one of the effects of the LNG-20 IUS is to thicken cervical mucus, this leads to interference with ascent of bacteria. In addition, the reduced blood flow associated with this device results in an environment that is less likely to enhance bacterial growth. The minor side effects of bleeding and cramping are less frequent with this device, except for irregular bleeding patterns during the first few months of use. Some women have reported headache, acne, or mastalgia, which could be related to the systemic effects of the progestin. Management of possible pregnancy and missing strings is similar to the approach used with the Copper T 380 A.

### **Hormonal Contraceptives**

The introduction of the oral contraceptive about 1960 initiated the modern era of hormonal contraception. Hormonal contraception is broadly defined as the use of steroid hormones (estrogens, progestins, androgens) to alter normal physiological function to inhibit fertility. At this time, all clinically available forms are directed toward altering female physiology. Although experimental studies suggest that use of high-dose androgens may inhibit spermatogenesis, there are no products on the market for clinical use. Of particular note, the 21st century brought the introduction of two new delivery systems for hormonal contraception, the transdermal patch and the vaginal ring.

Adolescents present significant challenges relative to motivating them to use effective contraception correctly and to practice safe sex. Use of interactive counseling regarding the risks of pregnancy, including medical, social, and economic consequences and the importance of condom use to prevent STIs and HIV infection can be effective. Because many young adolescents fear pelvic examinations, deferring such examinations in asymptomatic or low-risk women until a subsequent visit will allow contraception to be initiated promptly for those at risk for pregnancy. Finally, in an effort to improve compliance, some practitioners start hormonal methods such as OCs on the same day as the initial office visit, as opposed to menstrual cycle day 1 or a Sunday start. This approach, termed *Quick Start*, allows women to initiate contraception immediately and facilitates getting refills because it is much more likely that the last pill in a pack will be taken on a weekday, when the office is open. When using this approach, women need to be advised that they may experience irregular bleeding for the first few weeks and that they need to use backup contraception until the second package of oral contraceptives is started.

### **Combination Oral Contraceptives**

Combination OCs provide both an estrogen and progestin in each pill during the active phase of the oral contraceptive cycle. Most packages contain 21 pills containing hormones and 7 pills that are placebos. Virtually all preparations contain ethinyl estradiol as the estrogen, in doses ranging from 20 µg to 50 µg per pill. However, in general use, most preparations contain 35 µg or less. The most commonly used progestins in the United States are the estranes: norethindrone and norethindrone acetate; the gonanes: levonorgestrel, desogestrel, and norgestimate; and a spironolactone analog, drospirenone. In general, with the dosages utilized in combination OCs, the estranes are less potent relative to their effects on the endometrium than the other progestins. Further, it should also be noted that the overall

dosages of estrogen and progestins in combination OCs have been reduced by a factor of two to five over the past 40 years, resulting in an improved safety profile. Depending on the preparation, dosages may remain constant throughout a pill cycle or be used in a phasic pattern. More recently, an extended-use formulation that has users take active pills for 84 days followed by a week of placebos, has been introduced in the United States.<sup>11</sup> The intent of this formulation is to reduce the frequency of menstrual periods. All users of OCs are instructed to start OC use on either the first day of their menstrual cycle or on the Sunday following the first day of their menstrual period. The latter approach helps some women keep track of their pill use better. If using the Sunday start approach, use of backup contraception for the first week is recommended if the start date is more than 5 days from the start of the menstrual period. Although most women are candidates for combination OCs, there are some contraindications. These include current or past history of thromboembolism, myocardial infarction, stroke, breast cancer and other estrogen-dependent tumors, lupus, gallbladder disease, poorly controlled hypertension, diabetes with vascular complications, severe migraine headaches, lactation, and women over age 35 who smoke or who have cardiovascular risk factors.

Combination OCs suppress ovulation by diminishing the frequency of gonadotropin-releasing hormone pulses and eliminating the luteinizing hormone surge at midcycle. They also change the consistency of cervical mucus, resulting in less sperm penetration; make the endometrial lining less receptive to implantation; and alter tubal transport of both sperm and oocytes. The perfect use pregnancy rate is about 0.3 pregnancies per 100 women-years, although there is substantial variation due to use of differing methodology in clinical trials.<sup>5</sup> The typical use failure rate ranges from 3 to 8 pregnancies per 100 women-years. Incorrect pill taking unfortunately leads to contraceptive failure. In a study of 103 students who kept a pill-taking diary and who also were provided with an electronic pill pack to record when pills were removed from the pack, the electronic pack recorded missed pills at rates two to three times higher than those study subjects recorded in their diaries.<sup>12</sup> Other factors that also affect typical use effectiveness include perceived convenience, cost, and motivation.

A number of health benefits are associated with combination OC use. Table 58-1 outlines noncontraceptive health benefits associated with combination OCs. Benefits that are reasonably well established include reduction in risk of ovarian and endometrial cancer, ectopic pregnancy, PID, menstrual disorders, benign breast disease, and acne. Emerging benefits include protection against bone mineral density loss, development of colorectal cancer, and progression of rheumatoid arthritis.

Multiple observational studies have demonstrated that combination OCs have a protective effect against development of ovarian cancer, with between a 40% and 80% overall decrease in risk among users compared to nonusers.<sup>13</sup> The protection begins approximately 1 year after initiating use and conveys about a 10% to 12% decrease in risk for each year of use. In addition, protection persists for 15 to 20 years after the patient has discontinued use of OCs. This protective effect primarily involves epithelial tumors of the ovary. The mechanisms by which OCs may produce their protective effects include suppression

of ovulation, thus resulting in a reduced frequency of “injury” to the ovarian capsule, and the suppression of gonadotropins. A recent theory based on a primate model suggests that induction of ovarian apoptosis, which in turn eliminates surface epithelium inclusion cysts, may play a role in reducing ovarian cancer risk among OC users.<sup>14</sup>

A number of studies have demonstrated that use of combination OCs conveys protection against endometrial cancer.<sup>15</sup> Overall, these studies suggest up to a 50% reduction in risk that begins about 1 year after initiation of use. Protection appears to increase with duration of use; indeed, some data indicate that the protection persists up to 20 years after OC use is discontinued. Protection has been demonstrated for adenocarcinoma, adenosquamous tumors, and adenoacanthomas. However, the strength of the protective effect has varied in studies for women with potential risk factors, such as obesity and nulliparity. The purported protective mechanism is a reduction in the mitotic activity of endometrial cells by the action of the progestin component of OCs.

Based on results of various epidemiologic studies, combination OCs convey an approximately 90% reduction in risk of ectopic pregnancy. The likely mechanism is through suppression of ovulation, an effect that obviously prevents all types of pregnancy.

The use of OCs has been associated with a reduction of risk of acute salpingitis or PID by 50% to 80% compared to use of no contraception or use of barrier methods in a number of studies. A more recent multicenter study, in contrast, failed to show a protective effect of combination OC use.<sup>16</sup> Interestingly, there is no protective effect against the acquisition of lower genital tract STIs, including *Chlamydia trachomatis* and *Neisseria gonorrhoeae* infections of the uterine cervix. Purported mechanisms by which OCs exert protection include progestin-induced changes to cervical mucus, making it thick and viscous such that ascent of bacteria is substantially inhibited. Additional theories include reduced menstrual flow such that there is less retrograde menstrual flow to the fallopian tubes, resulting in a less favorable environment for promoting growth of bacterial organisms, and possible changes in uterine contractility such that ascent of organisms is less likely.

## Reproductive Endocrinology and Infertility

It is well accepted that combination OCs reduce menstrual blood loss. In addition, recent data indicates that combination OCs can be used effectively in the treatment of abnormal bleeding. For example, a randomized clinical trial demonstrated that both the investigators' and subjects' perceptions of the amount of reduction in blood loss were similar.<sup>17</sup> More importantly, the combination OC reduced blood loss substantially more than the comparative placebo. The mechanism of action is probably a stabilization effect of the estrogen and progestin combination on the endometrium. Dysmenorrhea has also been shown to be reduced through use of combination OCs. These preparations remain one of the mainstays in the treatment of primary dysmenorrhea. Combination OCs may reduce pain by reducing the prostaglandin content of menstrual fluid, leading to less local vasoconstriction and ischemia, and by reducing uterine contractility.

Results of several studies reveal a significant decrease in the incidence of benign fibrocystic conditions of the breast with oral contraceptive use, with a 30% to 50% decrease overall. The occurrence of fibroadenomas, specifically, decreases among women younger than age 45. These effects are mainly seen in current and recent long-term users of combination OCs. The likely mechanism is through suppression of ovulation, and, therefore, inhibition of the breast cell proliferation that normally occurs in the first half of an ovulatory menstrual cycle.

Randomized, placebo-controlled clinical trials have demonstrated that some combination OCs will reduce acne lesions. Although it is likely that many formulations will lead to acne reduction, the data to date are not well controlled. The mechanisms by which combination OCs achieve these effects include elevation of sex hormone-binding globulin, which binds and decreases available testosterone; suppression of the enzyme that converts testosterone to dihydrotestosterone; and suppression of gonadotropins, resulting in decreased levels of ovarian androgens. In addition, combination OCs appear to improve BMD in many studies, although other studies have shown no effect. No studies have demonstrated a negative effect on BMD. It appears that combination OCs are most effective at preventing bone loss during times of low estrogen and have a further protective effect with increased duration of use. Women who have used OCs for 5 to 10 years or longer are afforded the greatest protection. One study has shown a 25% reduction in hip fracture risk.<sup>18</sup> Estrogens act on bone by increasing calcium absorption, decreasing calcium loss, and directly inhibiting bone reabsorption through inhibition of osteoclasts.

Several observational studies have suggested that combination OCs may protect against colorectal cancer. Potential mechanisms of action leading to the protective effect include reduction of bile acid production and concentration and effects on colonic mucosa or flora. A large meta-analysis has also suggested that combination OCs may prevent progression of rheumatoid arthritis to the more severe varieties.<sup>19</sup> However, this protective effect was noted in hospital-based studies but not population-based studies, which suggests the possibility of confounding or bias.

The major risks associated with combination OCs, although uncommon, relate to cardiovascular events (venous thromboembolism, myocardial infarction [MI], stroke) and possibly breast cancer.<sup>20</sup> Tables 58-2 and 58-3 provide estimates of the

Table 58-2 Incidence* of Cardiovascular Disease Among Low-Dose Oral Contraceptive <sup>†</sup> Users by Progestin Type, Ages 20–24 Years			
Condition	Oral Contraceptive Type		
	None	Levonorgestrel/ Norethindrone	Gestodene/ Desogestrel

risk of cardiovascular morbidity and mortality for combination OC users in women age 24 or younger. As shown, use of most current combination OCs roughly triples a user's risk of venous thromboembolism, although some studies of formulations containing desogestrel suggest that the risk could climb as high as sevenfold. However, it is important to recognize that even with the worst-case scenarios, the attributable risk annually is about 18 additional events per 100,000 users compared with nonusers of combination OCs. Venous thromboembolism risk is enhanced by risk factors such as recent leg trauma, pelvic surgery, stasis (but not varicose veins), and the presence of the mutation known as factor V Leiden. Although the presence of this latter clotting abnormality markedly elevates a user's risk of venous thromboembolism, the absolute risk is still low such that routine screening for the disorder among all potential oral contraceptive users would not be cost effective.<sup>21</sup> Obesity is also inconsistently cited as a risk factor; smoking, hypertension, and diabetes are not risk factors that increase the risk of venous thromboembolism among OC users. MI is a rare condition in reproductive-age women. This disorder occurs among

Table 58-3 Mortality* from Cardiovascular Disease Among Low-Dose Oral Contraceptive <sup>†</sup> Users by Progestin Type, Ages 15–24 Years			
Condition	Oral Contraceptive Type		
	None	Levonorgestrel/ Norethindrone	Gestodene/ Desogestrel
Venous thromboembolism	0.1	0.3	0.2–0.7
Stroke	1.0	1.5	1.5
Myocardial infarction	0.1	0.3	0.1

\*Incidence per 100,000 annually.

combination OC users only in the presence of risk factors such as hypertension, diabetes, severe dyslipidemia and, in particular, cigarette smoking. In fact, it has been estimated that 80% of the cases of MI among combination OC users are directly attributable to cigarette smoking. Age above 35 years and smoking also act synergistically to increase risk; prescription of combination OCs is not recommended to women over age 35 who smoke. However, even with a 20- to 30-fold relative risk of MI among smoking combination OC users, this risk only equates to a maximum of 500 to 600 events per million women-years. However, unlike venous thromboembolism, in which the case-fatality rate in the reproductive age group is less than 1%, the case-fatality rate for MI is about 50%. Stroke is also a rare condition among women in the reproductive age group, with hemorrhagic stroke being somewhat more common than ischemic stroke. Among nonsmoking women, the rates range from 6 to 46 events per million women-years; combination OC use increases that risk only if risk factors are present. The major risk factors include age, cigarette smoking, migraine headaches (for ischemic but not hemorrhagic stroke), and especially hypertension. Overall, the relative risk of stroke varies between twofold and tenfold, depending on the number of risk factors present.

For several decades, concern has been expressed regarding the possible association between OC use and breast cancer. Unfortunately, many epidemiologic studies reported conflicting results. The discrepancies probably related to how well potential biases and confounding were addressed in the individual studies. In 1996, a collaborative project representing a reanalysis of most of the better epidemiologic studies in the literature was published.<sup>22</sup> In total, 54 studies were included in the analysis, representing 53,297 women with breast cancer and 100,239 control subjects. For current users of OCs, the relative risk of breast cancer compared with those who had never used OCs was 1.24. This small increase in risk persisted for about 10 years after OC use was discontinued, with the risk essentially disappearing after that time. In addition, there was no overall effect of OC use by dosage, specific formulation, duration of use, age at first use, age at time of cancer diagnosis, or by family history of breast cancer. The comparison of ever-users of OCs with never-users revealed that the relative risk for tumors that had spread as opposed to localized disease was 0.88. Thus, although OC users face a modest increase in risk of breast cancer, the disease tends to be localized. In addition, the pattern of disappearance of risk after 10 years coupled with the tendency toward localized disease suggests that the overall effect may represent detection bias or perhaps a promotional effect. More recently, a large population-based case-control study from the United States analyzed risk of breast cancer among women aged 35 to 64.<sup>23</sup> Neither current nor past use of any type of OC increased the risk of breast cancer compared to population-based controls. Further, the results did not vary according to potential risk factors, such as estrogen dose, duration of use, family history of breast cancer, or age at initiation of use. Thus this study also indicates that breast cancer risk associated with OC use is negligible for most women.

Minor side effects reported in association with combination OC use include abnormal bleeding, nausea, breast tenderness, headache, and weight gain. Effective management of these

problems markedly improves the overall compliance with this method. Whether women start combination OCs for prevention of pregnancy or regulation of their menstrual cycles, a significant proportion have abnormal bleeding after initiation. Abnormal bleeding patterns on OCs are associated with improper pill taking, although fully compliant users also can experience changes in bleeding patterns. Patients need to be counseled to expect some change in their bleeding and be reassured that it does not indicate a gynecologic cancer. Lower doses of estrogen have been associated with an increase in breakthrough bleeding. Therefore, in patients with a particular concern about abnormal bleeding, a 30- to 35-mg ethinyl estradiol content may be indicated. Although extended-use OCs were introduced in an effort to reduce the frequency of menstrual periods, initial data suggests that abnormal bleeding or spotting is common as one approaches the end of the extended-use time period, although the effect is somewhat ameliorated with time. Persistent abnormal uterine bleeding on OCs should be investigated. The initial evaluation should include assessment for cervicitis or cervical neoplasia. The evaluation may also include an endometrial biopsy and sonohysterography.

Up to half of women report a feeling of nausea on initiation of combination OCs; many fewer experience vomiting. The incidence of these side effects has decreased with the decrease in the estrogen content of the pill under 50 mcg, but it is still frequently experienced. Anecdotal reports suggest a 50-mcg daily dose of vitamin B<sub>6</sub> may be effective for amelioration of symptoms. Other strategies include taking the pill with meals or at bedtime, decreasing the dose to 20 mcg, or switching to a progestin-only contraceptive. Reassuring the patient of the likely transient nature of the nausea is an important part of contraceptive counseling. There is no evidence that combined OCs directly cause weight gain. Users should be counseled that eating and exercise patterns are major contributors to weight gain.

Estrogens are known to stimulate breast tissue and lead to increased growth and tenderness. This side effect seems to decrease in frequency with continued use as endogenous levels of estrogen and progesterone are suppressed. Lower levels of ethinyl estradiol, as in the 20-mcg combination pills, could theoretically decrease this side effect. If patients are experiencing increased breast tenderness immediately before the pill-free interval, they may actually benefit from a higher-dose estrogen combination pill that more effectively inhibits ovulatory cycles. Patients should be reassured that the tenderness is not evidence of growth of a breast cancer, and that with time the overall incidence of benign breast disease will decrease.

Headache is a common complaint among reproductive-age women. Unfortunately, there are few controlled data on the incidence of headache in OC users or on the potential interaction with dose, formulation, or duration of use. One study indicated that the frequency of headache overall has not changed with the introduction of the new lower-dose formulations, suggesting that the occurrence of many headaches is independent of OC use. From an overall management standpoint, careful history taking should allow one to differentiate between tension-like headache and migraine headache. If one suspects migraine headache, combination OCs should be used with care. Although there are no conclusive data on differences in stroke risk for migraine with or without aura, OC use in the former circumstance should

## Reproductive Endocrinology and Infertility

be considered only if other contraceptive methods cannot be used and only after detailed counseling. If migraine occurs without aura and if other risk factors are not present, most women can be given a trial of oral contraceptives. Follow-up should be initiated within the first 2 to 3 months to assess frequency and severity of headaches. If there is a slight increase in frequency during the trial, a change in formulation might be considered. If headache occurs more frequently in the hormone-free interval, the physician might consider the use of daily continuous OCs without a hormone-free interval. However, if the headaches become significantly more severe or frequent, OCs should be discontinued and other contraceptive approaches used.

### **Transdermal Patch**

The transdermal contraceptive patch is 20 cm<sup>2</sup>, roughly the size of a small Post-It pad. The patch consists of a matrix in three layers: an outer polyester protective layer, which is light tan in color; a middle layer containing an adhesive and the contraceptive steroids; and an inner clear polyester liner that is removed before applying the patch to the skin. The transdermal contraceptive patch is designed to deliver 150 µg of norelgestromin and 20 µg of ethinyl estradiol daily for a 7-day period. Norelgestromin, also known as 17-deacetyl norgestimate, is the active metabolite of norgestimate, a progestin contained in certain OCs. Ethinyl estradiol is the estrogen component of most OCs. After 7 days are completed, the patch is removed and a new one is applied to another skin site. Three consecutive 7-day patches are applied in a typical cycle followed by a 7-day patch-free period to allow withdrawal bleeding. Data also indicates that the efficacy of the transdermal contraceptive patch would be maintained even if a scheduled change was missed for as long as 2 full days.<sup>24</sup> Application sites that have been determined in clinical trials to be therapeutically equivalent include the buttocks, lower abdomen, upper outer arm, and upper torso except for the breasts. Because this is a combination steroid preparation, the same contraindications noted for combination OC use apply.

The efficacy of the transdermal contraceptive patch, as determined in three clinical trials, demonstrated a method use and typical use rate of 0.70 and 0.88 pregnancies per 100 women-years, respectively.<sup>24,25</sup> These rates are comparable to pregnancy rates achieved with current oral contraceptives. Further, the similarity of the two rates suggests that the ability to use the method correctly is high. This finding was confirmed in compliance studies, which showed that about 90% of women across all age groups used the method correctly.<sup>26</sup> However, a failure rate approaching the typical use failure rate seen with combination OC users was noted for women using the patch who weigh over 198 pounds.

Since this method was introduced, no reports have documented rates of serious adverse events. Until such data are available, one should assume that the events and risks will be similar to those noted for combination OCs. Similarly, there are no data available on noncontraceptive benefits, although one might assume that some of the benefits seen with combination OC users would accrue to patch users as well. The frequency of side effects such as headache and nausea is similar to that seen among combination OC users. Contraceptive patch users in clinical trials have application site reactions, more breast symptoms (only during the first two cycles), and more dys-

menorrhea than combination OC users. The pattern of breakthrough bleeding (bleeding requiring more than one pad or tampon daily) and spotting with the transdermal contraceptive patch is similar to that demonstrated in combination OC trials. Based on data from a placebo-controlled, randomized clinical trial over 9 months, there is no evidence that use of the patch influences body weight.

Women without contraindications to combination OC use constitute the initial set of potential users of the transdermal patch. However, women with a history of significant skin allergy or exfoliative dermatologic disorders may not be ideal candidates. Obese women also need to be counseled about the potential for reduced efficacy. Reminder systems to ensure appropriate weekly changing of the patch, using a different site for the next application, and avoiding use of lotions or occlusive dressings needs to be stressed during counseling. An obvious important attribute of any transdermal delivery system is its ability to remain adherent during the course of the dosing schedule. In the various trials, 1.8% of transdermal patches required replacement for complete detachment and 2.9% became partially detached. Detachment rates were similar for women living in warm, humid climates and for women who engaged in vigorous exercise, swimming, and sauna use. When patches do become detached, users should attempt to re-attach them if possible, without using ancillary adhesives or tape. If detachment is noted to last 24 hours or less, the cycle continues as usual, with the patch being changed on the previously determined change day. If detachment has lasted for longer than 24 hours, a new patch should be applied and backup contraception should be used for 1 week. The day the new patch is applied would then become the patch change day. When a new patch cycle is delayed beyond the scheduled start day, the user should apply a patch as soon as they remember and use backup contraception for at least 1 week. Further, the day the user applies the patch becomes the new patch change day. If a user forgets to change the first or second patch on time, various strategies can be employed to help get back on schedule and avoid an unplanned pregnancy. If a user changes the patch within 9 days of application, the patch change day remains the same and there is no need for backup contraception. Failure to replace a patch after this extra 2-day time period increases the risk for contraceptive failure. Therefore, users will need to use backup contraception or in some instances, emergency contraception if this occurs. In addition, the day she remembers to apply the patch becomes the new change day. Forgetting to remove the third patch on time carries less risk. The user should remove it when she remembers; the change day is not altered. Finally, if the user wishes to switch to a new patch change day, this should be done during the last week of a cycle, when patches are not usually used. The FDA has recently required a change in labeling, with a black box warning regarding adverse effects.

### **Vaginal Ring**

The contraceptive vaginal ring is flexible, about 5 cm in diameter and 4 mm in thickness. It releases ethinyl estradiol at a rate of 15 µg daily and etonogestrel, the active metabolite of desogestrel, at 120 µg daily.<sup>27</sup> The ring is worn for 3 weeks out of 4, although there is enough contraceptive steroid content in the ring's reservoir for about 14 more days. The ring maintains its efficacy even

if removed for up to 3 hours, although it is designed to be left in place even during intercourse. If removed for longer time periods, use of a backup method for 7 days is recommended while the user continues ring use. Users are instructed to insert it high into the vagina; fitting by a health professional is not required. In a large clinical trial, the overall pregnancy rate over 1 year of use was 0.65 pregnancies per 100 women-years.<sup>28</sup>

As with the transdermal contraceptive patch, there is no published data to indicate rates of major side effects or potential noncontraceptive benefits. However, because the vaginal ring contains steroids that are utilized in combination OCs, rates of serious side effects may be similar and some of the noncontraceptive benefits may accrue to users of this method. Minor side effects are similar to those seen with users of combination OCs. Of particular note, however, is the low frequency of breakthrough bleeding and spotting occurring in 2.6% and 6.4% of cycles, respectively, in a noncomparative trial conducted over 13 cycles.<sup>28</sup> The pattern is relatively constant for all cycles as opposed to the usual declining incidence seen in most OC trials. As with the transdermal patch, about 90% of users use the vaginal ring according to the instructions. Approximately 10% to 15% of users report vaginal-related symptoms such as slight discomfort, a sensation of a foreign body, leukorrhea, vaginitis, or coital problems.

When starting use, the vaginal ring can be inserted during the first 5 days of a menstrual period. However, backup contraception should be used for the first 7 days of ring use. Regardless of when use of the vaginal ring is initiated, as noted previously, if it is removed for more than 3 hours, backup contraception should be used. Also the vaginal ring has enough hormone content for up to 35 days of use. Therefore, failure to remove the ring on time is not a major issue with this method.

### **Progestin-only Hormonal Contraception**

Progestin-only contraceptives are ideal for women for whom estrogen is contraindicated. Particularly ideal candidates include women with seizure disorders (metabolism of OC components are affected by many seizure medications), sickle cell anemia, mental retardation (if using an injectable or implant), migraine headache, hypertension, or systemic lupus erythematosus; older women who smoke; and those who are breastfeeding.

### **Depot Medroxyprogesterone Acetate**

Depot medroxyprogesterone acetate (DMPA) has been utilized as a contraceptive in the United States for at least 40 years, although Food and Drug Administration approval did not take place until 1992. DMPA is an aqueous suspension of 17-acetoxy-6-methyl progesterone.<sup>29</sup> The usual dose is 150 mg administered intramuscularly into the gluteus maximus or deltoid every 3 months. DMPA's mechanisms of action include suppression of ovulation by suppressing the surge of gonadotropins, thickening cervical mucus to impede ascent of sperm, and thinning of the endometrium such that implantation of a blastocyst is less likely. Although labeled by the manufacturer as effective for up to 13 weeks, the contraceptive activity actually persists for about 4 months after an injection, such that some practitioners will allow a "grace period" of 1 to 2 weeks after the previous administration for the next injection. Others schedule the follow-up injections at about 11 weeks from the last injection

to allow greater latitude to reschedule missed visits yet reduce the chance of unintended pregnancy. During 1 year of use, the perfect use failure rate is 0.3 pregnancies per 100 women-years, and the typical use failure rate is 3 pregnancies per 100 women-years.

There are health benefits associated with use of DMPA. The risk of ectopic pregnancy is significantly lower among users compared to women not using contraception. In studies conducted by the World Health Organization, the risk of endometrial cancer was reduced by as much as 80%. As with use of OCs, the risk reduction for endometrial cancer is long term and is greater for women who use DMPA for prolonged periods. Although no protective effect has been demonstrated relative to ovarian or breast cancer, neither is there evidence of an increase in risk with use of this agent. Studies have shown as much as a 70% reduction in the frequency of sickle cell crises; the mechanism for this effect is not known. Finally, some women with endometriosis have improvement of symptoms with use of DMPA.

There is no evidence that DMPA or other progestin-only contraceptives increase the risk for arterial or venous disease. The most significant potential risk associated with DMPA use is a reduction in bone mineral density. Although several observational studies have demonstrated such changes, most lack rigorous study designs that would allow one to adjust for other risk factors or clearly determine duration effects. Overall, in studies that are prospective and at least 1 year in duration, a maximum reduction of 1.5% to 2.3% in bone mineral density has been shown. A cross-sectional study showed reductions in the range of 2.2% to 2.5%, depending on site. However, this study also noted that the decreases were greater among younger users. No studies to date have shown any increase in fracture risk. Finally, retrospective studies have shown improvement in bone mineral density when DMPA is discontinued. Until further data become available, adequate calcium intake should be encouraged for DMPA users, particularly young patients and longer term users. The most frequently cited side effects are menstrual pattern alterations, mood disturbances, weight change, and delay in restoration of fertility after discontinuation. For the first 6 months of use, irregular spotting and prolonged menstrual flow is not uncommon. However, with continued use, many women become amenorrheic. By 3 months of use, 20% of DMPA users are amenorrheic; at 1 year up to 70% experience no menses. Mood change and depression have been reported in association with DMPA use. However, most studies are uncontrolled. Studies that have attempted to use some type of comparison group have yielded conflicting results. Thus, it is unclear whether DMPA use is associated with either depression or mood change. Although earlier studies suggested DMPA users may gain on average 5 pounds after 1 year of use, a recent randomized clinical trial demonstrated that DMPA is not associated with significant weight gain or changes in variables that might lead to weight gain.<sup>30</sup> Finally, when DMPA users stop injections in an effort to achieve pregnancy, the return to baseline fertility may take on average 10 months.

Patient instructions relate to ensuring that users return for their re-injections. Specially designed calendars can be used to aid in scheduling re-injections on time. After injection, DMPA users should not rub the injection site because that may distribute the drug more rapidly than intended and can lead to

## Reproductive Endocrinology and Infertility

decreased efficacy near the end of the 3-month cycle. Because menstrual patterns are altered with DMPA, proactive counseling to alleviate future concerns is important.

### **Implants**

Currently, there are no implantable contraceptives available in the United States. However, research is under way in the United States with a single-rod implant that is 4 cm long and 2 mm in diameter.<sup>31</sup> This system releases etonogestrel, the major metabolite of desogestrel, at a rate of 67 µg daily. It maintains its efficacy for up to 3 years. The system is usually inserted in the upper arm using a trocar; removal, although requiring an incision, is easier than with other implants because of the single-rod system. The likely mechanism of action is similar to DMPA. Overall efficacy is extremely high, with no reported pregnancies in more than 70,000 cycles of use. No major complications have been reported to date. Side effects include menstrual abnormalities and weight gain. For example, up to 19% of women will develop amenorrhea over 1 year; irregular bleeding, although not infrequent, was not cited as a significant issue for most users. In a 3-year study, mean body mass index increased by 3.5%, but about 20% of users experienced increases in body mass index of more than 10% compared to baseline.

### **Minipill**

Available progestin-only oral contraceptives (the “minipill”) contain either 0.35 mg of norethindrone or 0.075 mg of norgestrel in packs of 28 pills without placebos. The mechanism of action is the same as for other progestin-only contraceptives. However, because dosing is daily, these actions may dissipate if the pills are not taken on schedule. Candidates for use of the minipill are the same as those for other progestin-only contraceptives. However, in the United States, the group who most widely use this method are lactating women. Perfect use failure rates are about 0.3 pregnancies per 100 women-years; typical use rates rise to 8 pregnancies per 100 women-years.

As with other progestin-only contraceptives, no major cardiovascular complications with use of this method have been reported. Irregular spotting and occasional amenorrhea are the side effects most frequently reported. Reduction of endometrial cancer is the only major noncontraceptive benefit that may accrue to users of this method.

For lactating women, in general the medication is started at the 6-week postpartum visit if the breastfeeding pattern is well established because lactational amenorrhea alone is effective as a “contraceptive” during the first few weeks postpartum. At the time that the decision to wean is made or when additional foods are added to the infant’s diet, the patient can then switch to combination OCs if she is a candidate.

### **Emergency Contraception**

Emergency contraception is an approach to prevent pregnancy after unprotected intercourse or with known failure of a contra-

ceptive method, such as a leaking condom.<sup>32</sup> The major methods used for emergency contraception include combination OCs containing the progestin levonorgestrel, levonorgestrel tablets, or the Copper T 380 A IUD. The hormonal methods prevent pregnancy by delaying or inhibiting ovulation or by disrupting the function of the corpus luteum. The IUD may inhibit implantation or possibly interfere with sperm function. The usual combination hormonal formulation consists of 100 µg of ethynodiol and 500 to 600 µg levonorgestrel in several tablets administered twice, 12 hours apart. Currently it is recommended that the first dose be administered within 72 hours of intercourse. The levonorgestrel-alone formulation requires the administration of 750 µg of the progestin twice, also 12 hours apart. Initial dosing within 72 hours is currently recommended by many authorities, although there is data to suggest this approach may be effective as long as 5 days after intercourse. Further, data suggests that a single dose of 1500 µg of levonorgestrel may be as effective as the two-dose regimen. The Copper T 380 A is inserted within 7 days from the time of unprotected intercourse.

Emergency contraception, if used appropriately, can reduce the risk of unintended pregnancy by as much as 75%. One midcycle episode of unprotected intercourse carries a pregnancy risk of about 8%. Use of the combination hormonal method, the levonorgestrel-only method, and the Copper T 380 A IUD reduce this rate to 2%, 1%, and 0.5%, respectively. Data suggests that the earlier one initiates emergency contraception, particularly the combination hormonal approach, the more effective it will be.

Nausea is seen in about 50% and vomiting in 20% of users of combination hormonal emergency contraception. Administration of an antiemetic such as meclizine an hour before may reduce this effect. Levonorgestrel-only emergency contraception is associated with rates of nausea and vomiting that are 50% and 70% lower, respectively, than those experienced with combination emergency contraception. Women selecting the Copper T 380 A IUD will have side effects and risks as noted in the discussion of this method but will have the added advantage of initiating a highly effective long-term method at the same time.

## **SUMMARY**

With approximately one half of pregnancies in the United States being unintended or unplanned, there is a need for safe and effective contraceptive methods. Currently, many methods are available, each with their advantages and disadvantages. Further, emergency contraception is a highly effective backup method when methods fail or when it is known they have not been used correctly. Table 58-4 outlines some of the differences among methods. Regardless of the method selected, successful use requires that health care providers counsel on proper use of the method as well as expected risks, side effects, and possible noncontraceptive health benefits.

## KEY POINTS

- The *menstrual cycle* is the term used to refer to the process by which the primate ovary produces and releases an ovum. In primates, ovarian cyclicity is signaled by uterine bleeding. The “typical” menstrual interval is roughly 29 days. Regular uterine bleeding is often taken as evidence of reproductive competence, although this is clearly not always the case. Nonetheless, the cyclic nature of the menstrual interval due to the pattern of ovarian function is indeed a prerequisite for female fertility.
- Coordination of the ovarian–uterine cycle requires appropriate interplay between the hypothalamic gonadotropin-releasing hormone “pulse generator,” pituitary gonadotropin release, and ovarian steroids and peptides.
- Hypothalamic, pituitary, and ovarian action differ during the three phases of the cycle, which are termed *follicular*, *ovulation*, and *luteal* when referring to ovarian events and *proliferative* and *secretory* when referring to endometrial events.
- The follicular phase is the first half of the cycle, during which the dominant follicle is selected from a pool of recruited follicles, estradiol levels rise, and the endometrium proliferates.
- Ovulation involves the release of the oocyte from the dominant follicle and the genesis of the corpus luteum in the ovarian follicle.
- The luteal phase is the second half of the cycle, during which the corpus luteum produces high levels of estradiol and progesterone to support a potential pregnancy and the endometrium is transformed to a secretory state to facilitate implantation.
- In the absence of pregnancy, menstruation occurs as the luteal phase terminates with decreasing estradiol and progesterone due to corpus luteum deterioration and the next wave of follicular recruitment and selection begins.
- Understanding of the physiology of the menstrual cycle is best achieved by examining the dynamics of each component of the hypothalamic-pituitary-ovarian axis at each phase of the cycle (Fig. 59-1).

## OOCYTE

Each oocyte is encircled by granulosa cells, which in turn are surrounded by theca cells and stroma in the ovarian cortex; this spherical ovarian structure is termed the *follicle*. In the embryo, germ cells migrate from yolk sac endoderm to the gonadal ridge

by 7 weeks of gestation. Peak ovarian oocyte quantity of 6 to 7 million occurs by 16 to 20 weeks of gestation. Approximately 400 of these oocytes will be released; the remainder undergo atresia via programmed cell death (i.e., apoptosis). After their genesis in fetal development, the oocytes remain as dormant primordial follicles, each composed of an ovum arrested in the diplotene stage of meiotic prophase surrounded by a single epithelial layer of flattened granulosa cells (Fig. 59-2).

Gonadotropin-independent growth from primordial follicle (0.05 mm) to preantral follicle (0.2 mm) occurs by yet to be fully defined mechanisms in both ovulatory and anovulatory states from infancy to perimenopause (Fig. 59-3). During each cycle from puberty to menopause, a cohort of oocytes compete to be the dominant ovulatory follicle. The cohort’s journey begins 3 months before ovulation with gonadotropin-independent follicular development. Cohort selection and continued follicular development requires gonadotropin exposure. Antral follicles (2 mm) are either selected, and thus become part of the preovulatory cohort, or become atretic (Fig. 59-4). From the preovulatory cohort of antral follicles emerges the dominant graafian follicle (Fig. 59-5) that will be released at ovulation.

Menopause occurs when the primordial follicle count is depleted to approximately 1000. The average age for menopause is 51.7 or 52 years (Fig. 59-6).

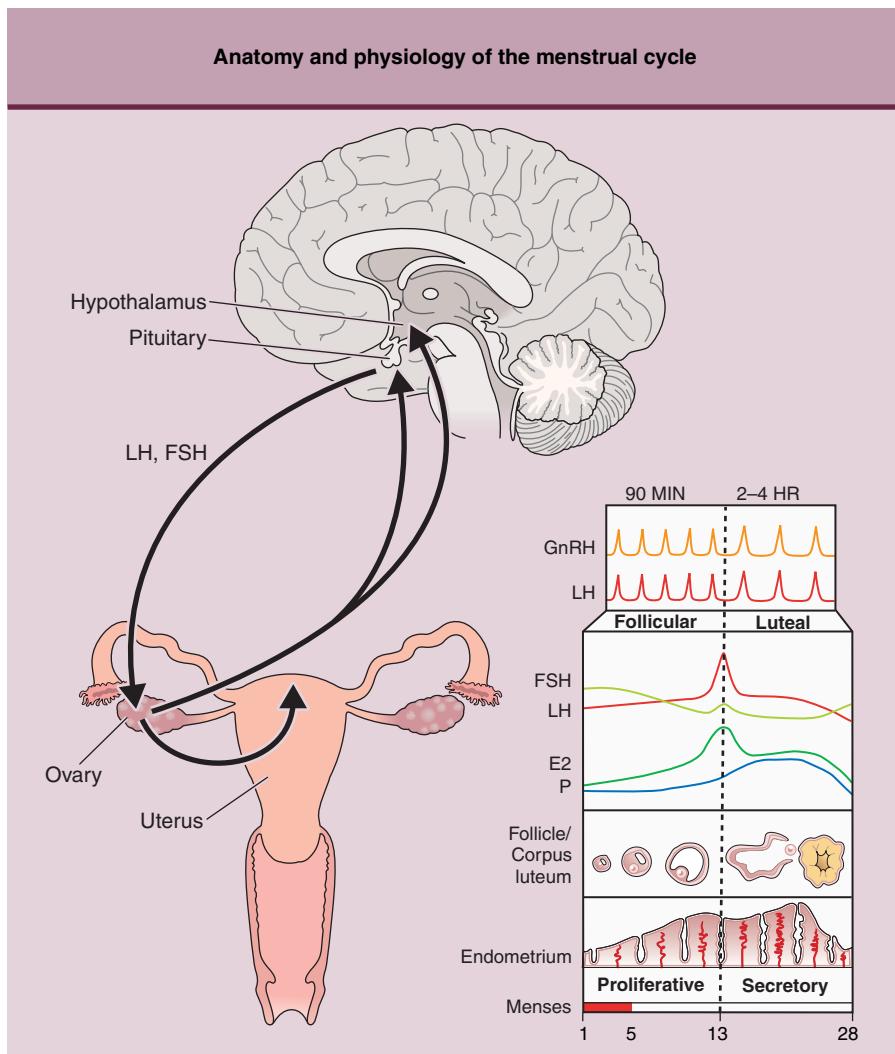

## HYPOTHALAMUS

The neurons that secrete gonadotropin-releasing hormone (GnRH) are located in the arcuate nucleus of the mediobasal hypothalamus at the base of the third ventricle. These cells that comprise the GnRH pulse generator migrate from the olfactory placode during early gestation; the pulse generator is active by 20 weeks of fetal life.

## CLINICAL CORRELATION

GnRH deficiency leading to primary hypothalamic amenorrhea associated with anosmia, or Kallmann syndrome, results from insufficient GnRH neuron migration to the hypothalamus from the olfactory placode. The more common X-linked recessive form affects men, whereas an autosomal dominant form affects men and women. Mutations in genes affecting pituitary gonadotropins can also cause idiopathic hypogonadotropic hypogonadism; these patients are normosmic.<sup>1</sup>

Afferent input to the hypothalamic GnRH neurons includes neural signals located in the brain stem, limbic lobe, and frontal

**Figure 59-1 Anatomy and physiology of the menstrual cycle.** (From Berga SL: Menstrual cycle. In Knobil E, Neill JD [eds]: Encyclopedia of Reproduction, Vol. 3. San Diego, Academic Press, 1998: pp 189–194.)

cortex. Putative central neuromodulators include corticotropin releasing hormone, endogenous opioids,  $\gamma$ -amino butyric acid (GABA), dopamine, norepinephrine, neuropeptide Y, and serotonin. GnRH neurons receive peripheral signals from the circulation via the fenestrated blood-brain barrier.

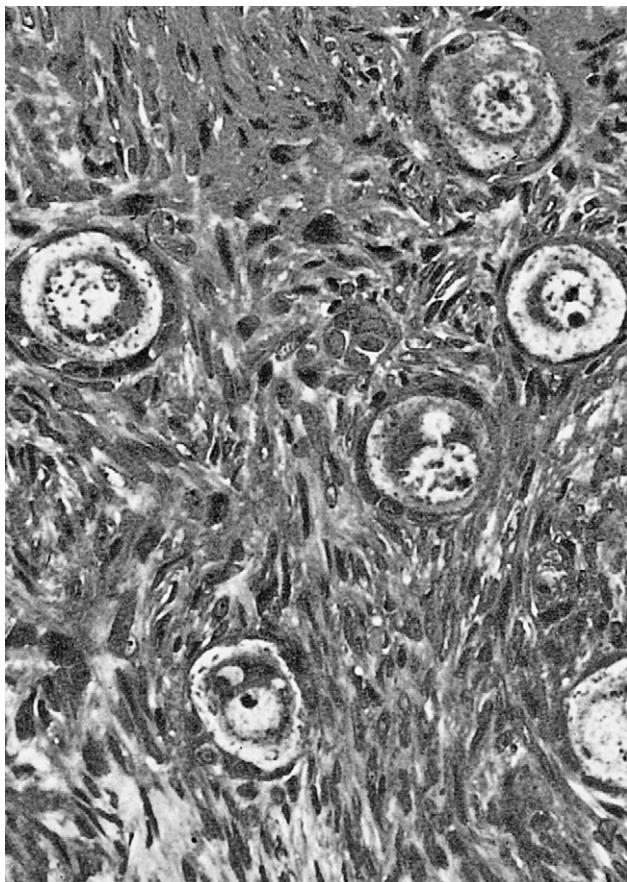

#### Pulsatile Nature of GnRH Release

Gonadotropin-releasing hormone is produced by neurons located in the ventral and anterior hypothalamus. GnRH is released in a pulsatile fashion into the hypophyseal portal circulation to stimulate the anterior pituitary to release the gonadotropins, follicle-stimulating hormone (FSH), and luteinizing hormone (LH). The pulsatile nature of GnRH release and its effect on pituitary gonadotropin release is of central importance to the regulation of the ovarian cycle (Fig. 59-7).<sup>2</sup> Because GnRH has a short half-life and is therefore not measurable in the peripheral circulation, GnRH pulse frequency is inferred by measuring LH pulses in the circulation. LH, and therefore GnRH pulse frequency, changes with menstrual cycle phase. In the follicular phase, LH is released at a frequency of one pulse every 60 to 90 minutes, with an increase in frequency preceding ovulation. LH pulse amplitude decreases in the midfollicular phase. In the

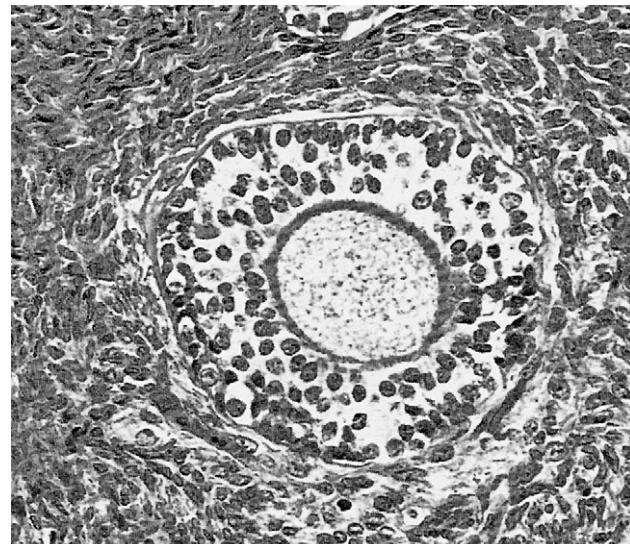

luteal phase, GnRH pulse frequency decreases from one pulse every 60 to 90 minutes to one pulse every 2 to 4 hours. This may be due in part to the induction of endogenous opioidergic modulation of GnRH.<sup>3</sup> The result is slowing of LH pulse frequency but amplification of LH pulse amplitude.

In the first months after birth, pulsatile GnRH secretion permits FSH secretion. Then, hypothalamic GnRH drive becomes suppressed until puberty. GnRH secretion resumes again at puberty, resulting in increases in pituitary gonadotropins, first at night and then around the clock. Neuropeptide Y and GABA are two factors that may act to restrain GnRH secretion from infancy to puberty. Increasing leptin levels associated with increasing body fat may permit the resumption of pulsatile GnRH release.<sup>4</sup>

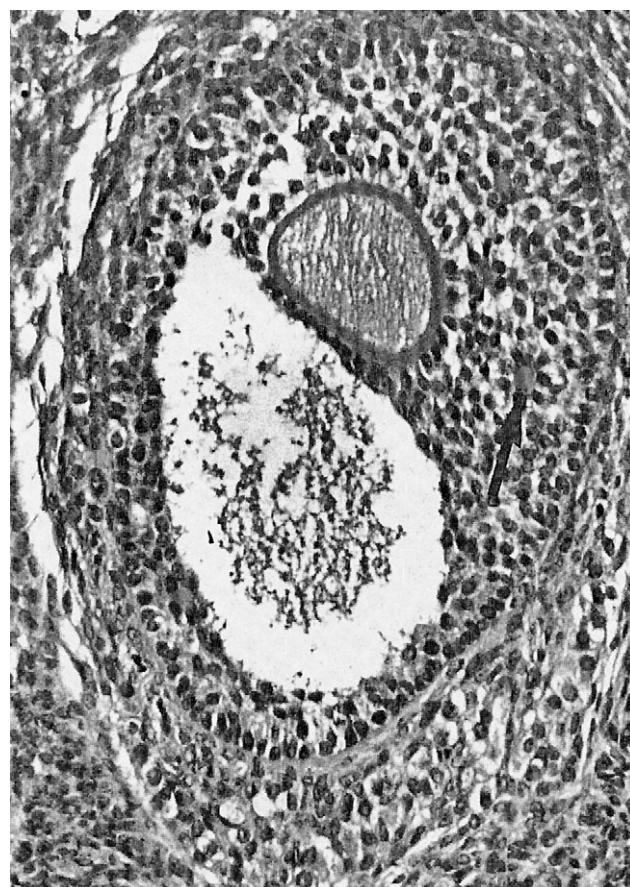

Disruptions in GnRH pulse frequency lead to anovulation and subsequent infertility. Endogenous or exogenous opiate administration causes a slowing in GnRH pulsation that can be reversed with the opioid antagonist naloxone. The slowing of the GnRH pulse frequency with increase in pulse amplitude in the luteal phase is in part mediated by endogenous opiates, because it is reversible with naloxone. GnRH agonists given intramuscularly occupy the pituitary GnRH receptor in a sustained,

nonpulsatile fashion. These agonists have high binding affinity to the receptor and a longer half-life. Prolonged occupation of the GnRH receptors causes their evolution. Thus GnRH agonist use “desensitizes” the pituitary gonadotropes to endogenous GnRH drive. When given in a depot formulation or continuous fashion, GnRH agonists initially cause GnRH and gonadotropin secretion to rise, an effect which is often termed a *flare*. Thereafter, pituitary GnRH receptors involute and profound suppression of gonadotropin release ensues.

### CLINICAL CORRELATION

- In clinical practice, GnRH agonists are used to suppress ovarian and menstrual cyclicity and decrease estradiol production to treat estrogen-dependent pathology such as fibroids or endometriosis.
- GnRH pulse frequency is increased causing LH to exceed FSH in polycystic ovary syndrome (PCOS), a syndrome characterized by chronic anovulation and androgen excess. However, PCOS involves a constellation of metabolic adjustments, and treatment may involve targeting insulin resistance.
- GnRH pulse frequency is suppressed in functional hypothalamic amenorrhea, a syndrome characterized by decreased pituitary gonadotropins, anovulation, and estrogen deficiency. However, functional hypothalamic amenorrhea is more than an isolated disorder of GnRH drive because other neuroendocrine perturbations accompany the reproductive compromise.

**Figure 59-7 GnRH pulses from the hypothalamus stimulate luteinizing hormone (LH) and follicle-stimulating hormone (FSH) secretion.** (From Berga SL: Menstrual cycle. In Knobil E, Neill JD [eds]: Encyclopedia of Reproduction, Vol. 3. San Diego: Academic Press, 1998, pp 189–194.)

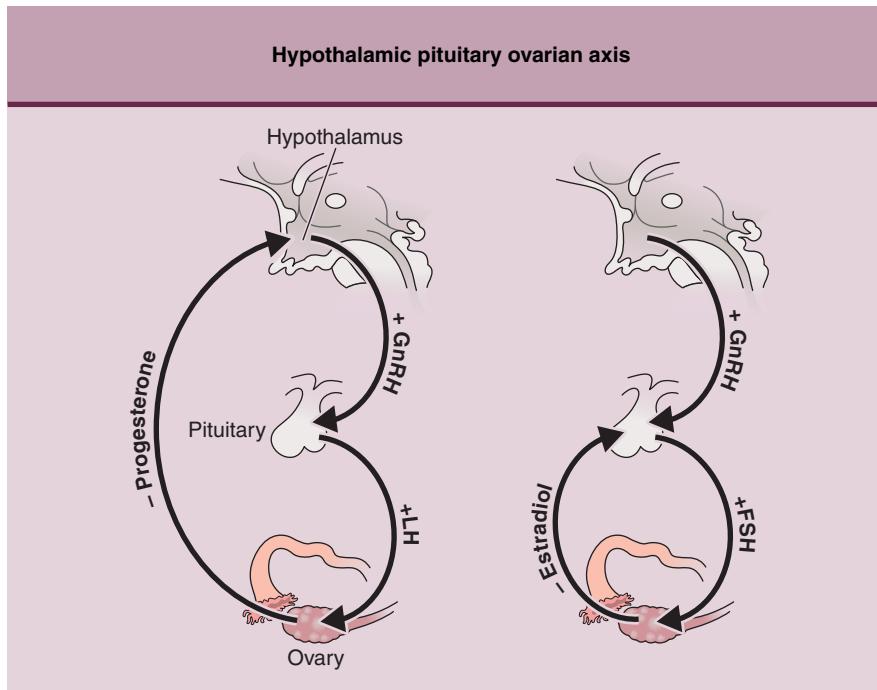

In animals that breed seasonally, melatonin from the pineal gland synchronizes the GnRH pulsatility to the ambient light-dark cycle, so that parturition occurs at a time when the environment is supportive (a link to metabolism). Humans are only weakly seasonal, although they are highly circadian, and melatonin may serve to gate the timing of the LH surge. There is no evidence that melatonin per se can disrupt human reproduction. Nocturnal secretion of melatonin is increased in women with hypothalamic amenorrhea; however, secretion has not been found to vary with menstrual cycle phase in normal control subjects.<sup>5,6</sup> In contrast to normal control subjects, subjects with premenstrual dysphoric disorder exhibit decreased nocturnal melatonin concentrations during the luteal phase that change with therapeutic light therapy.<sup>7</sup> From this, it has been postulated that melatonin rhythms signal altered states of neuroendocrine “imprinting.”

### Pituitary

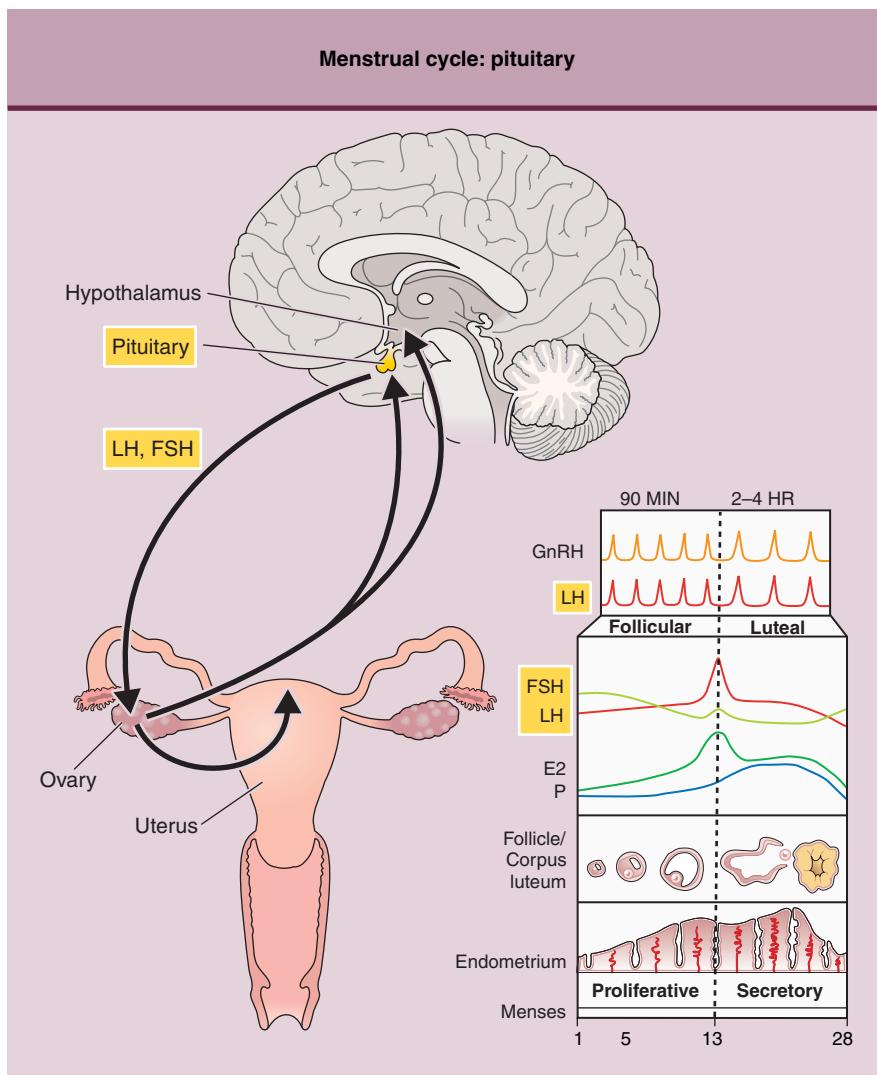

The anterior pituitary gonadotropins, LH and FSH, are composed of distinct beta subunits combined with a common alpha subunit also shared by human chorionic gonadotropin (hCG)

and thyrotropin. The anterior pituitary releases FSH and LH in a pulsatile manner in response to GnRH pulses from the hypothalamus (Fig. 59-8). FSH pulses are not detectable in the circulation because FSH has a long 4-hour half-life. LH pulses are detectable because LH has a shorter 20-minute half-life. GnRH has an ephemeral (2-minute) half-life, which provides a lower signal-to-noise ratio when the GnRH pulse frequency is slower; therefore, LH pulse frequency is utilized as a reliable indicator of GnRH release.

The rise of FSH during the early follicular phase of the menstrual cycle stimulates ovarian granulosa cell growth and induces aromatase. LH stimulates the theca cells to produce androgens. Androgens are aromatized in the granulosa cells to make estradiol. Initially estradiol exerts negative feedback on the pituitary FSH release. When rising exponentially and at peak levels, estradiol exerts positive feedback at the level of the pituitary and probably hypothalamus to create the ovulatory LH surge (Fig. 59-9). That estradiol exerts its feedback on gonadotropin secretion at the level of the pituitary is supported by studies of ovariectomized rhesus monkeys with hypothalamic lesions who, despite absence of functioning hypothalamus or

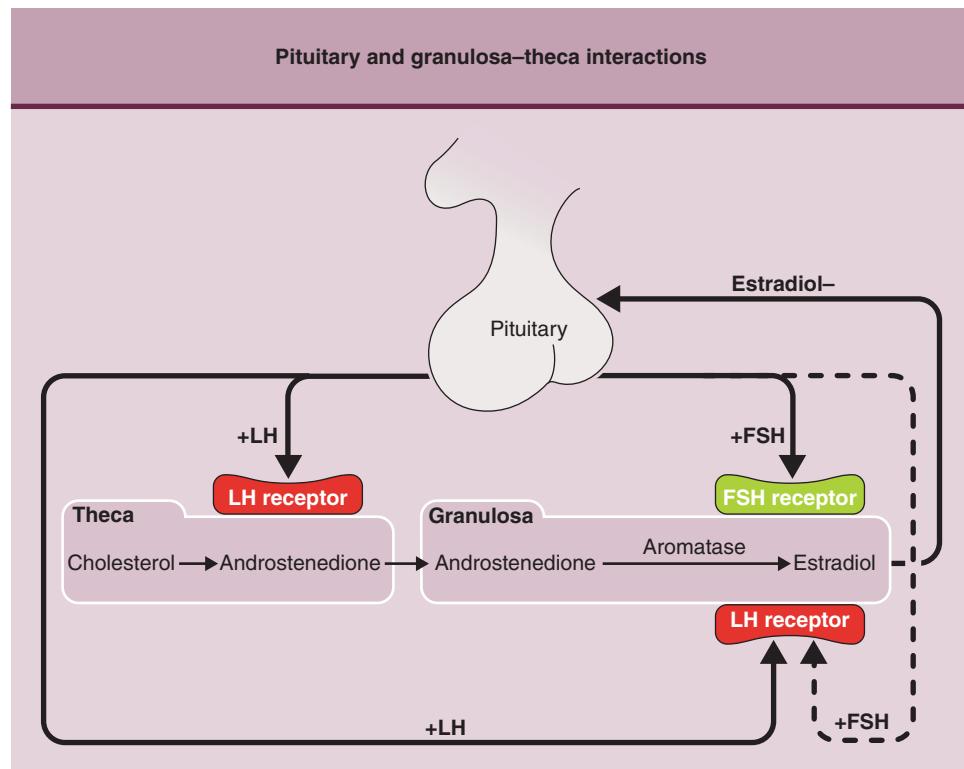

**Figure 59-8** The pituitary responds to GnRH stimulation by releasing follicle-stimulating hormone (FSH) and luteinizing hormone (LH) to stimulate follicular development in the ovary. The ovary secretes estradiol and progesterone that provides feedback to the pituitary and hypothalamus.

**Figure 59-9** The pituitary releases follicle-stimulating hormone (FSH) and luteinizing hormone (LH) to stimulate follicle development. The LH surge triggers ovulation of the dominant follicle. LH supports progesterone release from the corpus luteum. (From Berga SL: Menstrual cycle. In Knobil E, Neill JD [eds]: Encyclopedia of Reproduction, Vol. 3. San Diego: Academic Press, 1998, pp 189-194.)

**Figure 59-10 Pituitary luteinizing hormone (LH) stimulates the theca to produce androgens.** FSH stimulates the granulosa to aromatize androgens to estradiol and induces LH receptors on the granulosa. Estradiol provides feedback to the pituitary.

ovary, exhibited an LH surge when given exogenous GnRH followed by estradiol administration.<sup>8</sup> However, there may be a concomitant GnRH surge that reinforces the pituitary response.

## OVARY

The central importance of the dynamic interactions between the hypothalamus and pituitary is their effect on the ovary and ovulation. The changes in ovarian hormonal milieu intrinsic with each phase of the menstrual cycle are best illustrated by examining interactions between individual granulosa and theca cells.

The follicle is an oocyte surrounded by estradiol-producing granulosa cells, which, in turn, are surrounded by androgen-secreting theca cells. In the follicular phase, FSH stimulates the granulosa cells to become cuboidal and multiply. The surrounding thecal layers differentiate from stromal cells. The theca cell responds to LH by secreting androstenedione; only the granulosa cells have sufficient aromatase to actively convert androstenedione to estradiol (Fig. 59-10). Androstenedione is the predominant androgen secreted by the ovary. The granulosa cell lacks the enzyme to produce sufficient quantities of androgen, but has abundant aromatase to convert the androgens produced by the theca into estradiol. Estradiol and FSH increase production of follicular fluid, which accumulates into a cavity, thereby delineating the antral follicle stage.

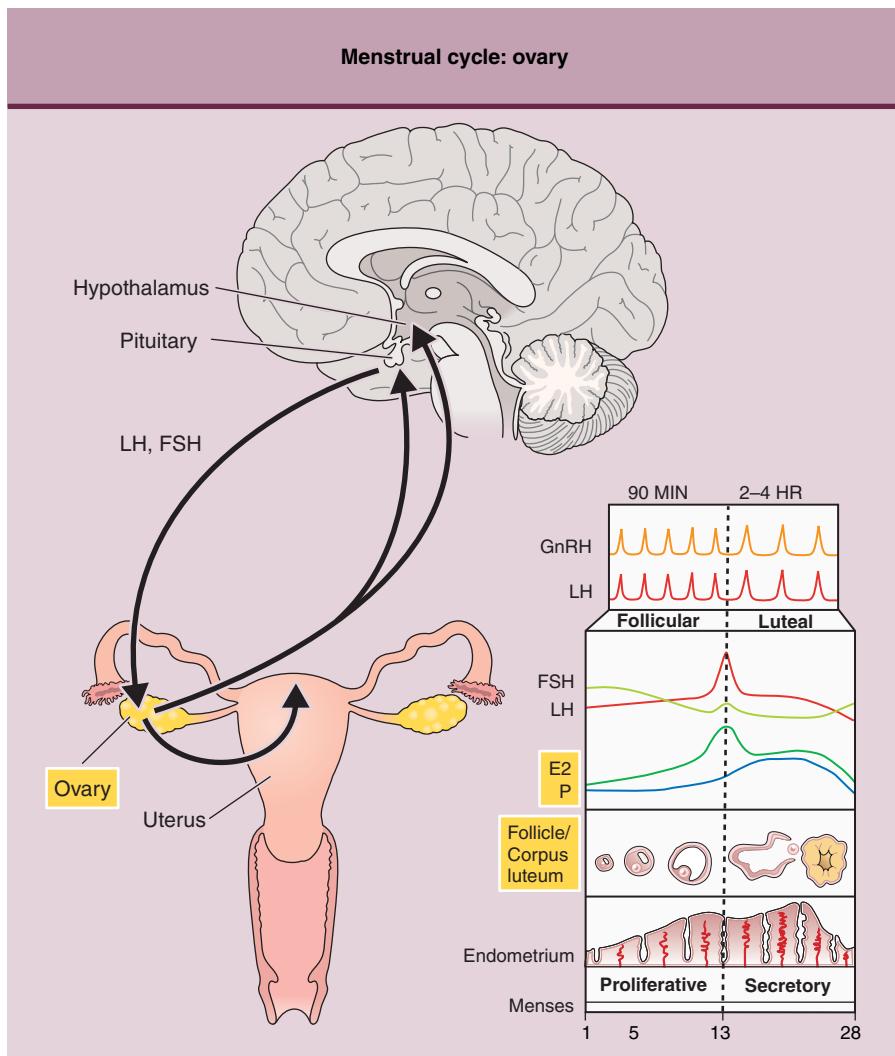

Granulosa cells of small follicles (<10 mm in diameter) favor conversion of androstenedione to dihydrotestosterone. Higher levels of FSH than LH early in the cycle are therefore needed to increase aromatization and create an estradiol-rich environment. Granulosa cells of larger follicles (>10 mm in diameter)

preferentially convert androstenedione to estradiol. The pre-ovulatory theca and granulosa compartments in the larger follicles therefore collaborate to produce the requisite rapid rise of estradiol seen in the late follicular phase (Fig. 59-11).<sup>9</sup>

Ovulation occurs 36 hours after initiation of the LH surge. The corpus luteum develops in the ruptured ovarian follicle. The length of the luteal phase is dictated by the longevity of the corpus luteum. Progesterone release from the corpus luteum is LH dependent. Progesterone slows GnRH drive, which secondarily leads to reduced LH and FSH release by the pituitary. This gonadotropin suppression, along with the suppression of pituitary FSH by high estradiol levels, prevents further follicular development during the luteal phase.

## Dominant Follicle

Selection of the dominant preovulatory or graafian follicle occurs in the mid- to late follicular phase. The dominant follicle must continue to mature while inhibiting the growth of other follicles. FSH induces aromatase within the granulosa cells, resulting in rising estradiol levels and subsequently declining circulating FSH concentrations. The follicle that is best able to produce estradiol from the available androgens and become FSH independent will become the dominant follicle. Follicles that are less able to convert androgens succumb to atresia as FSH levels decline. Thus, the rise in estradiol by the most mature follicle suppresses FSH and starves the other follicles.<sup>10,11</sup> Healthy oocytes are more likely to be found in follicles with the highest number of granulosa cells and estradiol levels and lowest androgen-to-estrogen ratio. Atretic oocytes are more likely to be found in follicles with low granulosa cell number, low estradiol level, and high ratio of androgen to estrogen.<sup>12</sup>

**Figure 59-11 Ovarian follicular development stimulated by the pituitary gonadotropins results in rising estradiol levels, peaking at ovulation.**

The corpus luteum supported by pituitary LH produces progesterone in the luteal phase. (From Berga SL: Menstrual cycle. In Knobil E, Neill JD [eds]: Encyclopedia of Reproduction, Vol. 3. San Diego: Academic Press, 1998, pp 189–194.)

Follicle-stimulating hormone also induces LH receptors on the granulosa cells that activate the same intracellular cyclic adenosine monophosphate pathway as FSH receptors. Women undergoing ovulation induction with FSH stimulation were randomized to subsequently receive FSH, LH, or saline once the lead follicle diameter reached 14 mm. Estradiol levels continued to rise in both the LH- and FSH-treated groups.<sup>13</sup> Thus, FSH-stimulated granulosa cells in the maturing dominant follicle acquire the ability to respond to LH and survive declining FSH concentrations.<sup>10</sup>

The LH receptors acquired by the granulosa cells will also facilitate response to the LH surge. Sustained administration of late follicular estradiol followed by GnRH elicits gonadotropin release in a dose-dependent fashion.<sup>14</sup> At midcycle, the rise in estradiol from the mature dominant follicle is exponential, with peak levels around 300 to 400 pg/mL. This pattern and amount of estradiol elicits a pituitary LH surge. The LH receptors on the granulosa cells then permit the corpus luteum to secrete progesterone during the luteal phase and during early pregnancy.

Rising estradiol levels intrinsic to the follicular phase are important not only for follicular development and ovulation,

but also for preparation for successful fertilization. Estradiol promotes endometrial proliferation and progesterone receptor induction as well as changes of the cervical mucus to a watery consistency to facilitate motile sperm penetration.

### Inhibin, Activin, and Follistatin

Inhibin, activin, and follistatin are peptides synthesized by the granulosa cells; their roles in cycle regulation are beginning to be delineated.<sup>15</sup> Inhibin has two forms, inhibin A and B, that share a common alpha subunit but different beta subunits. Inhibin B predominates in the early follicular phase, falling in the late follicular and luteal phase; inhibin B rises rapidly during the luteal-follicular transition and is found in higher concentration in follicular fluid. Inhibin A rises in the late follicular phase, peaking at the midluteal phase (Fig. 59-12).<sup>16</sup> Inhibin B levels have been suggested to reflect the growth of the follicular cohort, and inhibin A levels to reflect secretion from the dominant follicle.<sup>15</sup> Inhibin acts on the pituitary to inhibit FSH secretion by many mechanisms, including blockade of FSH synthesis and release and decrease in pituitary sensitivity to GnRH.<sup>17</sup> In the follicular phase, FSH induces granulosa cell

**Figure 59-12 Plasma concentrations of inhibin A and B (A), estradiol and progesterone (B), and luteinizing hormone (LH) and follicle-stimulating hormone (FSH) (C) during the menstrual cycle.**  
(Groome NP, Illingworth PJ, O'Brien M, et al: Measurement of dimeric inhibin B throughout the human menstrual cycle. J Clin Endocrinol Metab 1996;81:1401-1405.)

secretion of inhibin. Inhibin feedback to the pituitary decreases FSH secretion. The suppression of the pituitary by inhibin facilitates selection of the dominant follicle, which remains capable of continued steroidogenesis despite declining FSH levels. Inhibin B concentrations are lower in women with diminished ovarian reserve, evident by elevated FSH concentrations. Lower inhibin B concentrations are thought to result from less robust granulosa cells associated with the aging follicle.<sup>18</sup>

Activin combines the two beta subunits of inhibin to create three forms—activin A, AB, and B. Despite similar structure, activin exerts opposing action to inhibin, augmenting FSH action at the level of the ovary and stimulating FSH secretion from the pituitary.

Follistatin suppresses FSH by inhibiting pituitary synthesis and secretion. It decreases activin activity by binding and thereby sequestering it.

In the early follicular phase, FSH induces granulosa cell secretion of inhibin and activin. Activin up-regulates granulosa cell proliferation, increases FSH receptors and aromatization, but inhibits thecal cell production of androgens. Inhibin up-regulates thecal cell androgen production (Fig. 59-13).<sup>19</sup> As the follicular phase progresses, activin enhances LH receptor expression on the granulosa cells, thereby enhancing inhibin production despite declining FSH concentrations.

### Insulin-like Growth Factors

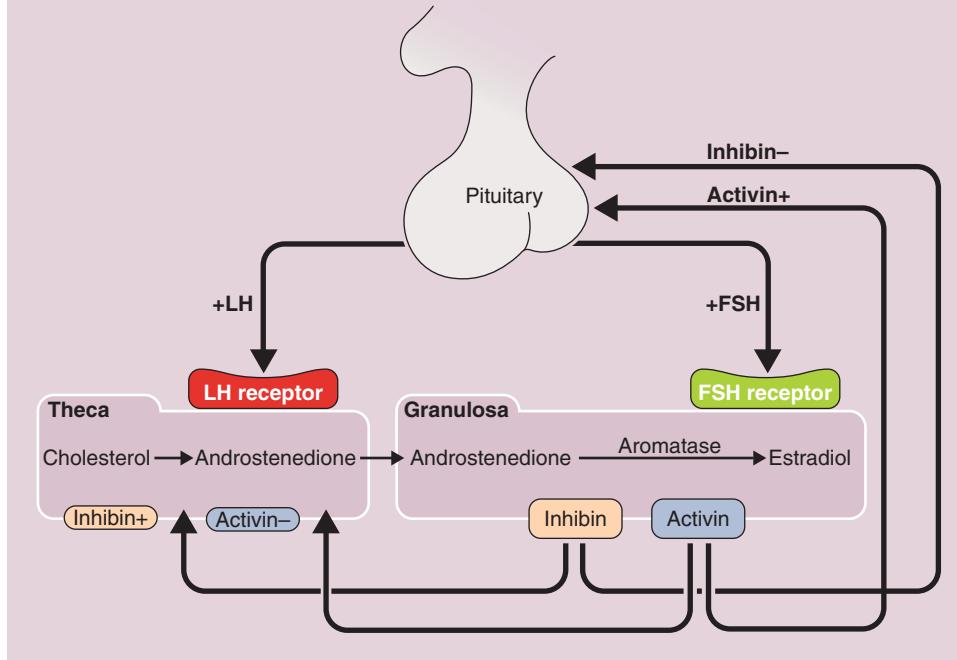

Insulin-like growth factors (IGFs) have received much attention as potential intraovarian gonadotropin modulators that augment FSH action on the granulosa cell.<sup>20</sup> The primary insulin-like growth factor in the ovary is IGF-2, which is synthesized in the theca of small antral follicles and in the granulosa of large dominant follicles.<sup>21</sup> FSH stimulates IGF-2 expression; IGF-2 stimulates steroidogenesis and estradiol secretion. IGF-binding proteins inhibit IGF-2 action. Granulosa cell-derived IGF-binding proteins are modified by FSH in a dose- and time-dependent manner.<sup>22</sup> Androgen-dominant follicles have high inhibitory IGF-binding protein levels with subsequently lower bioavailable IGF and less estradiol production associated with follicular atresia. In estradiol-dominant follicles, IGF-binding proteins are depleted, enhancing IGF availability and estradiol production.<sup>23</sup>

### OVULATION

Ovulation occurs 36 hours after the onset of the LH surge that induces oocyte maturation. Two to three days before ovulation, the dominant follicle expands and estradiol levels rise rapidly. Granulosa cells produce more fluid, thecal vascularity increases, and the follicle reaches 20 mm in diameter before enzymatic digestion of the basal lamina facilitates follicular rupture and oocyte release. The granulosa cells closest to the oocyte, referred to as the *cumulus layer*, remain adherent to the oocyte after the release and are the first layer the inseminating sperm must pass through to initiate binding of the egg. The first meiotic division of the oocyte with extrusion of the first polar body is completed before ovulation. Completion of meiosis requires fertilization, at which time the second polar body is extruded with reduction to the haploid DNA complement.

Sustained exponential estradiol elevation is required to initiate the midcycle gonadotropin surge. The LH surge following increases of estradiol alone is of shorter duration than in natural cycles. The addition of progesterone is required to restore the normal dimension of the surge.<sup>24</sup> Therefore, progesterone in low doses after estradiol priming facilitates the LH surge. Progesterone administered before estradiol or in high doses inhibits the LH surge and subsequent ovulation by suppressing GnRH drive.

### Pituitary and granulosa–theca interactions: inhibin and activin

**Figure 59-13** Inhibin, produced by the granulosa cell, acts locally to up-regulate thecal androgen synthesis and inhibits follicle-stimulating hormone (FSH) secretion. Activin, produced by the granulosa cell, inhibits the production of androgens by the theca and stimulates FSH secretion.

### CLINICAL CORRELATION

- The ability of progesterone (progestin) to inhibit the LH surge and subsequent ovulation, when administered in high doses before peak estrogen, is one mechanism by which emergency contraception preparations decrease risk of unwanted conception when administered prior to the LH surge.<sup>25</sup>
- Follicle rupture and oocyte release by ovarian smooth muscle depends on prostaglandin production to induce enzymatic digestion of the follicular wall. Therefore, nonsteroidal anti-inflammatory drugs should be avoided at midcycle by women attempting conception.

FSH begins to rise after release from estradiol and inhibin suppression, and follicular recruitment resumes. In fertile cycles, the corpus luteum is rescued by hCG made by the developing pregnancy; hCG sustains luteal progesterone production until 8 to 12 weeks of gestation, when the placenta takes over. Progesterone domination of the luteal phase prepares the uterus for pregnancy. Progesterone causes secretory endometrium, suppresses uterine contractions, increases cervical mucus viscosity, induces development of breast tissue, and increases body temperature.

### CLINICAL CORRELATION

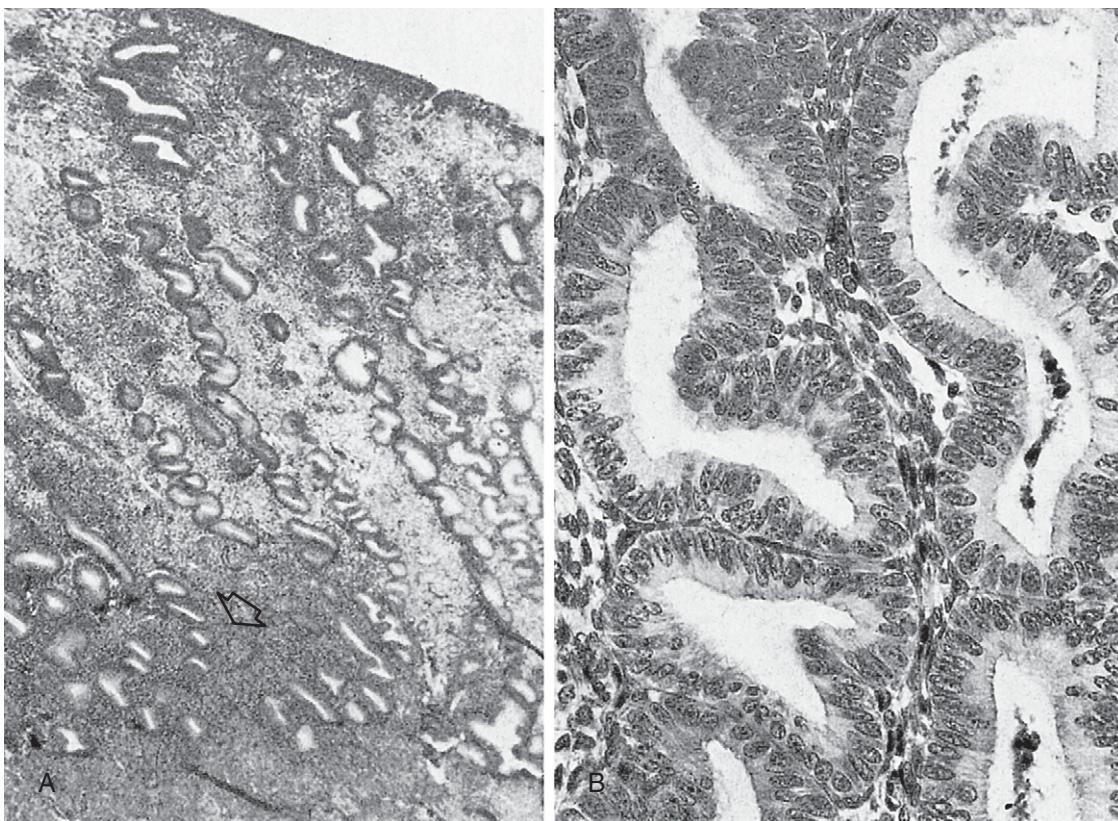

The increase in body temperature secondary to progesterone release after ovulation is the basis for the basal body temperature charting method of tracking ovulation.

### LUTEAL PHASE

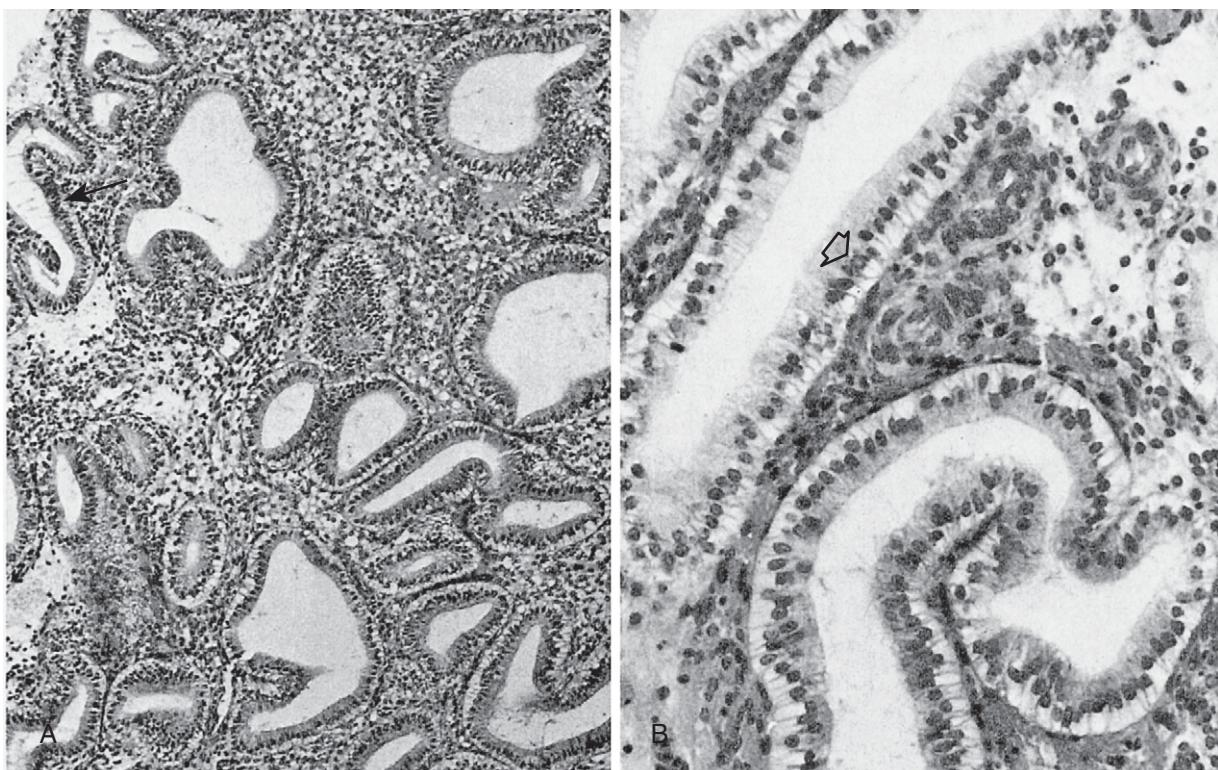

After ovulation, the follicular remnant closes around the antrum. The granulosa, theca, and stromal cells become large and fill with cholesterol, new blood vessels occupy the area, and steroidogenesis begins. The resulting structure is the *corpus luteum*, from the Latin “yellow body,” which produces estradiol, progesterone, and inhibin A in response to LH. Estradiol, progesterone, and inhibin in turn suppress FSH release to prevent follicular development during the luteal phase. The life of the corpus luteum includes 10 days of maximal function followed by 3 to 4 days of regression if pregnancy does not occur. Menses occurs with the drop in progesterone, estradiol, and inhibin that follow the demise of the corpus luteum. In the days preceding menses,

### ENDOMETRIUM

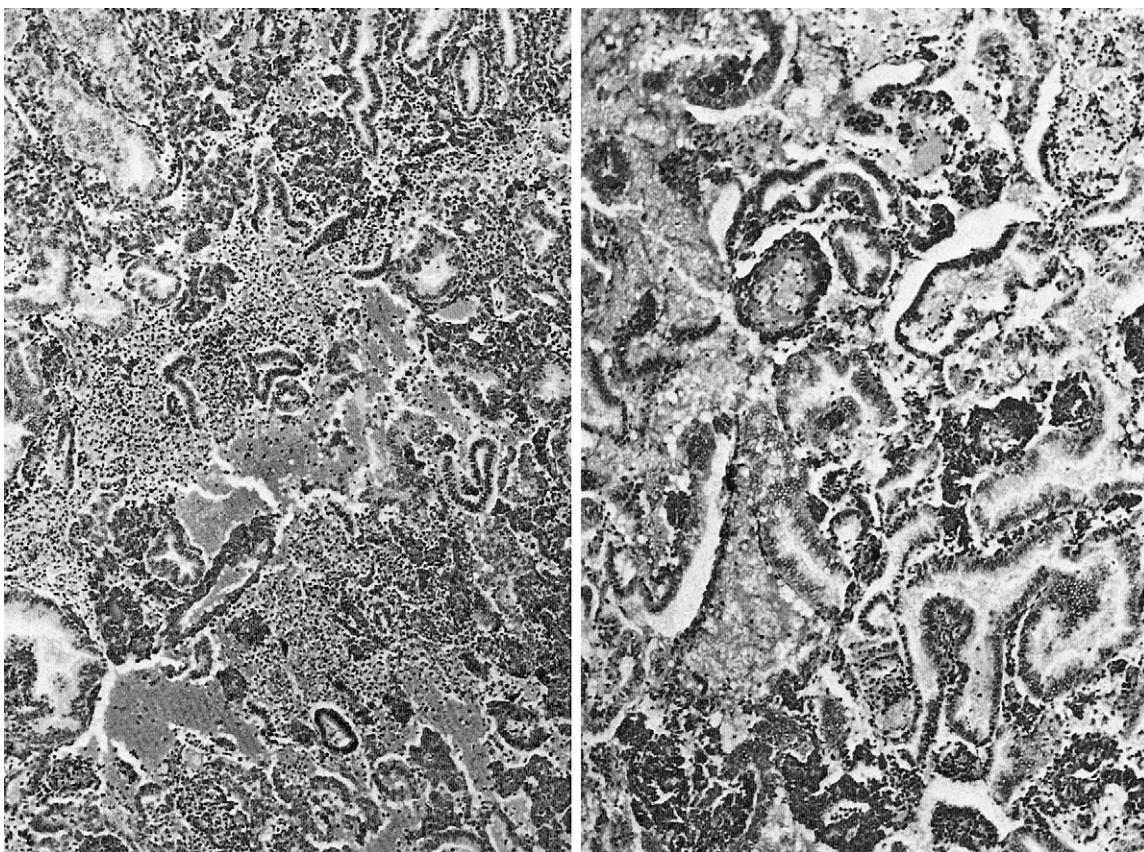

The endometrium proliferates during the estrogen-dominated follicular phase. The endometrial lining develops from 1 mm in thickness early in the follicular phase to 8 to 12 mm at the time of implantation (Fig. 59-14). When progesterone rises in the luteal phase, the endometrium differentiates to become secretory (Fig. 59-15). Progesterone from the corpus luteum prevents the endometrial lining from shedding. Decreases in estradiol, progesterone, and inhibin from the dissolution of the corpus luteum trigger menstruation (Figs. 59-16 and 59-17).

## MENSTRUAL CYCLE VARIATIONS

Within the overall structure of the menstrual cycle there are variations. A withdrawal bleed does not always confirm a preceding ovulation (Fig. 59-18). If the dominant follicle was not of sufficient quality to become FSH independent, ovulation will not occur, but bleeding may result from fluctuations in estradiol levels as the follicle succumbs to atresia. During the anovulatory cycle depicted in Figure 59-18B, a low-amplitude estradiol rise and fall triggers uterine bleeding, but the gonadotropin surge and luteal rise in progesterone characteristic of an ovulatory cycle, as seen in Figure 59-18C, are absent.

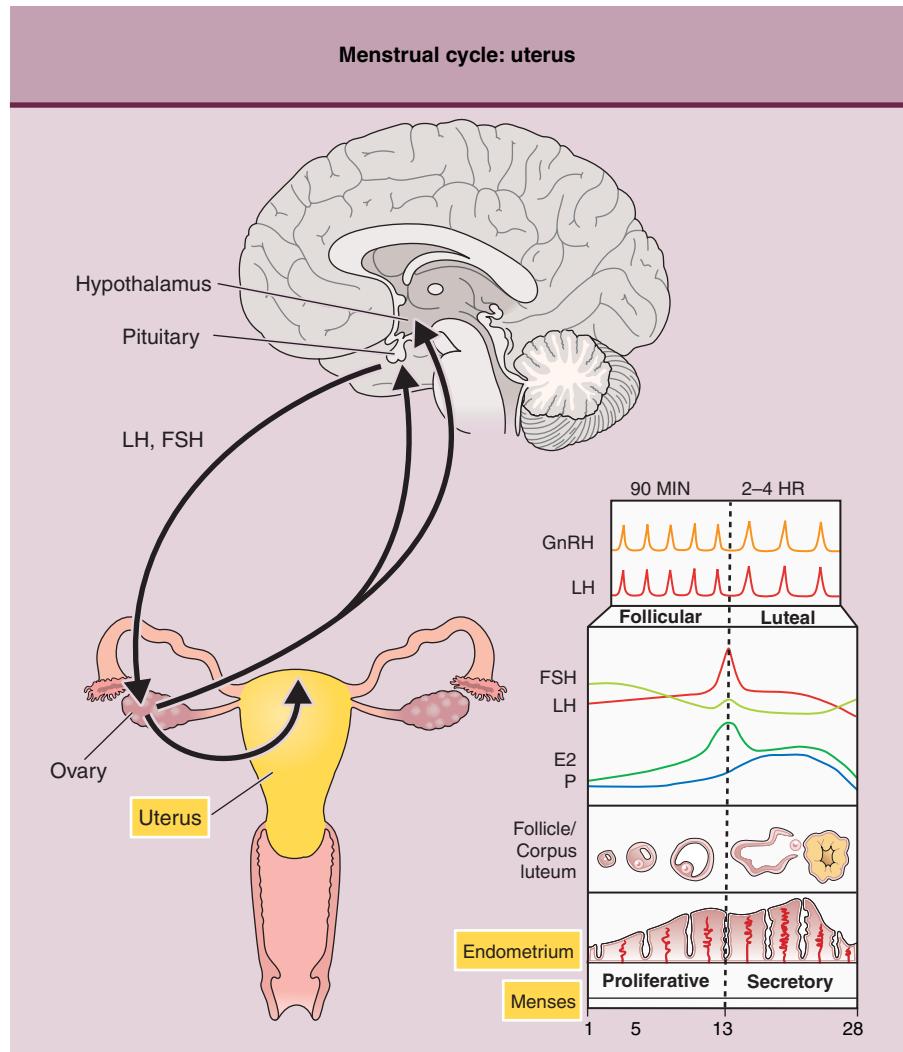

The luteal phase is described as being 14 days in duration; however, poor progesterone production due either to an inadequate LH surge or poor corpus luteal development can result in shorter luteal phases (<10 days) or normal-duration luteal phases with inadequate progesterone production. Either pattern is referred to as a *luteal phase deficiency* or *luteal insufficiency*. During the luteal phase deficiency cycle depicted in Figure 59-18A, the follicular phase is lengthened and the luteal phase progesterone is of lower amplitude and duration than seen in the ovulatory cycle (see Fig. 59-18C).

An inadequate luteal phase can be seen in perimenopausal women due to dysfunction of the follicular apparatus consistent with incipient ovarian failure. Perimenopausal women exhibit a

shortened follicular phase in ovulatory cycles, with periods of anovulation as well as higher estrogen excretion throughout the ovulatory cycles and lower luteal progesterone excretion.<sup>26</sup>

An inadequate luteal phase can also be seen in chronic exercisers; the mechanism is primarily a decrease in GnRH drive. A rigorous study of regularly menstruating women found a higher frequency of luteal phase deficiency and anovulation in recreational women runners compared to sedentary women. Luteal-follicular transition FSH elevation was lower in exercising women with luteal phase defect, potentially leading to the lower early follicular estradiol and luteal phase progesterone excretion. Energy availability was lower in anovulatory cycles.<sup>27</sup> Recreational runners with evidence of luteal phase defect also exhibit evidence of a hypometabolic state, including decreased serum total T<sub>3</sub>, leptin, and insulin.<sup>28</sup> Decreases in LH pulse frequency and increases in LH pulse amplitude are seen during periods of decreased energy availability; this effect is more pronounced in women with shorter luteal phases.<sup>29</sup>

Energy availability has also been linked to likelihood of conception, pregnancy duration, and resumption of menstrual cyclicity postpartum. Studies of Lese horticulturalist women reveal lower salivary progesterone and estradiol levels during weight loss in the preharvest season that results in a seasonal conception pattern. Similar low salivary progesterone is seen in Polish farm women during times of increased agricultural

**Figure 59-17** Endometrium exhibits proliferation during the estrogen-dominant follicular phase and secretory changes during the progesterone-dominated luteal phase. (From Berga SL: Menstrual cycle. In Knobil E, Neill JD [eds]: Encyclopedia of Reproduction, Vol. 3. San Diego: Academic Press, 1998, pp 189–194.)

workload.<sup>30</sup> These less robust menstrual cycles decrease conception rates during times of inadequate energy supply. The independent role of psychogenic variables is difficult to gauge; however, high levels of cortisol, regardless of cause, induce metabolic demands. Thus, psychogenic stress, with or without weight loss, has the potential to disrupt GnRH drive and produce anovulation.<sup>31</sup>

## SUMMARY

Understanding the roles and interactions of the hypothalamus, pituitary, ovary, and uterus in the menstrual cycle facilitates diagnosis-driven treatment of menstrual cycle alterations. Before appreciation of the different causes of menstrual irregularity, patients with menstrual dysfunction were either treated with

oral contraceptives for cycle regulation or clomiphene for fertility enhancement. This approach did not address the underlying cause of the dysfunction or the associated morbidities. Knowledge of the connection between polycystic ovary syndrome (PCOS), hyperinsulinemia, and the metabolic syndrome, discussed in Chapter 62, allows the clinician to more completely treat the disease and assist the patient in initiating lifestyle modifications to prevent cardiac morbidity and improve longevity as well as fertility. Awareness of the hypoestrogenic state resulting from hypothalamic amenorrhea, which is discussed in Chapter 57, allows one to focus therapy on osteoporosis prevention while helping patients initiate lifestyle modifications that treat the underlying energy imbalance.<sup>32</sup> Through knowledge of the menstrual cycle, health care providers can delineate the appropriate diagnosis and tailor treatment to prevent the related negative sequelae and best facilitate fertility.

## KEY POINTS

- Menopause is a natural process, tolerated well by many women, which may be attended by obvious adverse symptomatology (vasomotor symptoms or urogenital atrophy) or insidious disease processes (accelerated osteoporosis and cardiovascular disease) that, when revealed by adverse events, have the potential to significantly reduce quality of life.
- Counseling is essential to allow women to arrive at correct decisions about the lifestyle changes and medical options that will promote well-being and delay onset of disease.
- Hormone replacement therapy remains a safe and effective treatment for vasomotor symptoms and urogenital atrophy and will maintain bone while being used systemically.
- Available evidence suggests little if any increased risk for breast cancer with hormone replacement therapy (either estrogen alone or combined estrogen-progestin) for less than 5 years' duration. A small increase in the risk of breast cancer is seen with longer use of hormone therapy; this risk is comparable to the risk of breast cancer associated with several other lifestyle variables, such as delayed parenting, lack of breastfeeding, postmenopausal obesity, excessive alcohol ingestion, and lack of exercise.
- Hormone replacement therapy has not been shown to delay the onset or slow the progression of cardiovascular disease, stroke, or dementia when started several to many years after the menopause (the effect of early initiation of hormone therapy at the time of menopause on these conditions remains controversial).
- Women with spontaneous or induced premature menopause are at risk for premature cardiovascular disease and osteoporosis. Whether hormone replacement therapy in such women will avoid the increased cardiovascular disease risk is unknown, but it will delay the development of osteoporosis.

The “baby boomers” have finally reached the age of menopause. Estimates suggested that in the late 20th century one female baby boomer was entering menopause every 10 seconds, resulting in a postmenopausal population in excess of 50 million when the world celebrated the turn of the century (Fig. 60-1).

Now, more than ever, the health concerns of the aging population in developed countries focus on health promotion, disease prevention, and maintenance of a high quality of life. Health care providers to menopausal women will be called on to counsel the worried well, to determine who is truly at risk for disease and to suggest appropriate preventive strategies for these

women, to offer effective interventions for those with established disease(s), and to provide care that is both compassionate and comprehensive to an increasingly dependent population in the final years of their lives.

## EPIDEMIOLOGY, RISK FACTORS, AND PATHOGENESIS

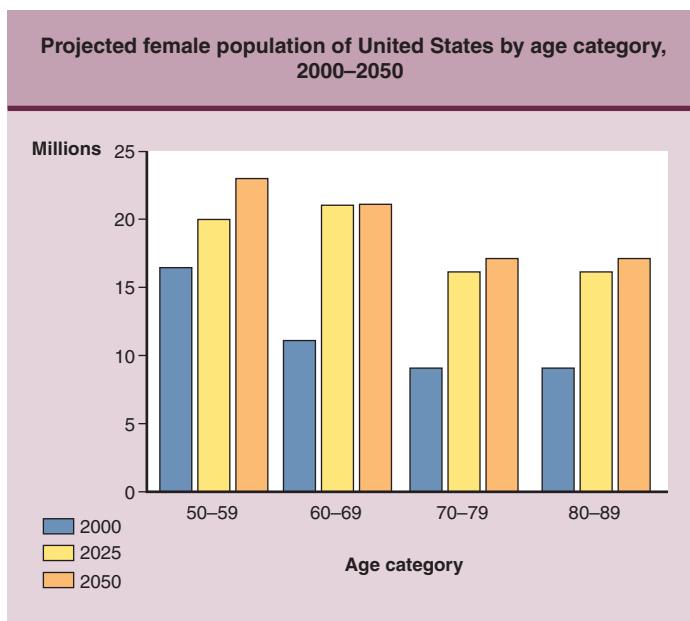

### Physiologic Changes of Menopause

During the reproductive years the main source of circulating estrogen is the developing ovarian follicle, in which the ovarian androgens, androstenedione and testosterone from the theca cell layer, are aromatized by granulosa cells within the follicle into estrone and estradiol, respectively. Inhibin B, also a product of the granulosa cells, feeds back to suppress follicle-stimulating hormone (FSH) released from the pituitary.

With advancing age the number of primordial follicles within the ovary is progressively depleted, resulting in reduced negative feedback by inhibin B, elevated FSH, and increased estradiol production from the remaining follicles. Eventually antral follicle count is sufficiently reduced such that even the elevated FSH cannot maintain regular follicular development with release of estrogen into the circulation. Typically this process is intermittent in the perimenopausal transition, resulting in periods of amenorrhea and typical menopausal vasomotor symptoms interspersed with episodes of menstrual cyclicity during which symptoms abate. In the postmenopausal years the elevated luteinizing hormone drives the interstitial cells of the ovary to produce androgens. These androgenic steroids may have a positive effect on energy and libido in the postmenopausal woman. In the periphery, particularly in fat cells, ovarian and adrenal androstenedione can be converted to the weak estrogen, estrone, which may, in turn, ameliorate estrogen deficiency symptoms to some extent in obese women.

### Cultural Differences with the Experience of Menopause

In cultures where high value is placed on youth, many women see menopause as one further sign of aging—a sign that is attended by distressing symptoms that foreshadow age-related deterioration in health and quality of life. In cultures where elders are revered, menopause is often seen as a sign of maturity and experience—the elderly woman or “crone” being a source of wisdom and guidance in the community. Although there has been speculation that these cultural differences may exert a strong influence on the perception or expression of menopausal symptoms, cross-cultural studies confirm the presence of similar menopausal symptoms in women from different ethnic and cultural backgrounds.

## CLINICAL FEATURES

### Overview

The onset of menopause heralds a time of diminished estrogen exposure, which may have both acute and chronic effects on health and quality of life. However, it is important to remember that estrogen deficiency cannot be blamed for all the ills occurring in the menopausal woman. Menopause typically occurs at a time in life when women are dealing with teenage children and/or ailing parents. In addition, work-related transitions, marital discord, and/or ill health of a life partner are all common reasons for mood disruption at the time of menopause.

Estrogen deficiency symptoms may be categorized as acute (vasomotor flushes, night sweats, palpitations, headache, irritability, or mood swings) or chronic (urogenital atrophy with vaginal dryness, dyspareunia, vaginal itching or burning, urinary frequency, urgency, or nocturia). Other chronic degenerative diseases of advancing age may have clear links to estrogen deficiency (i.e., osteoporosis) or may be suggested by epidemiologic evidence (i.e., cardiovascular disease, cognitive impairment, impaired vision due to macular degeneration).

### Diagnosis

Amenorrhea by itself will not establish a diagnosis of menopause nor will the presence of vasomotor flushes. Although vasomotor flushes have long been considered the hallmark of the menopausal transition, flushes that appear identical from a physiological perspective have been documented in the luteal and menstrual phases of the cycle in most women reporting premenstrual syndrome.<sup>1</sup> FSH measurements fluctuate during the perimenopausal transition so that a single high FSH, though suggestive, is not diagnostic of menopause. Researchers are studying whether the fall of antimüllerian hormone, which

reflects the pool of primary, secondary, and antral follicles, may afford a more predictive measure of incipient menopause than measures of FSH, inhibin B, or ultrasound-determined antral follicle count, each of which correlates only with the number of antral follicles.

At present menopause is a retrospective diagnosis that can be made with reasonable certainty in the presence of elevated FSH or vasomotor symptoms in a woman after 12 months of amenorrhea. Typically menopause occurs around the mean age of 51.5 years, with a wide range from age 40 to 58. A mother's age at menopause shows a modest correlation to her daughter's age at menopause, suggesting genetic determinants, although cigarette smoking and prior hysterectomy can advance the normal age when ovarian estrogen production stops by 2 to 5 years.

### Early Estrogen Deficiency Symptoms

#### Menopausal Hot Flashes

The majority of women report hot flashes developing with increasing severity in the menopausal transition (a period of intermittent ovarian activity lasting on average 5 years before menopause) and becoming incessant in the years following the last menstrual period. These hot flashes have been linked to estrogen withdrawal that results initially from intermittent ovarian activity and ultimately from the complete loss of ovarian follicular estrogen production.

Typically these hot flashes (or flushes) are associated with an increased pulse rate, a rise in skin temperature, peripheral vaso-dilatation and sweating, and a gradual fall in core temperature. For some this means nothing more than an occasional transient sensation of warmth; however, others experience hourly waves of heat, drenching sweats, and increased heart rate. Cold chills by themselves or following a "heat wave" are reported by some women. In addition, sleep may be disrupted by night sweats several times a night, resulting in fatigue and irritability. Frequent hot flashes may be disabling, with attendant social, psychological, and economic consequences. Anecdotal reports suggest that alcohol, caffeine, and spicy foods may trigger hot flashes; women often report that hot flashes are less severe if the ambient temperature is kept cool.

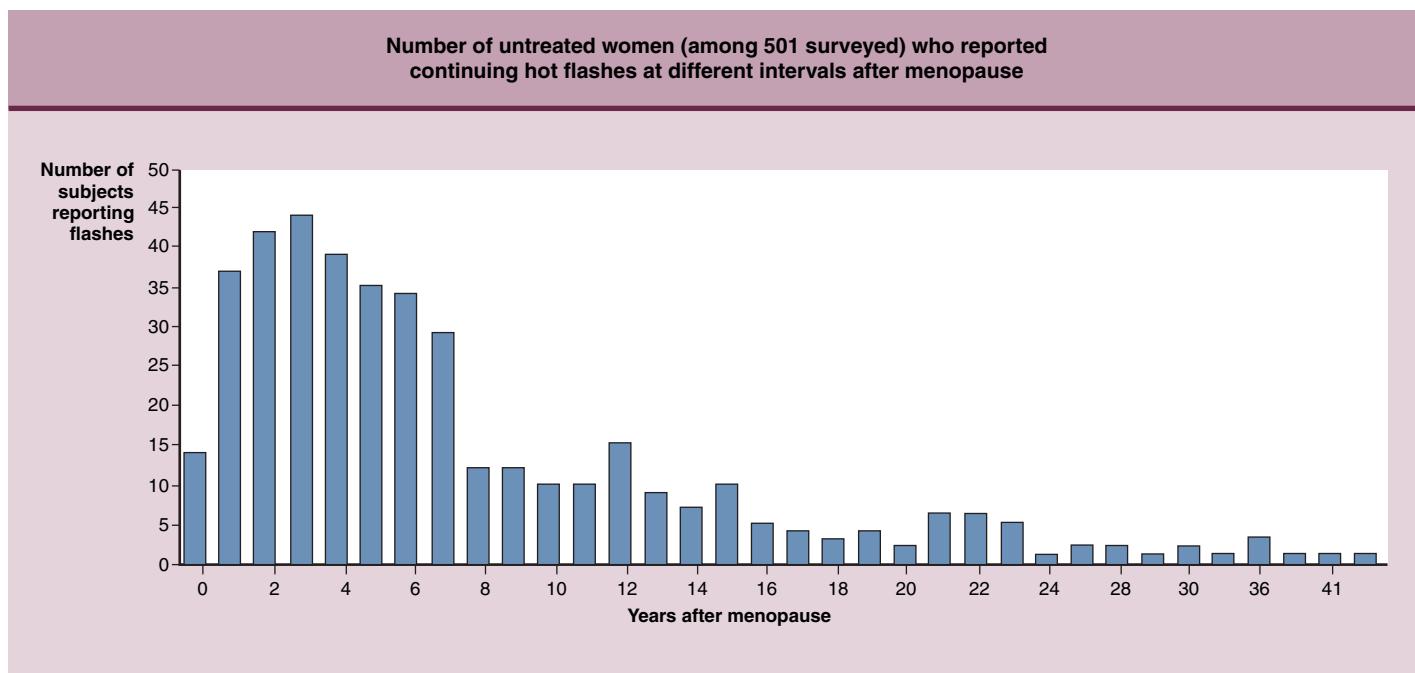

Observational studies suggest that as many as 75% of women will experience hot flashes after menopause. Left untreated, most women will have spontaneous cessation of hot flashes within 5 years, although some women continue to experience distressing symptoms for 30 years or more (Fig. 60-2). Hot flashes are the primary reason approximately 50% of menopausal women seek medical treatment.

#### Sleep Disturbance

Sleep disturbance is frequently reported in the menopausal years; although many women perceive that sleep is disrupted by the occurrence of night sweats, sleep laboratory data do not confirm a tight correlation between vasomotor symptoms and recorded sleep disruption.<sup>2</sup> In any event it is clear that frequent nighttime awakenings may contribute to daytime fatigue, irritability, and mood change in some postmenopausal women.

#### Changes in Mood, Cognition, and Memory

Abrupt loss of estrogen has been associated with development of depression in some circumstances, and the clinical response

**Figure 60-2 Number of untreated women (among 501 surveyed) who reported continuing hot flashes at different intervals after menopause.** (Reproduced with permission from Kronenberg F: Hot flashes: epidemiology and physiology. Ann NY Acad Sci 1990;592:52-86.)

to estrogen in perimenopausal depression supports a causative relationship.<sup>3</sup> Several lines of investigation suggest that estrogen also has important beneficial effects on attention, oral reading, and short-term memory.<sup>4</sup> Some, but not all, studies have suggested a role for estrogen loss in accelerating the age-related decline in memory.

### Delayed Estrogen Deficiency Changes

#### Urogenital Atrophy

Loss of estrogen in the menopausal years results in gradual thinning of the vaginal epithelium and a decrease in vaginal secretions. Manifestations of this may include vaginal irritation, itching, or burning and frictional dyspareunia. A variety of senescent bladder symptoms, including urinary frequency, urgency, and recurrent urinary infections, have been linked to hypoestrogenism (Fig. 60-3).

Pelvic organ prolapse is common in elderly postmenopausal women; however, the role of estrogen deprivation remains under study. Although hormone therapy (HT) use does not appear to correlate with the incidence of prolapse, certain estrogen receptor modulators have been associated with either increased or decreased rates of genital prolapse.

#### Skin Aging

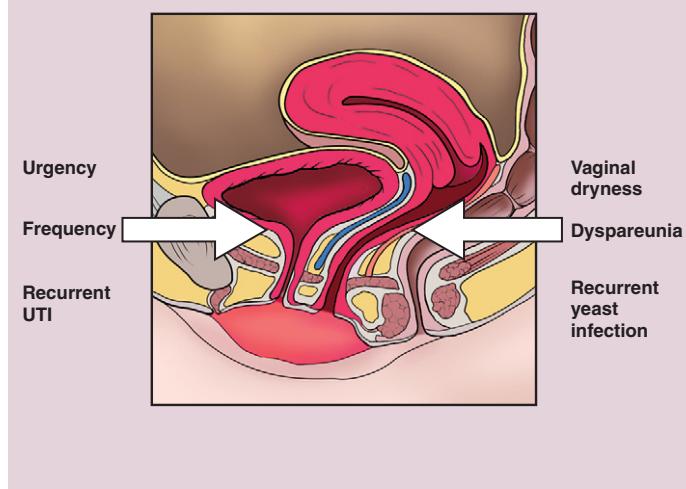

Several investigations have documented increased collagen content and skin thickness in estrogen users compared to nonusers, suggesting a role for estrogen in the maintenance of skin integrity and health.

#### Eye Diseases

Observational studies in humans seem to indicate that estrogen loss at menopause is one factor contributing to lens opacities

(cataracts) associated with aging. Macular degeneration, the major cause of bilateral central retinal blindness in the elderly, also appears to occur with greater frequency in women who have not used estrogen replacement during the menopausal years. Maturational changes are induced in corneal cells by estrogen;

**Both bladder and vagina may be sites of symptoms related to prolonged hypoestrogenic states**

**Figure 60-3 Both bladder and vagina may be sites of symptoms related to prolonged hypoestrogenic states.**

## Reproductive Endocrinology and Infertility

this may account for the observed increase in complaints of “dry eye” syndrome in women on hormone therapy.

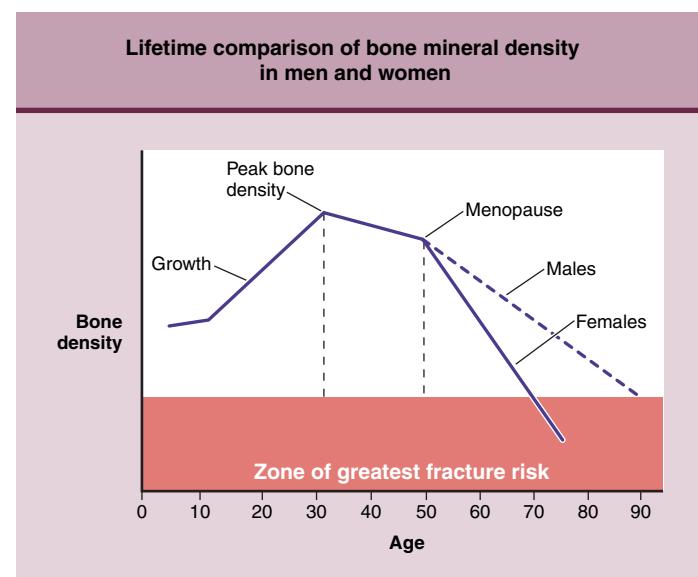

**Osteoporosis**

Osteoporosis is characterized by low bone mass, increased skeletal fragility, and susceptibility to fractures. Osteoporotic spinal compression fractures (affecting 20% of white women over age 60), fractures of the forearm (10 times more common in menopausal women than in their male counterparts), and hip fractures (increasing in frequency from 0.3 per 1000 at age 45 to 20 per 1000 at age 85) are major causes of pain, disability, and/or death in the postmenopausal woman. The cost to manage osteoporotic fractures and to provide care for women who have sustained them was estimated at \$14 billion in the United States in 1995; this cost is expected to soar exponentially as the older population grows in the next few decades.

Bone mass, measured as bone mineral density (BMD), has been known for some time to be inversely related to the risk for fracture. More recently bone quality (specifically the micro-architecture of bone) is being recognized as an equally important determinant of risk for fragility fractures. Of course most fragility fractures result from falls, so that BMD must be considered in the context of a person’s age and propensity to fall when trying to determine overall risk for osteoporotic fracture.

Peak bone mass in women is reached around age 30, and it is from this level that losses of bone reduce overall BMD. Accordingly, peak bone mass is an important determinant of subsequent fracture risk. A variety of factors are known to contribute to the risk of fragility fractures in postmenopausal women (Table 60-1).

An age-related decline in bone mass occurs until, in women, estrogen deprivation induces an accelerated rate of decline (Fig. 60-4). Estrogen deficiency increases bone turnover; biochemical markers of bone resorption increase by 90% in the years just after menopause while markers of bone formation increase by only 45%.<sup>5</sup> Premature loss of ovarian function (due to premature ovarian failure, oophorectomy, or medical ovarian suppression with gonadotropin-releasing hormone agonists) produces the same accelerated rate of bone loss. This accelerated loss of bone lasts from 4 to 8 years and is then followed by a return to the more gradual age-related decline once again (see Fig. 60-4). The rapid loss of bone in the early menopausal period means that postmenopausal women move more rapidly toward

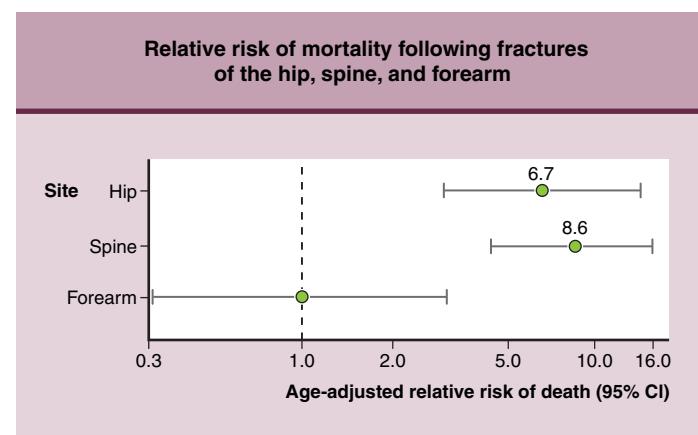

**Figure 60-4** Lifetime comparison of bone mineral density in men and women.

the fracture threshold (the level of BMD at which fracture risk increases). Although much attention has been focused on hip fractures as a cause of morbidity and mortality, recent evidence shows that the much more prevalent vertebral fractures can have a major negative influence on quality of life, morbidity, and mortality (Fig. 60-5).<sup>6</sup>

**Cardiovascular Disease**

Due, in part, to successful breast cancer prevention campaigns, many women still believe that breast cancer is the leading cause of death in women. The number of deaths from breast cancer relative to deaths from other (mostly cardiovascular causes) is dramatically displayed in Figure 60-6. Heart disease is the leading cause of death in women, accounting for some 500,000 deaths annually in North America.

**Figure 60-5** Relative risk of mortality following fractures of the hip, spine, and forearm. (Reproduced with permission from Cauley JA, Thompson DE, Ensrud KC, et al: Risk of mortality following clinical fractures. *Osteoporosis Int* 2000;11:556–561.)

**Table 60-1**  
Risk Factors for Osteoporosis-Related Fractures

Nonmodifiable	Modifiable
Female sex	Low bone mineral density
Advanced age	Low body weight
White race	Cigarette smoking
History of fracture as adult	Low calcium intake
Family history of osteoporosis	Vitamin D deficiency
Premature loss of ovarian function	Sedentary lifestyle
	Use of certain medications (e.g., glucocorticoids, heparin)
	Current estrogen deficiency
	Increased risk for falls

<b>Chance of development and death from breast cancer, compared to other causes of death, for women per decade</b>			
<b>Age</b>	<b>Cases of Breast Cancer /1000</b>	<b>Breast Cancer deaths /1000</b>	<b>All causes death /1000</b>
40	15	2	21
50	28	5	55
60	37	7	126
70	43	9	309
80	35	11	670

**Figure 60-6 Chances of development of breast cancer and death from breast cancer, compared to other causes of death, for women per decade.** (Reproduced by permission from Fletcher SW, Elmore JG: Mammographic screening for breast cancer. *New Engl J Med* 2003;348:1672–1680.)

More women than men die from this disease, and the gap continues to widen, with approximately \$30 million spent annually in the United States for treatment of heart disease in women. The incidence of cardiovascular diseases increases with advancing age, and while there is little doubt that these complications are an inevitable consequence of aging there is biologic and epidemiologic evidence to suggest that these conditions are accelerated by loss of estrogen.

Menopause is marked by an increase in total cholesterol, low-density lipoprotein cholesterol, and lipoprotein(a), all known risk factors for cardiovascular disease, and by a concomitant reduction in high-density lipoprotein cholesterol, a known cardioprotective factor. Estrogen-dependent genomic and nongenomic mechanisms that favorably modulate endothelial function and vascular tone become less active, potentially contributing to increased vascular resistance and hypertension, the incidence of which rises sharply in the early postmenopausal years. Postmenopausal women tend to gain weight, with a shift in distribution from gynecoid (peripheral) to android (central), which also is an established marker for cardiovascular disease. Android fat distribution may exert this effect by leading to increased insulin resistance, which is known to increase progressively after menopause. Hemostatic factors are also altered after menopause, with increased levels of procoagulant factor VII, fibrinogen, and plasminogen activator inhibitor-1.

Numerous observational studies have reported higher rates of cardiovascular disease in women with premature hypoestrogenism compared to those whose ovaries function normally until the usual age of menopause.<sup>7</sup>

## COUNSELING AND INTERVENTIONS FOR MENOPAUSAL WOMEN

### Therapy for Vasomotor Symptoms

Women who experience distressing hot flashes should initially be advised to avoid situations (hot environments) and triggers

(hot drinks, spicy foods) that provoke these symptoms whenever possible. Although exercise has been suggested as a means to reduce the frequency and severity of hot flashes, randomized clinical trial data indicates that the effectiveness of this approach is limited.<sup>8</sup> In contrast there is unambiguous clinical trial data demonstrating that systemic estrogen or estrogen-progestin therapy can dramatically reduce both the frequency and severity of flashes—an effect that can be seen at a range of doses by 4 weeks.<sup>9</sup> Progestin alone given in adequate dosage can also alleviate hot flashes.

Several nonhormonal agents have been reported to reduce hot flashes; these include Bellergal (a combination of phenobarbital, ergotamine, and belladonna), clonidine, vitamin E, and soy supplementation, but prospective, randomized clinical trials have demonstrated that these agents are only moderately more effective than placebo and may be associated with significant toxicity. Selective serotonin reuptake inhibitors have been shown to afford modest benefit for hot flashes in women trying to avoid estrogen (such as breast cancer survivors). Gabapentin has been used with some success for women with hot flashes who wish to avoid hormone exposure. This medication is very sedating, and its long-term safety in this situation has not been established.

In recent years aggressive marketing of “natural” or “nonhormonal” remedies for menopausal symptoms has led to widespread use of these compounds. Most of the initial reports on effectiveness of these agents were limited to uncontrolled trials in patients with mild symptoms. As more rigorous comparative trials have been performed, it is clear that few of these agents have significant benefits for vasomotor symptoms<sup>10,11</sup> and that many may have significant adverse interactions with other medications, particularly around the time of surgery.<sup>12</sup>

Phytoestrogens are nonsteroidal compounds derived from plants that are structurally similar to estradiol. They exhibit both estrogenic and antiestrogenic activity. The main classes of phytoestrogens are isoflavones, lignans, and coumestans. Isoflavones, which include genistein and daidzein, are found in soybeans, soy products, lentils, chickpeas, and red clover. Genistein and daidzein are believed to be responsible for the estrogen-like effects of soy. Lignans, which include enterodiol and enterolactone, are found in many fruits, vegetables, and cereals. Coumestans can be isolated in high concentrations from bean sprouts and fodder crops, such as alfalfa.

Mirroring the conclusion of the North American Menopause Society consensus panel,<sup>11</sup> a later meta-analysis of 22 randomized, controlled trials concluded that neither whole soy products nor isoflavone extracts were better than placebo at improving hot flush frequency or severity.<sup>13</sup>

### Sleep Disturbance

Research has suggested that the same hypothalamic trigger that incites the hot flush also triggers awakening. Not surprisingly, estrogen treatment has been shown to improve sleep and reduce daytime fatigue and irritability in symptomatic postmenopausal women. Estrogen therapy shortens the time between lights out and sleep onset (sleep latency), improves the quality of sleep by increasing the amount of rapid eye movement sleep and in some women may even improve sleep-disordered breathing such as sleep apnea.

### Vaginal Atrophic Symptoms and Urinary Symptoms

Estrogen therapy, whether systemic or local (intravaginal), has been shown to promptly relieve vaginal atrophy and associated symptoms of itching, burning, and frictional dyspareunia.<sup>14</sup> It is important to differentiate vulvar disease (lichen sclerosis) from vaginal atrophic symptoms because the former generally responds well to topical application of high-potency corticosteroids but not to topical estrogen. Estrogen replacement has been shown to improve tissue elasticity, to maintain urethral mucosal integrity, and to increase alpha-adrenergic sensitivity—all effects that, in theory, might reduce urinary incontinence. A meta-analysis found that estrogen alone afforded some benefit for urge incontinence.<sup>15</sup> Nevertheless, controlled trials in women with stress incontinence and urge incontinence have not shown improvement after HT.<sup>16</sup> Estrogen replacement is frequently recommended before surgery for genuine stress incontinence to improve blood flow, tissue quality, and healing.

### Sexual Function

Estrogen is required for normal blood flow to the vulva and vagina, to thicken and moisten the vaginal epithelium, and to make pelvic tissues resilient for comfortable intercourse. Estrogen may influence nerve transmission and sensory perception as well as promoting the activity of nitric oxide synthase—an enzyme responsible for mediating labial and clitoral engorgement.<sup>17</sup> Estrogen seems to have little direct impact on sexual arousal or sexual frequency—rather this function is subserved by testosterone from the ovaries and adrenal glands. Bioavailable testosterone, derived from free- and albumin-bound testosterone in circulation, seems to play an important role in maintaining a sense of energy and vitality and is the biologic component most responsible for female sexual interest and motivation.

Observational studies have demonstrated decreases in sexual responsiveness, libido, and sexual frequency along with increased vaginal dyspareunia and partner sexual problems in women around the time of menopause. Health and interpersonal factors appear to be as important as the hormonal changes of menopause on many of these problems. Many perimenopausal women are using selective serotonin reuptake inhibitors for depression, and many of these drugs are known to delay or inhibit orgasm. When diminished libido is the primary concern and factors such as depression, ill health of the woman or her partner, pelvic pain, and use of medications known to inhibit sexual function have been ruled out, consideration should be given to hormonal explanations. Total and free testosterone levels decline with age in premenopausal women such that women in their forties have half of the free testosterone of women in their twenties. Levels of testosterone (total and free) remain relatively stable into menopause but may show a further decline as adrenal function diminishes with advancing age. When hormonal therapies are being considered for the menopausal woman with diminished libido, adequate estrogenization of the vagina should be ensured before using supplemental androgens.<sup>18</sup> Topical moisturizers alone may be sufficient to relieve vaginal dryness in some women; however, local intravaginal hormone replacement (or systemic therapy if this is indicated for other reasons) is also highly effective for relief of vaginal dryness, itching, and dyspareunia. Transdermal estrogen replacement may be preferable when systemic hormone therapy is indicated because this results in

less liver production of sex-hormone-binding globulin and less reduction of bioavailable testosterone. Placebo-controlled trials have confirmed that in surgically menopausal women in whom ovarian androgen production has been lost and in premenopausal women with ovaries intact but complaints of diminished libido, androgen replacement was associated with greater sexual frequency, pleasure/orgasm, and feelings of well-being than was use of a placebo.

### Osteoporosis

Ideally strategies to reduce the numbers of osteoporotic fractures in postmenopausal women should be started early in life and maintained. These include such lifestyle initiatives as participation in a regular program of exercise, avoidance of prolonged hypothalamic amenorrhea (due to eating disorders, excessive exercise, or medications that suppress estrogen production), ingestion of adequate amounts of calcium and vitamin D, and avoidance of cigarette smoking and excessive ingestion of alcohol. When women reach menopause they should be encouraged to continue a regular program of exercise because this has been shown to reduce bone loss somewhat while improving muscle strength and balance, which are equally critical to the prevention of fractures. Women should consider supplements of calcium and vitamin D if they are not getting the daily equivalent of 1000 mg calcium and 400 to 800 IU vitamin D up to age 65 with 1500 mg calcium and 800 IU vitamin D per day thereafter. Most studies have shown that calcium and vitamin D alone have little impact on the accelerated bone loss in the early postmenopausal years, although they may retard the more gradual age-related bone loss that occurs in the later postmenopausal years.<sup>19</sup> Smoking cessation should be encouraged and assistance provided with counseling and substitution therapy as necessary.

If history reveals that the postmenopausal woman may be at risk for osteoporosis because she was exposed to adverse life-style variables or if she has other risk factors (see Table 60-1), she should be considered for BMD assessment to predict fracture risk and to chart an appropriate course of therapy to halt bone loss and prevent future fractures. Assessment of bone microarchitecture at this time requires bone biopsy, which is not practical in a clinical setting. Biochemical markers of bone turnover, while valuable in clinical research, are not presently recommended for routine assessment of women at risk for osteoporosis.

Although a variety of techniques for determination of bone mass have been employed (dual x-ray absorptiometry, quantitative computed tomography [central or peripheral], quantitative ultrasonometry, and radiographic absorptiometry) dual x-ray absorptiometry, measured at the hip, remains the single strongest predictor of fractures at all other sites. The World Health Organization (WHO) has established diagnostic criteria to assist with the interpretation of BMD readings taken at the hip. The BMD measurements are given as a T-score (which refers to the number of standard deviations from the young adult mean BMD; Table 60-2). When osteoporosis is identified, certain laboratory tests such as complete blood count, serum creatinine (to exclude renal disease), calcium (to exclude hyperparathyroidism), phosphate, alkaline phosphatase, thyroid function, and protein electrophoresis in women over age 60 may help to exclude secondary causes.

Table 60-2

World Health Organization Diagnostic Categories for Osteoporosis in Postmenopausal Women

Category	Criteria
Normal	T-score above -1
Osteopenia	T-score between -1 and -2.5
Osteoporosis	T-score at or below -2.5

Table 60-3

Strategies to "Fall Proof" Living Areas for the Elderly

- Ensure adequate lighting
- Suggest sensible footwear with soles that ensure traction
- Obtain orthopedic supports if foot problems contribute to instability
- Avoid throw rugs and loose electrical cords
- Install railings along walkways and steps
- Add white tape to highlight edges of any steps
- Wear appropriate outer footwear, especially in wet or icy conditions
- Provide care worker assistance and appropriate supports (cane or walker) as necessary

The risk for fragility fractures depends not only on BMD and bone microarchitecture, but also on the age of the woman and her propensity to fall.<sup>20</sup> Women with alcoholism, those who use certain medications (such as sedatives); those who are frail, of advanced age; or with slow gait, foot problems, or inappropriate footwear; those with impaired cognition and balance or bad eyesight; and those with neurologic disease or past stroke are at increased risk for falls and may benefit from "fall proofing" of their homes (Table 60-3).

#### Hormone Therapy

The efficacy of estrogen replacement therapy in preventing menopausal bone loss and osteoporotic fractures has been well documented in both retrospective and prospective studies (Figs. 60-7 and 60-8). Bone loss in women who continue HT is rare; women who use HT for control of vasomotor symptoms early in menopause can usually expect protection from the accelerated bone loss that typically occurs at this time. BMD

declines at a modest pace after discontinuation of HT<sup>21</sup>; on average, 3 years after cessation of HT mean vertebral BMD remains significantly higher than at baseline. Most studies suggest, however, that for HT to be effective in reducing osteoporotic fractures it needs to be taken for at least 10 years after menopause. Estrogen therapy is effective in reducing bone loss even if given in lower than standard doses or if started many years after menopause, although, ideally, therapy should commence when hypoestrogenism first appears. Women who do not use HT at menopause or who stop HT after symptoms subside need to be particularly vigilant about monitoring BMD at intervals of 1 to 2 years to detect evidence of osteopenia and to take appropriate steps with alternative therapies (such as selective estrogen receptor modulators [SERMs], bisphosphonates, or calcitonin) to retard this process before the risk of osteoporotic fractures rises further.

Hazard ratios (95% CIs) for outcomes in the Women's Health Initiative randomized clinical trial comparing continuous combined estrogen/progestin to placebo

### Selective Estrogen Receptor Modulators

Selective estrogen receptor modulators exert selective agonist and antagonist effects on various estrogen target tissues. In postmenopausal women with osteoporosis raloxifene decreases bone resorption marked by a decrease in markers of bone turnover (by 30% to 40%) after 1 year and an increased BMD by 2% to 3% after 3 years. The 50% decrease in vertebral fractures in women using raloxifene is comparable to the benefit seen with other agents such as bisphosphonates, which increase BMD by as much as 9%, suggesting that at least part of the benefit of raloxifene is through its modulation of bone microarchitecture.<sup>22</sup> Studies to date have demonstrated that unlike unopposed estrogen therapy raloxifene does not cause uterine bleeding and is not associated with any increase in endometrial cancer. In those studies raloxifene users had a 76% decrease in estrogen receptor-positive breast cancers. Like hormone therapy raloxifene has been associated with a slight increase in venous thromboembolism. Although raloxifene has favorable effects on markers of cardiovascular disease in experimental studies and has been shown to reduce cardiovascular risk in women at highest risk, its role as an agent for primary cardioprotection remains under investigation.

### Bisphosphonates

Bisphosphonates bind to mineralized bone surfaces and inhibit osteoclast activity that would normally remove bone during the bone remodeling process—hence their designation as *anti-resorptive agents*.

Etidronate, a non-nitrogen-containing bisphosphonate given cyclically, has been shown to reduce both vertebral and hip fractures. The major drawback with this agent is its tendency for poor absorption and gastrointestinal irritation. Alendronate and risedronate are nitrogen-containing bisphosphonates that are 1000 and 3000 times more potent, respectively, than etidronate.

When given continuously in low daily doses or in a slightly larger once-weekly dose, they have proven highly effective for prevention of bone loss in postmenopausal women and less irritating to the gastrointestinal tract.

### Calcitonin

Calcitonin, available as a nasal spray, is an effective therapy to prevent further vertebral compression fractures in those with osteoporosis while suppressing the back pain often associated with this complication. Its side effect profile is favorable, with some women reporting rhinitis, flushing, or nasal dryness.

### Parathyroid Hormone

Teriparatide is another addition to the therapeutic armamentarium for management of severe osteoporosis. This synthetic parathyroid hormone is indicated for treatment of severe osteoporosis that has failed to respond to conventional therapies. Initial studies have shown striking increases in BMD of as much as 10% by 18 months of treatment and a concomitant 40% reduction in subsequent fracture risk.

### Cardiovascular Disease

The mainstay for cardiovascular disease prevention remains a lifelong pattern of healthy living, incorporating a balanced diet, moderate exercise, weight control, and avoidance of smoking, limited use of alcohol, and attention to treatment of known risk factors such as hypertension if these arise. Randomized, controlled trial data confirm that an intervention involving diet and exercise can slow the progression of thickening of the intima-media layer of the carotid during the menopausal transition—an established early marker for coronary artery disease.<sup>23</sup> Known cardioprotective medications, including aspirin, statins, and beta-adrenergic antagonists, should be used where appropriate (indications for their use are beyond the scope of this chapter).

A variety of epidemiologic studies, observational studies, and clinical trials have provided support for the premise that estrogen has a cardioprotective role in women.<sup>24–27</sup> Exogenous estrogen has been found to have a favorable impact on lipids and lipoproteins, direct anti-atherosclerotic effects, antiplatelet-aggregating properties, and positive changes on endothelium-dependent vasodilation while exerting certain prothrombotic and pro-inflammatory effects (increases in C-reactive protein after oral administration) that may be greatest in the first years after estrogen is started.<sup>28</sup> Women on HT have a smaller increase in systemic blood pressure over time than do women not using hormones.<sup>29</sup> Observational trials have suggested that “ever-use” of estrogen was associated with a 30% to 40% reduction in the risk of cardiovascular events and cardiovascular mortality compared to nonuse of hormone therapy.<sup>30</sup>

Randomized clinical trials, however, have not confirmed the cardiovascular benefits reported in observational trials. The first large scale secondary prevention clinical trial was the Heart and Estrogen/Progestin Replacement Study (HERS) trial.<sup>31</sup> This randomized, placebo-controlled trial, which involved 2763 elderly women with documented coronary artery disease over a 4.1-year follow-up, showed no benefit from daily conjugated equine estrogen and medroxyprogesterone acetate started immediately following a myocardial infarction (MI) or coronary angioplasty, for the first time challenging the promising results of hormones for secondary prevention reported in earlier observational trials. Neither oral nor transdermal hormone replacement was found to delay progression of angiographically proven coronary artery lesions in randomized clinical trials comparing hormone therapy to placebo in older postmenopausal women with established cardiovascular disease.<sup>32–34</sup> Combined, these observations make a strong case for not starting women with known cardiovascular disease on hormone therapy as a means to delay progression of the disease.

The data on the role of hormone therapy for primary prevention of cardiovascular disease are more limited and have been the focus of ongoing debate. Clarkson's data in the nonhuman primate supports the notion that hormone therapy started early after loss of ovarian estrogen production may have significant benefits in terms of prevention of coronary artery disease.<sup>35</sup> Other data lend support to this notion. In the Estrogen in the Prevention of Atherosclerosis Trial, a randomized, double-blind, placebo-controlled trial involving 222 healthy postmenopausal women, hormone therapy started early in menopause was shown to delay the progression of subclinical cardiovascular disease (as determined by ultrasound measurement of carotid intima-media thickness).<sup>36</sup>

The Women's Health Initiative (WHI), described by its authors as a primary prevention trial, is the largest randomized, controlled trial to evaluate the risks and benefits of hormone therapy in postmenopausal women. This trial reported no cardiovascular disease benefit in “generally healthy” women randomized either to continuous combined conjugated equine estrogen and medroxyprogesterone acetate (combination HT) versus placebo<sup>37</sup> (or conjugated equine estrogen versus placebo in a separate trial for women with prior hysterectomy).<sup>38</sup> Although the initial WHI publication on the combination HT arm generated much public consternation by suggesting that hormone therapy actually increased rates of coronary artery

events, when the “adjudicated” findings were subsequently published there was no statistically significant overall increase in cardiovascular events or mortality in hormone users (see Fig. 60-7). There was, however, a significant elevation in cardiovascular events in combination HT users compared to women on placebo in the first year of therapy (nonfatal MIs, attributable risk 21/10,000 women-years—no significant differences after year one).<sup>37</sup> There was a very small increase in the risk of nonfatal ischemic stroke in women receiving combination HT (attributable risk, 7/10,000 women-years)<sup>39</sup> (see Fig. 60-7). In the conjugated equine estrogen arm of the WHI there was no increase or decrease in coronary artery events in estrogen users compared to women on placebo (see Fig. 60-8). There was a slight increase in the risk of nonfatal ischemic stroke in older postmenopausal women (only in those older than age 60) on estrogen alone (attributable risk, 9/10,000 women-years; see Fig. 60-8).

Those who accept that the results of the WHI effectively contradict numerous observational and clinical studies suggesting cardioprotective effects of HT point out that observational studies are potentially fraught with bias. In the case of hormone therapy it is known that women who seek hormones are better educated and from higher socioeconomic status; thus they have greater access to other health care resources where they may receive treatment for other cardiovascular risk factors such as diabetes, hypertension, or high cholesterol. In fact for many of the years covered by the observational studies these conditions, which increased the risk of cardiovascular disease, were considered relative contraindications to the use of hormone therapy. Those who adhered to hormones for their putative merits in disease prevention were more likely to adhere to other wellness advice—they tended to be leaner, to exercise more often, and to consume more alcohol, which, by itself, afforded a degree of cardioprotection. Women who became sick with comorbid conditions were more likely to stop hormones so that there would appear to be more deaths in nonusers or past users than in current users of hormone therapy. These and other biases of observational studies, they claim, could explain the discrepant findings of the WHI, which failed to confirm a cardioprotective benefit of hormone therapy in menopausal women.

However, many within the scientific community, while acknowledging the potential for bias in observational studies, do not agree that randomized clinical trial data is available that refutes the preponderance of experimental and clinical trial data suggesting cardioprotective benefits for hormone therapy when started early in postmenopausal women. They have challenged the premise that the WHI was a primary prevention trial because of the older ages of participants and the duration of elapsed time since loss of ovarian estrogen production (an average of 13 years).<sup>40</sup> Time since menopause has been shown to correlate with extent of subclinical atherosclerosis.<sup>41</sup> Clearly with close to 70% of women over age 60 at enrollment there must have been a large proportion of women with pre-existing subclinical cardiovascular disease in the trial—making it more of a secondary prevention trial. The first-year increase in cardiovascular events with no overall difference in cardiovascular mortality in this context is similar to the effect of hormone therapy started in older women in the other secondary prevention trial—the HERS trial. The prothrombotic or plaque-destabilizing effects

## Reproductive Endocrinology and Infertility

of hormone therapy in women with established coronary artery disease probably account for the initial small absolute increase in coronary artery events reported in the conjugated equine estrogen arm of the WHI.

A truer picture of the risk for early cardiovascular events in newly menopausal women emerged when investigators pooled data from two large randomized trials that had been conducted for reasons other than examining cardiovascular endpoints. In these pivotal trials, in which all cardiovascular events were carefully documented, no cases of MI were reported in younger postmenopausal women on hormone therapy during the first year of hormone use.<sup>42</sup> This data examines only the first year of therapy and does not follow subjects long enough to determine if there were long-term cardioprotective benefits or risks associated with hormone therapy. Another meta-analysis, however, examined the impact of HT on mortality in populations of younger and older postmenopausal women and concluded that HT reduced total mortality in trials in which women had a mean age younger than 60 but had no impact on mortality if the mean age exceeded this.<sup>43</sup>

The research challenge now is to confirm with an appropriate clinical trial whether early initiation of HT does indeed have cardioprotective effects for menopausal women. To conduct such a study would require very large numbers of newly menopausal women followed for a significant period of time—a type of study that is challenging for a number of reasons. Newly menopausal women are more likely to be symptomatic and many may not agree to be randomly assigned to hormone or placebo; long-term adherence is likely to be a problem because a recent survey of U.S. households revealed that only 3% of women on combination HT (10% for estrogen alone in women who have had a hysterectomy) stayed on their hormones for more than 5 years.<sup>44</sup> The challenges and costs of such an initiative would be staggering. At the present time clinicians are left to decide in the absence of good clinical trial data whether epidemiological and experimental data supporting the use of hormones for primary cardioprotection in newly menopausal women justifies the potential risks of long-term hormone replacement. Women with premature loss of ovarian function probably represent a special situation because exogenous hormone therapy generally results in exposure to a lower total dose of hormone than would have resulted from normal ovarian function until the time of menopause.

### Venous Thromboembolism

Population-based studies have shown that venous thromboembolism increases with advancing age (Table 60-4). Numerous observational studies and two randomized, controlled trials involving older postmenopausal women (HERS and WHI) have indicated that use of oral hormone therapy, either combined estrogen/progestin or estrogen alone, results in a twofold to fourfold increased relative risk of developing a venous thromboembolism.<sup>45</sup> In the older HERS population, this translated into an attributable risk of 2.3/1000 women-years. In WHI, women age 50 to 59 had half the risk for venous thromboembolism of women age 60 to 69 and about one quarter the risk for women age 70 and older. Obesity, a prevalent finding in the WHI population, was associated with a threefold increased risk for venous thromboembolism. Normal-weight women age 50 to 59 had

**Table 60-4**  
**Age-related Changes in Risk for Venous Thromboembolism**

Age (years)	Venous Thromboembolic Events per 1000 Person-Years
<20	.01
20–40	0.1
41–75	1.0
>75	10

From Gomes MPV, Deitcher SR: Risk of venous thromboembolic disease associated with hormonal contraceptives and hormone replacement therapy. *Arch Intern Med* 2004; 164:1965–1976.

an attributable risk for venous thromboembolism of 0.8/1000 women-years.<sup>46</sup> Most studies have shown the risk of venous thromboembolism to be greatest in the first year of HT—perhaps because initiation of therapy unmasks some women with an heritable thrombophilia. Limited data suggest that transdermal hormone therapy may be associated with lower rates of venous thromboembolism.<sup>47</sup>

### Cognitive Function and Dementia

Whether estrogen will reduce age-related cognitive decline remains controversial. Neurobiologists have demonstrated in animal models that estrogen can stimulate growth of neurons, increase synaptic connections, enhance neurotransmitters involved in memory, and stimulate cytokines responsible for repair of damaged neurons. Observational studies indicate that the incidence of Alzheimer's disease may be reduced by HT, with the greatest effect in those women who started it earliest and used it the longest. HT, however, affords no benefit to women who already have Alzheimer's disease.<sup>48</sup> As part of the WHI, selected women over age 65 were recruited to participate in studies on memory and cognition (the WHI Memory Study: WHIMS, and the WHI Study of Cognition and Aging: WHISCA). The results of the conjugated equine estrogen/medroxyprogesterone acetate (combination HT) and conjugated equine estrogen alone arms of the WHI have been similar. In women over age 65 rates of "probable dementia" were increased slightly in women receiving hormone therapy compared to those on placebo (attributable risks: conjugated equine estrogen, 12/10,000 women-years, combination HT, 23/10,000 women-years).<sup>49</sup> It is quite possible that elderly women with pre-existing atherosclerotic vascular disease became more vulnerable to minivascular accidents when started on hormones after age 65. The WHIMS authors remark that although the differences in performance between women on hormone therapy and those on placebo were statistically significant, the magnitude of the differences were "too small to have relevance in clinical practice." Nevertheless, this randomized clinical trial data shows clearly that hormone therapy should not be started in older postmenopausal women with the intent of reducing the incidence or severity of cognitive decline. Unresolved is the question of whether starting hormone therapy at the time of menopause might have long-term protective effects on neurovascular function, resulting in less cognitive impairment and dementia as the population ages.<sup>50</sup>

## Diabetes Mellitus

Consistent with the HERS trial, in which HT users had a 6.2% incidence of diabetes compared to 9.5% in placebo users, a secondary analysis of the WHI data also found a lower incidence of diabetes in HT users compared to placebo users (3.5% vs. 4.2%).<sup>51</sup> Given the economic and health impact of this disease in our aging population, these differences may be important.

## HORMONE THERAPY AND CANCER

### Breast Cancer

Until the recent publication of the WHI study, the best data on hormone therapy and breast cancer came from the reanalysis of data from the Collaborative Group on Hormonal Factors in Breast Cancer (CGHFB) published in 1997.<sup>52</sup> This research, which examined all prior publications on hormone therapy (most of which would have involved conjugated equine estrogen alone) and breast cancer reported that use of conjugated equine estrogen for 5 years or less did not influence breast cancer risk. Very small increases in breast cancer risk appeared in women using hormone therapy for longer durations—an absolute increase of 0.2 cancers per 100 women after 5 years, 0.6 cancers per 100 women after 10 years, and 1.2 cancers per 100 women after 15 or more years of use between ages 50 and 70. The worst-case scenario that they reported was basically a 1% absolute increase with long-term use of conjugated equine estrogen—a risk that is similar to the breast cancer risk of being overweight, drinking excessive amounts of alcohol, failing to exercise regularly, having first birth after age 35, or failing to breastfeed.<sup>53</sup>

Shortly thereafter a qualitative review of all the published information on HT and breast cancer risk was published.<sup>54</sup> This is a different way to evaluate the data—which looks at the direction of change in situations where a cause-and-effect relationship is suspected. For example, all research on the value of seatbelts for preventing injury in car accidents points to a beneficial effect, just as all studies on the effects of cigarette smoking on lung cancer point to an increased risk. The data on HT and breast cancer are mixed, with as many studies reporting a decreased risk as reporting an increased risk. The conclusion of that analysis was as follows:

The evidence did not support the hypotheses that estrogen use increases the risk of breast cancer and that combined hormone replacement therapy increases the risk more than estrogen only. Additional observational studies are unlikely to alter this conclusion. Although a small increase in breast cancer risk with long duration of use (15 years or more) cannot be ruled out, the likelihood of this is small, given the large number of studies conducted to date.<sup>54</sup>

Subsequently a large observational study (The Million Women Study) reported that both estrogen alone and combined estrogen/progestin increased the risk of new breast cancers in 830,000 women being followed with mammographic screening in the United Kingdom.<sup>55</sup> This study has been widely criticized for potential inclusion/exclusion biases that could have significantly altered the findings as well as for systematic underestimation of the years of hormone use in establishing “duration of use” categories. The rapid development of tumors within a mean of 1.2 years of enrollment in that report seems biologically

implausible based on known tumor biology and indicates a strong likelihood that many of the breast cancers detected during follow-up were in fact pre-existing.

More important to this question has been the WHI, a large randomized trial that evaluated breast cancer incidence in two separate arms—one in which the active drug was combined estrogen and progestin (combined HT) and one in which women who had undergone a hysterectomy received either estrogen alone or placebo. In the combination HT arm the 75% of women who had not used hormone therapy before enrollment showed no increase in the rate of breast cancer during the 5 years of the study—consistent with the results shown in the 1997 CGHFBC reanalysis. Also consistent with prior publications, the 25% of women who had previously received hormones had a slight increase in breast cancer after the 5 years of additional hormone therapy in the study (attributable risk for combination HT, 8/10,000 user per year). In the estrogen alone arm there was a lower rate of breast cancer diagnosis in the estrogen-treated women than in the placebo-treated women that just failed to achieve statistical significance (see Fig. 60-7). Together these findings should reassure women and their health care providers about the relative safety of hormone therapy for distressing vasomotor symptoms in the early menopausal years.

### Hormone Therapy in Women with Benign Breast Disease

Women with benign breast disease have a 1.8-fold to 3.6-fold increased risk of breast cancer, depending on whether past biopsies showed cellular atypia. The use of HT, even long term, by women with previous biopsy-proven benign breast disease had no further impact on breast cancer risk.<sup>56</sup> Similarly, it seems that HT does not interact with other known risk factors for breast cancer (e.g., benign breast disease, alcohol, parity, body mass index) to augment the overall risk of breast cancer.<sup>57</sup>

### Hormone Therapy with a Positive Family History for Breast Cancer

A common question faced by practitioners is whether a positive family history of breast cancer precludes use of HT. Family history by itself can provide useful information about a woman's personal risk for breast cancer. Women with a single first-degree family member (mother, sister, daughter) affected by breast cancer over age 50 have little increase in risk over the general population (approximately 12%). Those with two affected first-degree relatives over age 50 have an approximate doubling of their lifetime risk (to approximately 24%), and those with affected first-degree relatives under age 50 have a risk from 24% to 48%, depending on whether the number of affected first-degree relatives was 1 or 2, respectively. In a study designed to address the question about the safety of hormone therapy in women with a positive family history, the use of hormones was not associated with an increase in the overall risk for breast cancer yet was associated with a reduced overall mortality.<sup>58</sup>

### Hormone Therapy in Symptomatic Breast Cancer Survivors

Some 30,000 premenopausal women with a diagnosis of breast cancer are rendered acutely symptomatic subsequent to chemotherapy-induced ovarian failure each year in North America. There are more than 2.5 million breast cancer survivors in North America, many of whom have been unable to achieve

## Reproductive Endocrinology and Infertility

a satisfactory quality of life because alternative approaches to vasomotor symptoms remain largely unsatisfactory.

A limited number of observational studies have reported on outcomes in women who choose to use HT after breast cancer compared to those who do not. When compared to “low-risk” controls, women on HT in these studies have not had a worse outcome.<sup>59</sup> Many people have now forgotten that high-dose estrogen once was a treatment for metastatic breast cancer. When tamoxifen was shown in a randomized clinical trial from the Mayo Clinic<sup>60</sup> to have equal benefit with fewer side effects, it became the mainstay of therapy in this circumstance. A recent report with a 20-year follow-up of the original trial participants revealed two surprising findings.<sup>61</sup> First, the diethylstilbestrol (DES)-treated participants survived longer than tamoxifen-treated women (35% of DES vs. 16% of tamoxifen-treated group were alive at 5 years;  $P = 0.03$ ). Secondly, 30% of women who failed to respond to tamoxifen went on to show a clinical improvement when switched to DES treatment. A possible mechanism for this effect has been recently uncovered with the discovery that *in vitro* estrogen treatment of previously estrogen-deprived breast cancer cells promotes rapid cell death.<sup>62</sup>

Data from the first randomized clinical trials to examine this issue have recently appeared. The HABITS trial from Scandinavia found that women who used hormones after a diagnosis of breast cancer had a higher recurrence risk than did women assigned to placebo. Among 434 randomized to the study there were 26 recurrences in women assigned to hormone therapy and 6 recurrences in women receiving placebo.<sup>63</sup> Surprisingly a concurrent study conducted in Sweden failed to find any adverse effect of hormone therapy, leaving this issue unresolved. Both studies were stopped prematurely on the basis of the HABITS trial findings and the concern that ongoing recruitment would no longer be possible because of the adverse publicity about the preliminary findings.

Women who wish to consider HT for quality of life issues after a diagnosis of breast cancer should understand that a definitive answer to the question of whether HT will influence prognosis is lacking. Observational studies, which are fraught with potential biases, have been reassuring; however, a single, randomized, controlled trial suggested that HT had an adverse effect on recurrence rates. Alternative nonhormonal therapies exist for many menopausal symptoms (such as SSRIs for hot flashes and topical estrogen for urogenital atrophy). If these options are unsuitable and quality of life is seriously impaired, individual women with low risk of tumor recurrence may still wish to explore the option of HT.

### Uterine Cancer

The absolute risk of endometrial cancer in an untreated postmenopausal woman is approximately 1/1000 per year such that her lifetime risk after menopause is in the order of 2% to 3%. To put this risk into perspective, it is worth noting that merely being overweight by 25 to 50 pounds can produce a comparable increase in risk for endometrial cancer. Persson and colleagues, following a cohort of 23,244 patients for 6 years, reported a threefold increase in the relative risk for developing endometrial cancer in women using estrogen alone. In the PEPI trial, unopposed estrogen was associated with a significantly increased risk of adenomatous or atypical hyperplasia (35% vs. 1% com-

pared to women receiving progestational supplementation) and of subsequent hysterectomy (6% vs. 1% compared to the same group). Cure rates for estrogen-associated endometrial cancer are excellent, exceeding 95% in properly treated cases. Although annual office endometrial biopsy remains the gold standard, vaginal ultrasound monitoring of endometrial thickness may provide needed reassurance if the combined endometrial thickness is less than 5 mm.

To avoid the increased risks of endometrial hyperplasia and cancer associated with unopposed estrogen, most physicians prescribe combination HT to women who have a uterus. Progestins have multiple effects that impede endometrial growth. First, progestins decrease estrogen receptor number, decrease DNA synthesis, and modify growth factors, all of which impede estrogen-mediated transcription of oncogenes.<sup>64</sup> Second, progestins induce the enzyme estradiol 17 $\beta$ -dehydrogenase, resulting in enhanced local endometrial conversion of the more potent estradiol to the weaker estrogen, estrone. Finally, exposure to progestin will result in secretory transformation of the endometrium that may or may not be associated with endometrial sloughing, depending on whether the progestin is administered cyclically or continuously. Although the move toward using lower doses of estrogen for protection against postmenopausal bone loss may have merit<sup>65</sup> and may be less likely to induce endometrial hyperplasia, vigilance is required in any woman with unscheduled bleeding. Newer approaches are examining the possibility that progestin-releasing intrauterine systems or intravaginal progestin creams could achieve endometrial inhibitory concentrations of progestin without the same systemic progestin exposure that occurs with oral progestin therapy.

### Colorectal Cancer

Several past observational studies reported reduced rates of colorectal cancer in women on combined HT. In the WHI, combined HT (but not estrogen alone) was associated with a small reduction in the rate of colorectal cancer.

### CLINICAL MANAGEMENT OF POSTMENOPAUSAL WOMEN

Postmenopausal women need individual assessment and counseling. The factors that motivate consultation for different women and that determine an individual's propensity to seek treatment may be very different. Some women are motivated to obtain relief from their own symptoms, whereas others are driven more by fear that they will suffer the fate of a mother or relative who struggled with cancer, heart disease, or dementia. Positive lifestyle choices should be encouraged long before the menopause; however, when the onset of menopause creates an opportunity to discuss maintenance of health and disease prevention, strategies such as smoking cessation, moderation of alcohol intake, weight control, and regular exercise should be reinforced.

Clinicians should be aware of the fact that most women will have tried alternative therapies before seeking medical assistance and should make enquiries about the approaches that have been tried. While keeping an open mind to such approaches, it is also wise to be armed with available information and evidence that

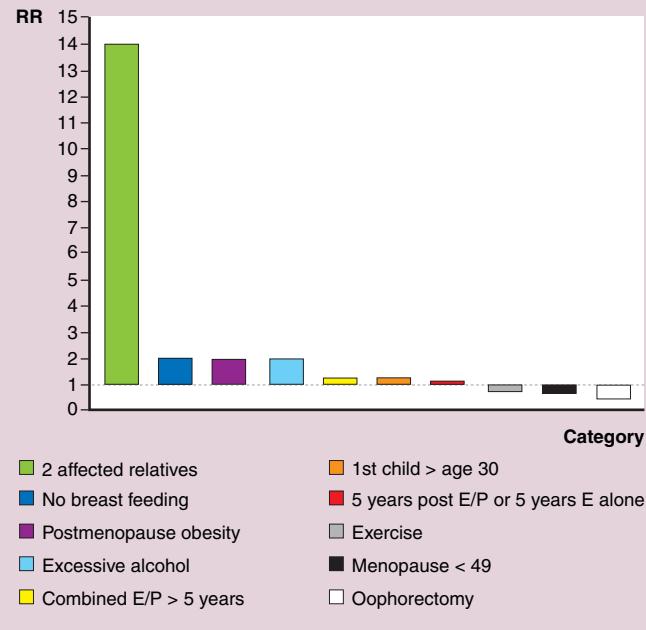

examines the effectiveness of such approaches to facilitate a balanced and informed interaction. Several excellent articles are available that have examined the claims and effectiveness of alternative therapies for menopausal vasomotor symptoms.<sup>11</sup>

The first issue in counseling is to determine and document any reasons to consider HT. Issues such as distressing hot flashes, night sweats, sleep disturbance, daytime fatigue and irritability, vaginal dryness, or dyspareunia might all be reasonable grounds to consider starting some form of hormone therapy. This should be followed by a brief but thorough discussion, again well documented, about potential benefits and potential risks of hormone therapy (Table 60-5).

It is important to remember that the risks reported in the media since the recent publications from the WHI have been average risks for a population of old and young women combined. As pointed out in the editorial that accompanied the WHI publication on the conjugated equine estrogen alone arm, "Women in their 50s have half the (baseline) risk of women in their 60s and one quarter the risk of women in their 70s." Accordingly it is likely that younger, newly menopausal women will have risk profiles that are even lower than the small overall risks reported for hormone users in the WHI reports. For example, the risk of stroke in the conjugated equine estrogen alone arm of the WHI was reported to be increased by 39% overall (44/10,000 in estrogen users vs. 32/10,000 in placebo users), yet in women under age 60 the rate for women suffering stroke was identical for both estrogen users and women on placebo (16/10,000).

To assist health care providers in explaining risks attributable to medical interventions the WHO convened a panel of experts

### Putting breast cancer risk factors into perspective by comparing hormone-related risks to risks associated with other lifestyle choices

**Figure 60-9 Putting breast cancer risk factors into perspective by comparing hormone-related risks to risks associated with other lifestyle choices.** E, estrogen; P, progestin.

**Table 60-5**  
**Summary of Risks and Benefits of Hormone Therapy**

Benefits	Risks
Effective control of hot flashes, night sweats, and associated sleep disturbance	<b>Systemic hormone therapy</b> Increased venous thromboembolic disease with oral estrogen (0.8/1000 with combination HT; Cushman 2004) but not transdermal estrogen (Scarabin 2003)
Improved energy and sense of well-being	Increased risk of biliary tract surgery (absolute increase 1/185 treated women; Simon 2001)
Preservation of bone and reduction in fragility fractures (56/10,000)	
Maintenance of vaginal and urinary health	
Improved sexual functioning	<b>Combination hormone therapy</b> Stroke—WHI, 8/10,000 per year overall (4/10,000 per year under age 60) Breast cancer—WHI, 8/10,000 per year after 5 years Probable dementia—over age 65 WHIMS, 23/10,000
Diminished skin aging	
Less central weight gain	
Reduced colorectal cancer (6/10,000 with combination hormone therapy)	<b>Estrogen replacement</b> Stroke—WHI, 8/10,000 overall (no increase under age 60) Breast cancer—no significant change after 7 years Probable dementia—no significant change

to develop standardized nomenclature to describe the risk for adverse events. The Council for International Organizations of Medical Sciences (CIOMS) task force released its report in 1998—providing a strict form of risk categorization to assist health care professionals and the public when interpreting risk.<sup>66</sup> According to the CIOMS classification, risks occurring in less than 1/1000 people, like all the risks reported by the WHI, are considered “rare.”

Another effective way to put risks into context is to compare them with risks related to other lifestyle choices or other commonly prescribed medications. The risks of breast cancer associated with failure to exercise, postmenopausal obesity, excessive alcohol ingestion, delayed parenting, and failure to breastfeed probably all outweigh the risks associated with short-term hormone replacement<sup>54</sup> (Fig. 60-9).

Aspirin is widely prescribed and extensively utilized for prophylaxis against MI. Not generally recognized is the fact that this use of aspirin is associated with an absolute increase in the risk of hemorrhagic stroke of 12 per 10,000 individuals (more than the risk of heart attack or stroke reported in the WHI). The benefits of this intervention are assumed to outweigh this potential risk for most individuals (with an absolute risk reduction in MIs of 137 per 10,000 users, and in ischemic strokes of 39 per 10,000 users).<sup>67</sup>

If, on balance, the health care provider and the menopausal woman agree that the potential benefits outweigh potential risks, the second issue in counseling is to decide whether she needs

## Reproductive Endocrinology and Infertility

combined HT or estrogen alone. The only reason to use combination HT is if the uterus is intact. Women who have had an endometrial ablation usually continue to require progestin therapy because the possibility remains that there is some sequestered endometrium that could become cancerous under the influence of unopposed estrogen. In the absence of a uterus, progestin therapy is not indicated. In those with hysterectomy and bilateral salpingo-oophorectomy estrogen alone may be supplemented with an androgen-containing product in selected circumstances where estrogen alone has been inadequate to restore satisfactory sexual drive and enjoyment and other relationship and health issues have been excluded as contributory factors. Normally this decision would not be made until a 3-month trial of estrogen replacement had been completed.

Once a woman has decided that she wishes to try hormone therapy her input should be sought in determining the most appropriate regimen for her. The third issue to discuss, then, is whether she is prepared for or prefers to have regular periods or whether she wishes amenorrhea (and understands there may be some unpredictable bleeding until this is achieved). Some women early in menopause prefer to stick with a familiar monthly bleeding pattern, whereas others are just happy that menstruation is "over." This will determine if continuous estrogen and sequential progestin (for the first 12 to 14 days each month) or continuous combined therapy is optimal.

A fourth issue is which route of delivery (Table 60-6) appeals to her (oral, vaginal, transdermal [patch or gel], or intramuscular). Evidence suggests that a woman's participation in the choice of delivery route is critical to adherence to the prescribed regimen.

Follow-up is essential after 2 months to provide reassurance and to determine if symptom control and bleeding are acceptable. Sometimes persistent symptoms with an oral route may dictate the need for a switch to a transdermal route or persistent vaginal dryness may indicate the need for additional local vaginal estrogen therapy.

**Table 60-6**  
Options for Hormone Therapy

<b>Oral</b>
Estrogen alone
Progestin alone
Estrogen/progestin combination (continuous or sequential)
<b>Transdermal</b>
Patch
Estrogen alone
Estrogen/progestin combination
Testosterone
Gel or emulsion
<b>Vaginal</b>
Systemic
Tablet (estrogen alone)
Gel (progesterone alone)
Local
Cream, tablet, ring (estrogen alone)

## KEY POINTS

- Perimenopause is the period preceding menopause, characterized by menstrual irregularity (both cycle and flow) and increasing months of amenorrhea when anovulatory cycles are more prevalent and cycle length increases.
- Perimenopause is marked by decreased inhibin and increased FSH and estrogen levels and decreased progesterone which correlate with menstrual irregularity, dysfunctional bleeding and endometrial hyperplasia.
- Menstrual irregularity and dysfunctional bleeding is the hallmark of perimenopause. Selective evaluation by endometrial biopsy, transvaginal sonography, saline-infused sonohysterography and/or hysteroscopy is mandatory for accurate diagnosis.
- Fertility continues in a significant number of women during perimenopause. Oral contraceptives, if not contraindicated, are ideal therapy for perimenopausal symptoms of irregular menses, hot flashes, residual fertility, and may be continued until early menopause.
- Perimenopause may serve as an ideal time to reinforce the importance of good health practices, periodic medical screening, and disease prevention.

## CLASSIC CASE PRESENTATION

A 42-year-old female bank executive comes in for a well-woman examination. She complains of increasing menstrual irregularity over the past 6 months. In addition, she states that she has experienced several episodes of hot flashes at night and is not sleeping well. As a result, she has noticed increasing irritability that has affected her job performance. She is quite disturbed by these occurrences and seeks advice regarding therapy.

## INTRODUCTION

The preceding case scenario is a classic presentation of perimenopausal symptoms. Physicians and the lay public have long recognized menopause as a defined state of female transition from reproductive to postreproductive years. However, only in the relatively recent past has the importance of symptom recognition, evaluation of pathophysiology, and treatment of perimenopause been recognized and addressed as a biologic process distinct from the menopause.

With the aging of the “baby boom” population, the number of women aged 50 to 59 years will increase by 50% by 2006. As life expectancy increases, a female may expect to spend approximately one third of her life as a postmenopausal person. There were an estimated 42.9 million women over the age of 50 in the United States in 2000. By 2020, the number of women over age 55 is estimated to increase to 45.9 million (Table 61-1).<sup>1</sup> A woman who reaches age 54 today may expect to survive to age 84.3 years. About two thirds of the U.S. population may survive to age 85 or longer. No data exist on how many women will reach menopause in a given year. Based on assumptions about spontaneous, premature, surgical, and induced menopause, it is estimated that approximately 4200 women become menopausal per day in the United States.

The transition defined by perimenopause and menopause may be viewed as a problematic period of menstrual, emotional, and physiologic changes. Beginning with perimenopausal changes in hormones, females may begin the common degenerative process of aging, which includes the possibility of cardiovascular disease, diabetes, and osteoporosis, among other diseases. However, medically, perimenopause may present an opportunity for improvement of health screening, recognition of otherwise silent disease, and motivation for a healthier life style for the rest of the patient’s life.

This chapter describes the pathophysiology, clinical signs and symptoms, and therapy of perimenopause (Table 61-2).<sup>2</sup>

## DEFINITIONS AND TERMINOLOGY

In 2001, the Stages of Reproductive Aging Workshop (STRAW), sponsored by the North American Menopause Society (NAMS), and others addressed nomenclature and staging of menopause. A continuum was devised; however, it was recognized that some women may “seesaw” between or skip some stages<sup>1</sup> (Fig. 61-1). Menopause is the anchor point defined as 12 months of amenorrhea following the final menstrual period (FMP).<sup>1</sup> Menopause occurs at an average age of 51.4 years with a Gaussian distribution of 40 to 58 years.

Perimenopause (peri = around) is defined as beginning with stage 2 (see Fig. 61-1) and ending 12 months after the FMP. STRAW suggests using climacteric as synonymous with perimenopause. STRAW recommends use of perimenopause and climacteric only with patients or in the lay press; however, owing to widespread usage in the medical community and NAMS, the term is used in its stated context in this chapter. Postmenopause is the span of time dating from the FMP whether spontaneous or induced. It is early (stage +1) within 5 years of FMP and late (stage +2) when more than 5 years after FMP.

Table 61-1 Increase in the Number of Postmenopausal Women in the United States				
Age	July 1, 1999	July 1, 2000	Percentage Change	Postmenopausal
Age 50+	41,000,000	42,189,280	+2.9	39,944,824
Age groups				
Age 40–44	11,188,000	11,312,761	+1.1	1,134,000
Age 45–49	9,832,000	10,202,898	+3.8	2,017,600
Age 50–54	8,439,000	8,977,824	+6.4	6,733,368

Data from U.S. Census Bureau, 2000 Census; and Stages of Reproductive Aging Workshop (STRAW): Menopause 2001;8:402–407.

## PATHOPHYSIOLOGY

### Ovarian Follicles

The pathophysiology of perimenopause is directly related to the aging ovary. The human ovary contains approximately 7 million oocytes at the fifth week of gestation. After this time, the number is reduced by atresia to approximately 1 to 2 million at birth and 400,000 by menarche. By menopause, only a few hundred oocytes remain (Figs. 61-2 and 61-3). During reproductive life, only 300 to 400 follicles will grow to ovulatory status. Follicular atresia occurs on a monthly basis, as a cohort of up to 50 follicles may be recruited, resulting in one dominant follicle proceeding to ovulation while the others are absorbed. However, 80% of follicular atresia may be due to a gonadotropin-independent process.

Table 61-2 Most Common Signs and Symptoms of Perimenopause	
Cycle irregularities	Physical discomfort
Hot flashes	Reduced libido
Menorrhagia	Sexual dysfunction
Menstrual changes	Spotting
Night sweats	Vasomotor disturbances

From Association of Professors of Gynecology and Obstetrics: Managing the Perimenopause. APGO Educational Series on Women's Health Issues. Washington, DC, APGO, 2001, pp 1–20.

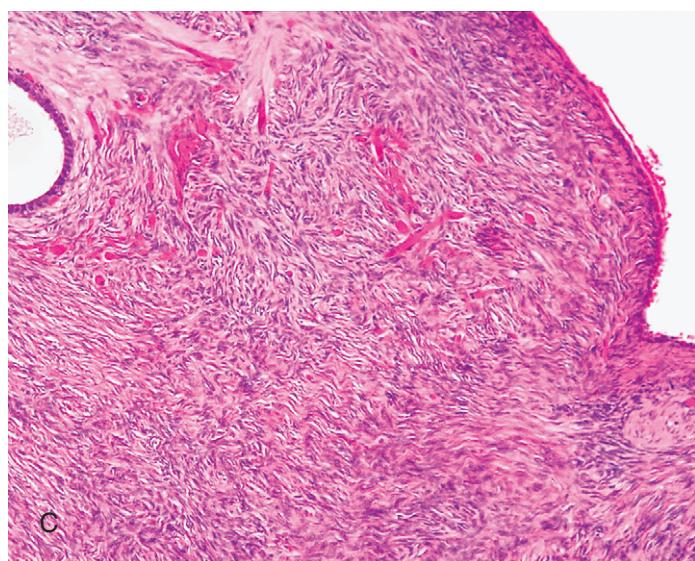

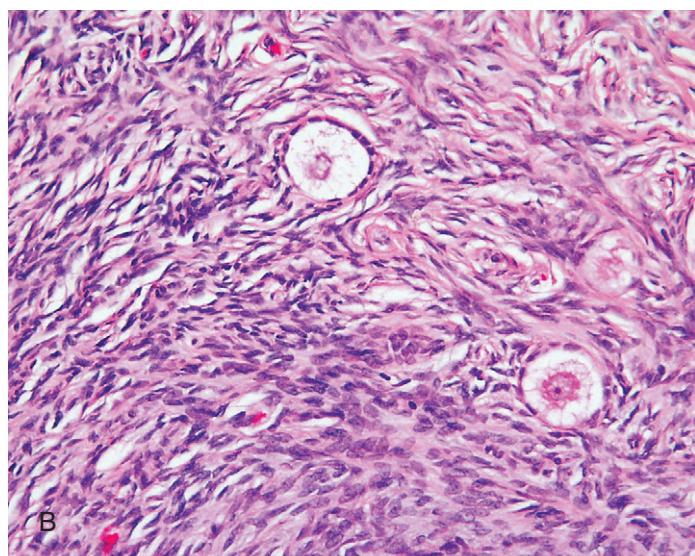

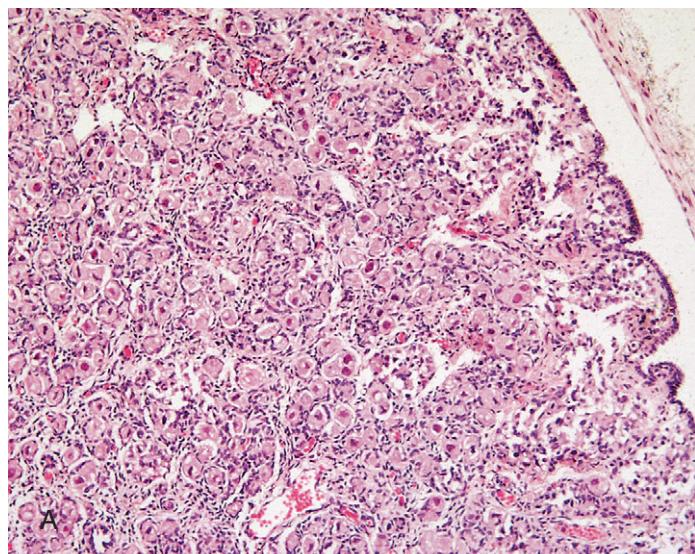

### Endocrine Changes

Although the exact nature of the endocrine changes occurring in perimenopause are not totally understood, variation and finally persistent elevation of, first, follicle-stimulating hormone (FSH) and then luteinizing hormone (LH) and loss of ovarian secretion of inhibin characterize this period. The age of menopause appears to have changed little since early Grecian times. The perimenopausal transition may begin as early as the fourth decade (late 30s) and may vary between 2 and 8 years in length. The Massachusetts Women's Health Study (MWHS)<sup>4</sup> and a longitudinal study by Treloar<sup>5</sup> are two of the classic studies most often quoted when defining the age of onset and duration of

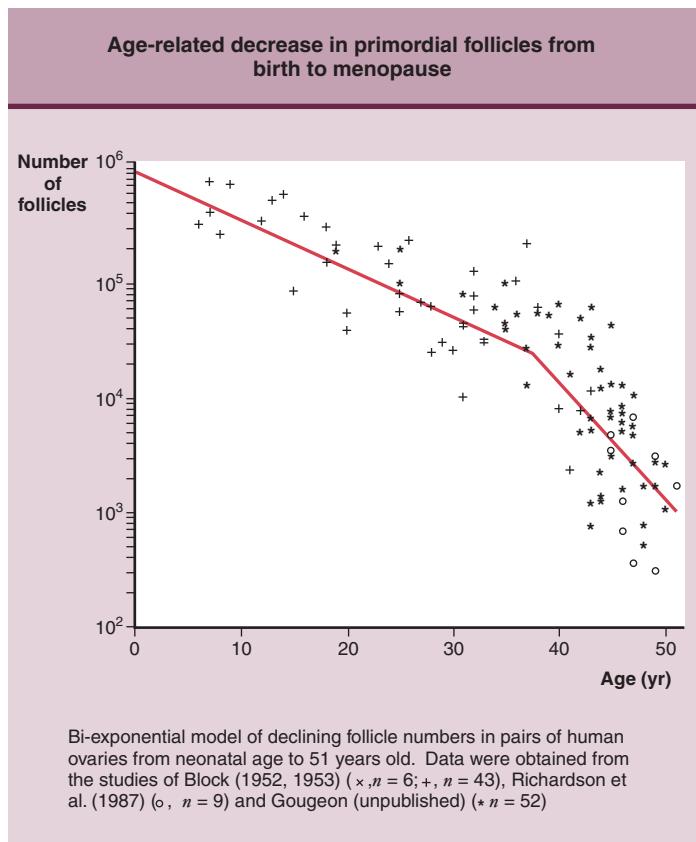

Stages/nomenclature of normal reproductive aging in women								
Stages:	Final menstrual period (FMP)							
	Reproductive			Menopausal transition		Postmenopause		
Terminology:	Early		Peak	Late	Early	Late*	Early*	Late*
	Perimenopause							
Duration of stage:	Variable			Variable		(a) 1 yr	(b) 4 yrs	Until demise
Menstrual cycles:	Variable to regular	Regular		Variable cycle length (>7 days different from normal)	2 skipped cycles and an interval of amenorrhea (60 days)	Amen. x 12 mos	None	
Endocrine:	Normal FSH		↑ FSH	↑ FSH		↑ FSH		

\*Stages most likely to be characterized by vasomotor symptoms.

**Figure 61-1 Stages/nomenclature of normal reproductive aging in women.** (From Stages of Reproductive Aging Workshop (STRAW). Menopause 2001;8:402–407.)

**Figure 61-2 Stages of ovarian senescence.** A, Newborn. B, Age 25. C, Age 50.

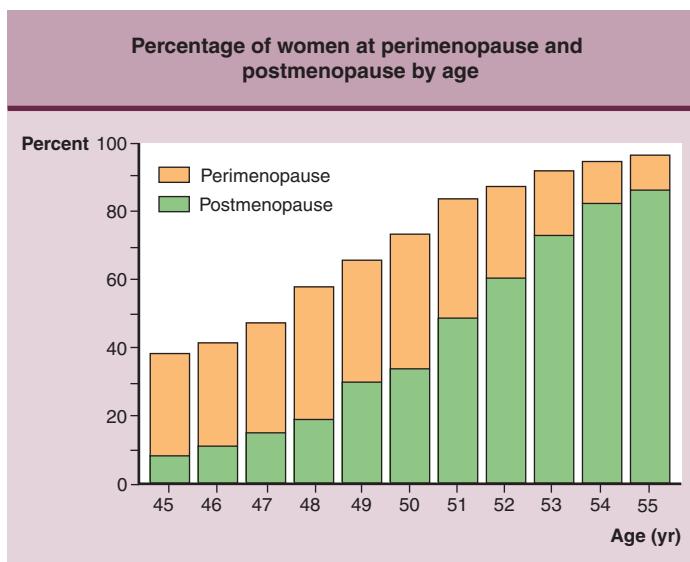

**Figure 61-3 The age-related decrease in the total number of primordial follicles (PFs) within both human ovaries from birth to the menopause.** As a result of recruitment (initiation of PF growth), the number of PFs decreases progressively from about 1 million at birth to 25,000 at 37 years. At 37 years, the rate of recruitment increases sharply, and the number of PFs declines to 1000 at menopause (about 51 years of age). (From Faddy MJ, Gosden RG, Gougeon A, et al: Accelerated disappearance of ovarian follicles in mid-life: implications for forecasting menopause. *Hum Reprod* 1992;7:1342–1346.)

the menopause. The MWHS followed 2570 women aged 45 to 55 years over a 5-year period. The median age at onset for perimenopause was 47.5 years and median age of FMP was 51.3 years (Fig. 61-4).<sup>4</sup> Only 10% of women cease menses without any menstrual irregularity. In the study by Treloar, the average age of menopause was 50.7 years and the range was 44 to 56 years. Treloar prospectively studied the record of 2700 women constituting 25,825 woman years. He demonstrated an age-related shortening of menstrual cycle length of median 28 days at age 20, to 26 days at age 40. The shortened cycle length is due to a progressive shortening of the follicular phase without a significant change in the luteal phase. The overall decreased cycle length continues to approximately age 43, when both average cycle length and interval begin to increase.

#### Inhibin

The secretion of FSH is mainly influenced by inhibin. Inhibin is a family of glycoprotein hormones produced by the granulosa cells of the ovary. The two inhibin species found in humans, A and B, are composed of a common  $\alpha$ -subunit and one of two

**Figure 61-4 Percentage of women at perimenopause (yellow) and postmenopause (green) by age.** Median age of onset for the perimenopause was 47.5 years; median age for the menopause was 51.3 years. (From McKinlay SM, Bremilla DJ, Posner JG: The normal menopause transition. *Maturitas* 1992;14:107.)

$\beta$ -subunits,  $\beta\alpha$  and  $\beta\beta$ . The physiologic role of inhibin is due to the  $\beta$ -subunits, which show functional, structural, and molecular differences. Males make only inhibin B while females produce both inhibins A and B. While estradiol appears to be mainly produced by the dominant follicle, inhibin is produced by follicles in both ovaries. These hormones act both *in vitro* and *in vivo* to suppress FSH secretion. Plasma levels of the  $\alpha$ -subunit are high; however, it is biologically inactive in FSH suppression. In the menstrual cycle, inhibin B is produced by antral follicles, but little is produced by the dominant follicle or corpus luteum. Inhibin A is produced by both the developing and the dominant follicle and corpus luteum. Inhibin A concentrations remain stable throughout much of the follicular phase of the cycle and increase in the first half of the luteal phase followed by a decline as menses approaches (Fig. 61-5).<sup>6</sup> Functionally, inhibin exerts negative feedback on regulation of pituitary FSH secretion. FSH administration stimulates inhibin production, and inhibin levels are inversely correlated with FSH concentrations. Inhibin B is important in FSH regulation in the follicular phase of the cycle, whereas inhibin A is dominant in the luteal phase. Inhibin B levels correlate with serum FSH during the early stages of the menstrual cycle, which suggest inhibin B is under FSH regulation. In the later follicular phase, inhibin B levels increase while FSH falls, which supports feedback of inhibin on FSH secretion. FSH is elevated in the cycles of perimenopausal women and is associated with a decrease in inhibin B but not in inhibin A. This decreased serum inhibin B is attributed to decreased follicle count and competency. Inhibin is undetectable after both normal and premature menopause.

#### FSH, LH, Estrogen, and Progesterone Levels

Perimenopause is marked by changes in the secretion of gonadotropins. Urinary FSH, LH, estrogen, and progesterone levels

were studied in a group of 6 cycling women, 47 years or older, for 6 months (Fig. 61-6).<sup>7</sup> Perimenopausal women had shorter cycles due to an attenuated follicular phase. Estrone excretion was greater in perimenopausal than in mid-reproductive-aged women, both overall and in the follicular and luteal phases of the cycle. Basal pregnanediol concentrations did not differ between perimenopausal and control groups; however, overall they were lower in the perimenopausal group.

FSH and LH levels, especially FSH, were elevated in the early follicular phase of the cycle. Mean follicular-phase FSH was elevated in perimenopausal women (median, 14 IU/g creatinine) compared with mid-reproductive-aged women (median, 4 IU/g creatinine). LH was also elevated though less markedly. In contrast, age-appropriate postmenopausal women demonstrated

Data displayed with respect to the day of the midcycle LH peak. (From Groome NP, Illingworth PJ, O'Brien M, et al: Measurement of dimeric inhibin B throughout the human menstrual cycle: *J Clin Endocrinol Metab* 1996;81:1401–1405.)

Rights were not granted to include this figure in electronic media.  
Please refer to the printed publication.

**Figure 61-6 Mean  $\pm$  SEM daily urinary gonadotropin and sex steroid excretion patterns in 11 perimenopausal women aged 43 to 52 years (red circle) compared with those in 11 mid-reproductive-aged women (blue circle).** Data are standardized to day 0, the putative day of ovulation, as described in the test. E<sub>1</sub>, estrone conjugates. (From Santoro N, Brown JR, Adel T, et al: Characterization of reproductive hormonal dynamics in the perimenopause. J Clin Endocrinol Metab 1996;81:1495–1501.)

little variation in gonadotropins and estrogen. FSH and LH were clinically elevated and estrone conjugate excretion was low (hypergonadotropic-hypoestrogenism; see Fig. 61-6).<sup>7</sup>

The elevation of estrone conjugates suggests that although follicular numbers are decreasing, the ability of the ovary to produce estrogen continues. This finding is consistent with the observed increase in uterine myoma size, endometrial hyperplasia, and dysfunctional bleeding noted in these women, which are commonly attributed to anovulation.

However, hyperestrogenism was noted even in ovulatory cycles. The decline in luteal-phase progestin may aggravate the already relatively unopposed estrogen state noted in these women. Therefore, from an endocrine point of view, management of the perimenopausal woman should be viewed as treatment of a hyperestrogenic, hypoprogesterogenic state. These data also appear to negate concerns about potential bone loss and decreased estrogen.

Perimenopausal women in the study also demonstrated occasional periods of hypogonadotropic hypoestrogenism interspersed with periods of cyclic ovulatory and anovulatory activity. As expected, the periods of hypoestrogenism became

more frequent with proximity to menopause. This implies that progression from reproductive life to postmenopause represents not a continuous but a discontinuous process of intermittent ovulation and anovulation.

### Physiologic Menstrual Irregularity

Our understanding of menstrual irregularity is largely due to the classic studies of Treloar.<sup>5</sup> Volunteers were initially recruited in the 1930s and asked to record menstrual cycles until menopause. Initial reports were in 2702 women representing 25,825 woman-years of menstrual experience with the later addition of longer term data. The mean age of menopause was 49.8 years and duration of menstruation was 35.9 years. Cycle variability began 6 years prior to menopause in 10% to 15% of women, with an increase in variability in another 30% 2 to 3 years prior to menopause. The data demonstrated a wide variability in menstrual cycle length associated with defective luteal function increasing from 8% of cycles at 31 to 35 years to 36% at 40 to 50 years. Also, the study demonstrated an increase in anovulation from 8% at 31 to 35 years to 16% of cycles at 45 to 50 years.

## Reproductive Endocrinology and Infertility

A recent Scandinavian study<sup>8</sup> examining 1616 women aged 45 to 54 confirmed that irregular cycles increased from 58.3% at age 45 to 46 years to 100% at 53 to 54 years. Irregularity was accompanied by both increased variation in length and subjective assessment of heaviness of bleeding episodes in individuals and between women. Spotting and prolonged bleeding were common. Heaviness of bleeding episodes was higher in women with regular cycles.

The relationship of menstrual variability to menopause was addressed in a recent study in a group of 326 menstruating women with irregular perimenopausal periods.<sup>9</sup> Of six definitions of menstrual variability, “60+ days of amenorrhea” showed the best balance of sensitivity (94%) and specificity (91%) for ascertained menopause within 2 years. Specificity was 90% or better with all the definitions of “more than 90 days since LMP,” “60+ days amenorrhea” and “cycles too variable to represent a usual length” for ascertained menopause within 2 years and within 4 years, respectively.

**Abnormal Uterine Bleeding**

While physiologic alteration in menstrual pattern is the hallmark of perimenopause, abnormal uterine bleeding accounts for more than two thirds of office visits to the gynecologist. Examples of abnormal bleeding include heavier than usual bleeding, prolonged bleeding, menses more often than every 3 weeks, bleeding or spotting between menses, and postcoital bleeding. A differential diagnosis for abnormal bleeding is listed in Table 61-3.<sup>10</sup>

Ruling out bleeding related to unexpected pregnancy is the first order of business, followed by evaluation of possible endometrial neoplasia resulting from unopposed estrogen (Table 61-4).<sup>11</sup> Risk factors associated with endometrial neoplasia are listed in Table 61-5.<sup>10</sup>

**Table 61-4**  
**Mechanism of Increased Endometrial Estrogen Exposure**

Anovulatory menses (lack of luteal-phase progesterone)
Increased precursor androgen (functional or nonfunctional endocrine tumors, liver disease)
Increased aromatization (obesity, hyperthyroidism, liver disease)
Increased direct secretion of estrogens (ovarian tumors)
Decreased levels of sex hormone-binding globulin leading to increased levels of free estrogen
Iatrogenic (nonjudicious use of prescribed unopposed estrogen)

From Menopause and the perimenopausal transition. In Speroff L, Glass RH, Kase NG (eds): Clinical Gynecologic Endocrinology and Infertility, 6th ed. Philadelphia, Lippincott Williams & Wilkins, 1999, pp 643–724.

**Evaluation of Abnormal Uterine Bleeding**

In a patient with abnormal uterine bleeding, a detailed history is mandatory. Data regarding the last episode of bleeding, length, character, duration, and amount of flow are important. Ascertain not only when the last episode of bleeding occurred but also the pattern of bleeding over the previous 6 months to 1 year to establish whether the bleeding is abnormal or a variation in the normal perimenopausal pattern.

The history should include possible interruption of normal daily activities, contraception type and possible relation to bleeding (e.g., intrauterine device, depot medroxyprogesterone acetate), current medications and concomitant disease states. Laboratory testing including pregnancy assessment (serum hCG), prolactin, thyroid-stimulating hormone, complete blood count, and coagulation studies should be obtained depending on the patient's history.

Farquhar<sup>12</sup> reviewed a laboratory data base of 1033 endometrial samples over a 30-month period from 1995 through

**Table 61-3**  
**Possible Causes of Abnormal Uterine Bleeding in Perimenopausal Women**

Anovulation (dysfunctional uterine bleeding)
Benign reproductive tract conditions
Pregnancy
Leiomyomata uteri

Adapted from Farquhar CM, Lethaby MA, Sowter M, et al: An evaluation of risk factors for endometrial hyperplasia in premenopausal women with abnormal menstrual bleeding. Am J Obstet Gynecol 1999;181:525–529; and Kaunitz AM: Gynecologic problems of the perimenopause: evaluation and treatment. Obstet Gynecol Clin North Am 2002;29:455–473.

1997 to determine clinical risk factors for endometrial hyperplasia in perimenopausal women. Forty-six cases of endometrial hyperplasia and 6 cases of endometrial cancer were diagnosed. The following factors were independently associated with risk of endometrial hyperplasia or presence of carcinoma: age  $\geq 45$  (odds ratio [OR] 3.1, 95% confidence interval [CI] 1.5–6.1), weight  $\geq 90$  kg (OR 5.5, CI 2.9–10.6), history of infertility (OR 3.6, 95% CI 1.3–99), family history of colonic carcinoma (OR 5.0, 95% CI 1.3–19.1) and nulliparity (OR 2.8, 95% CI 1.1–7.2). The authors noted no increased association of endometrial hyperplasia on the basis of menstrual cycle irregularity or duration of menstrual bleeding. Overall the rate of hyperplasia or carcinoma in women who underwent endometrial biopsy for abnormal uterine bleeding was 5%. Ash<sup>13</sup> reported a rate of 6.7% in a similar study. In light of the greater than 60% rate of overweight and obesity currently epidemic in the United States, the finding that body mass index (BMI) and weight gain are independent risk factors for endometrial cancer is significant. A body weight equal to or greater than 90 kg is the most important risk factor in the current study,<sup>13</sup> probably based on peripheral conversion of estrogen precursors.

Outpatient office sampling of the endometrial cavity is fundamental to the evaluation of abnormal uterine bleeding. Traditional dilation and curettage (D&C) under anesthesia and biopsy by rigid Novak curette has been replaced by flexible cannula biopsy (e.g., Pipelle cannula and Milex cannula). The device may usually be placed without requirement of cervical dilation and causes brief and minimal discomfort. If it is difficult to insert the 3 mm cannula secondary to cervical stenosis in a nulliparous or elderly patient, 1% lidocaine may be utilized to infiltrate the cervix in a circumferential fashion. Small Pratt or Hagar dilators starting with 1 mm may then be utilized to explore the cervical canal and axis of the endometrial cavity. Once the axis of the upper cervical canal is noted, the cervix may be safely dilated to 4 mm to accommodate the flexible biopsy cannula. In general, more than 90% of patients may be safely sampled in the office without significant discomfort. If small graduated dilators are not available, a standard Papanicolaou (Pap) smear brush may be utilized to give an assessment of cervical axis and patency. An attempt should be made to sample the endometrial cavity in a 360-degree rotation, and adequate sampling is usually obtained.

Transvaginal ultrasound has replaced abdominal ultrasound as the standard technique of initial pelvic anatomy and endometrial evaluation. Goldstein et al<sup>14</sup> reviewed 433 women who had abnormal uterine bleeding in perimenopause. Sixty-five percent were able to be adequately evaluated by transvaginal study. The remainder underwent saline-infused sonohysterography secondary to endometrium greater than 5 mm or inadequate assessment. The author recommended hysteroscopic biopsy if an abnormality was demonstrable.

Saline infusion sonohysterography and hysteroscopy are currently playing a larger role in the evaluation of perimenopausal women with abnormal bleeding. Hysteroscopic biopsy has been considered the gold standard of comparison; however, it requires an anesthetic or at least conscious sedation to provide adequate comfort for the patient. Bernard and colleagues<sup>15</sup> prospectively reviewed 233 perimenopausal and postmenopausal patients, finding a sensitivity of 85.7% and specificity of 95.4% in the

diagnosis of polyps and submucous myomas. A review of sonohysterography findings in 100 asymptomatic women 30 years of age or older matched to 80 similar women with abnormal bleeding by Clevenger-Hoeft et al<sup>16</sup> revealed a higher incidence of polyps, intracavitary myomas, and intramural myomas.

Bronz et al,<sup>17</sup> deVries et al,<sup>18</sup> and Farquhar et al<sup>19</sup> have compared transvaginal sonography, saline-infused sonography (SIS), and hysteroscopy in the evaluation of perimenopausal women with abnormal bleeding. Bronz and deVries found specificity was significantly improved by saline infusion (95% vs 21%). Farquhar performed a review of 19 studies, finding that while all studies were accurate in detection of intrauterine pathology, SIS and hysteroscopy performed better than transvaginal sonography in detecting submucous fibroids. Transvaginal sonography was noted to be a sensitive test for the diagnosis of endometrial hyperplasia in perimenopausal women when the endometrial thickness was equal to or greater than 12 mm.

DeVries et al<sup>18</sup> studied 62 patients who underwent transvaginal ultrasonography (TVS), SIS, and finally hysteroscopy for abnormal uterine bleeding. Most of these women were perimenopausal (mean age, 44 years; range, 36 to 54). SIS demonstrated higher accuracy in the diagnosis of intracavitary abnormalities than did TVS.

The study also reviewed accuracy of TVS in diagnosis of endometrial hyperplasia in premenopausal women. Previously, cutoff levels of 8 mm, 10 mm, and 12 mm had been proposed. However, in the study, endometrial measurement alone provided poor diagnostic results. TVS definition of an abnormality (i.e., endometrial thickness of  $>5$  mm) yielded sensitivity of 85% and specificity of 21%, but would have resulted in many unnecessary D&Cs or hysteroscopic procedures. If SIS had been used as the triage method in the study, diagnostic hysteroscopy would have been avoided in 72% of cases. SIS was also able to distinguish characteristics of the myometrium and therefore would have been more suitable for defining the degree of extension of myomas. In fact, Widrich and coworkers<sup>20</sup> found diagnostic accuracy of SIS to be similar to that of hysteroscopy (Table 61-6).<sup>18–20</sup> The authors concluded that SIS was the diagnostic tool of choice in evaluation of perimenopausal women with abnormal uterine bleeding (sensitivity of 88% to 100%, specificity of 76% to 98%) for diagnosing intracavitary abnormalities.

Kaunitz<sup>10</sup> has recommended an algorithm for the evaluation of perimenopausal abnormal uterine bleeding. A thorough history and physical examination are performed. Pregnancy and other intrauterine causes of bleeding are ruled out, and an in-office endometrial biopsy is then performed. If the histology study is benign, medical management is instituted. If medical management does not result in a satisfactory bleeding profile, the next step is transvaginal sonography. If measurements are greater than 5 mm, saline-infused sonohysterography is the next step.

Hysteroscopy may be utilized as an alternative to SIS and permits direct visualization of polyps and submucous myomas and may be performed in an appropriate office setting<sup>21</sup>; however, it requires local anesthesia and or conscious sedation to avoid significant patient discomfort. Goldstein et al<sup>14</sup> and Kaunitz<sup>10</sup> recommend reserving hysteroscopy for the patient with an unclear diagnosis, recurrent bleeding after treatment of other findings, and with lesions requiring biopsy or excision that are

noted on SIS. Figure 61-7 demonstrates one of several logical schema for management of abnormal bleeding in the perimenopausal female.

### MEDICAL MANAGEMENT OF ABNORMAL UTERINE BLEEDING

If the evaluation outlined previously reveals no evidence of pathology requiring surgical excision or correction, a variety of options exist for therapy of hormonally induced bleeding.

Proliferative endometrium or hyperplasia without atypia may be treated with cyclic or acyclic progestational agents or oral contraceptives (OCs). Medroxyprogesterone acetate 10 mg daily for at least 10 days per month, or micronized progesterone 200 mg daily at bedtime, should result in menstrual cycle regulation and reversal of hyperplasia. If abnormal bleeding does not resolve, then hysteroscopy and D&C should be considered to rule out malignancy.

#### Oral Contraceptives

In the nonsmoking, nonhypertensive patient without a history of deep vein thrombosis or other contraindication, combination estrogen/progesterone contraceptives are ideal for control of menstrual irregularity. Some currently available options are listed in Table 61-7.<sup>14</sup> Kaunitz<sup>22</sup> has recently reviewed use of OCs in menopause. The American College of Obstetricians and Gynecologists Practice Bulletin recommends OC formulations as the treatment of choice for anovulatory uterine bleeding.<sup>23</sup>

A variety of preparations including triphasic<sup>24</sup> and low-dose monophasic OCs are effective in correction of anovulatory bleeding. However, to date no OC has received FDA approval for this purpose. Many clinicians prefer formulations containing 20 µg of ethinyl estradiol (EE) for perimenopausal women. However, cycle control may not be as good with lower estrogen

doses. Newer, 25 µg EE triphasic low-dose OC formulations provide good cycle control.<sup>25</sup> Other options including transdermal contraceptive patches and vaginal rings have been used with good success.

Hormone therapy regimens used for postmenopausal therapy have been utilized in some women. However, these regimens do not suppress ovulation and may make bleeding worse.<sup>22</sup> Kaunitz<sup>26</sup> has reviewed use of oral or transdermal estradiol and depot medroxyprogesterone acetate in these women as opposed to standard postmenopausal hormone therapy. The combination suppresses ovulation, produces amenorrhea, and treats vasomotor symptoms commonly encountered in this group. Another option is use of fixed-dose hormone therapy combinations containing estradiol 1 mg plus norethindrone acetate 0.5 mg or ethinyl estradiol 5 µg plus norethindrone acetate 1 mg. The preceding

**Table 61-7**  
**Contraceptive Formulations**

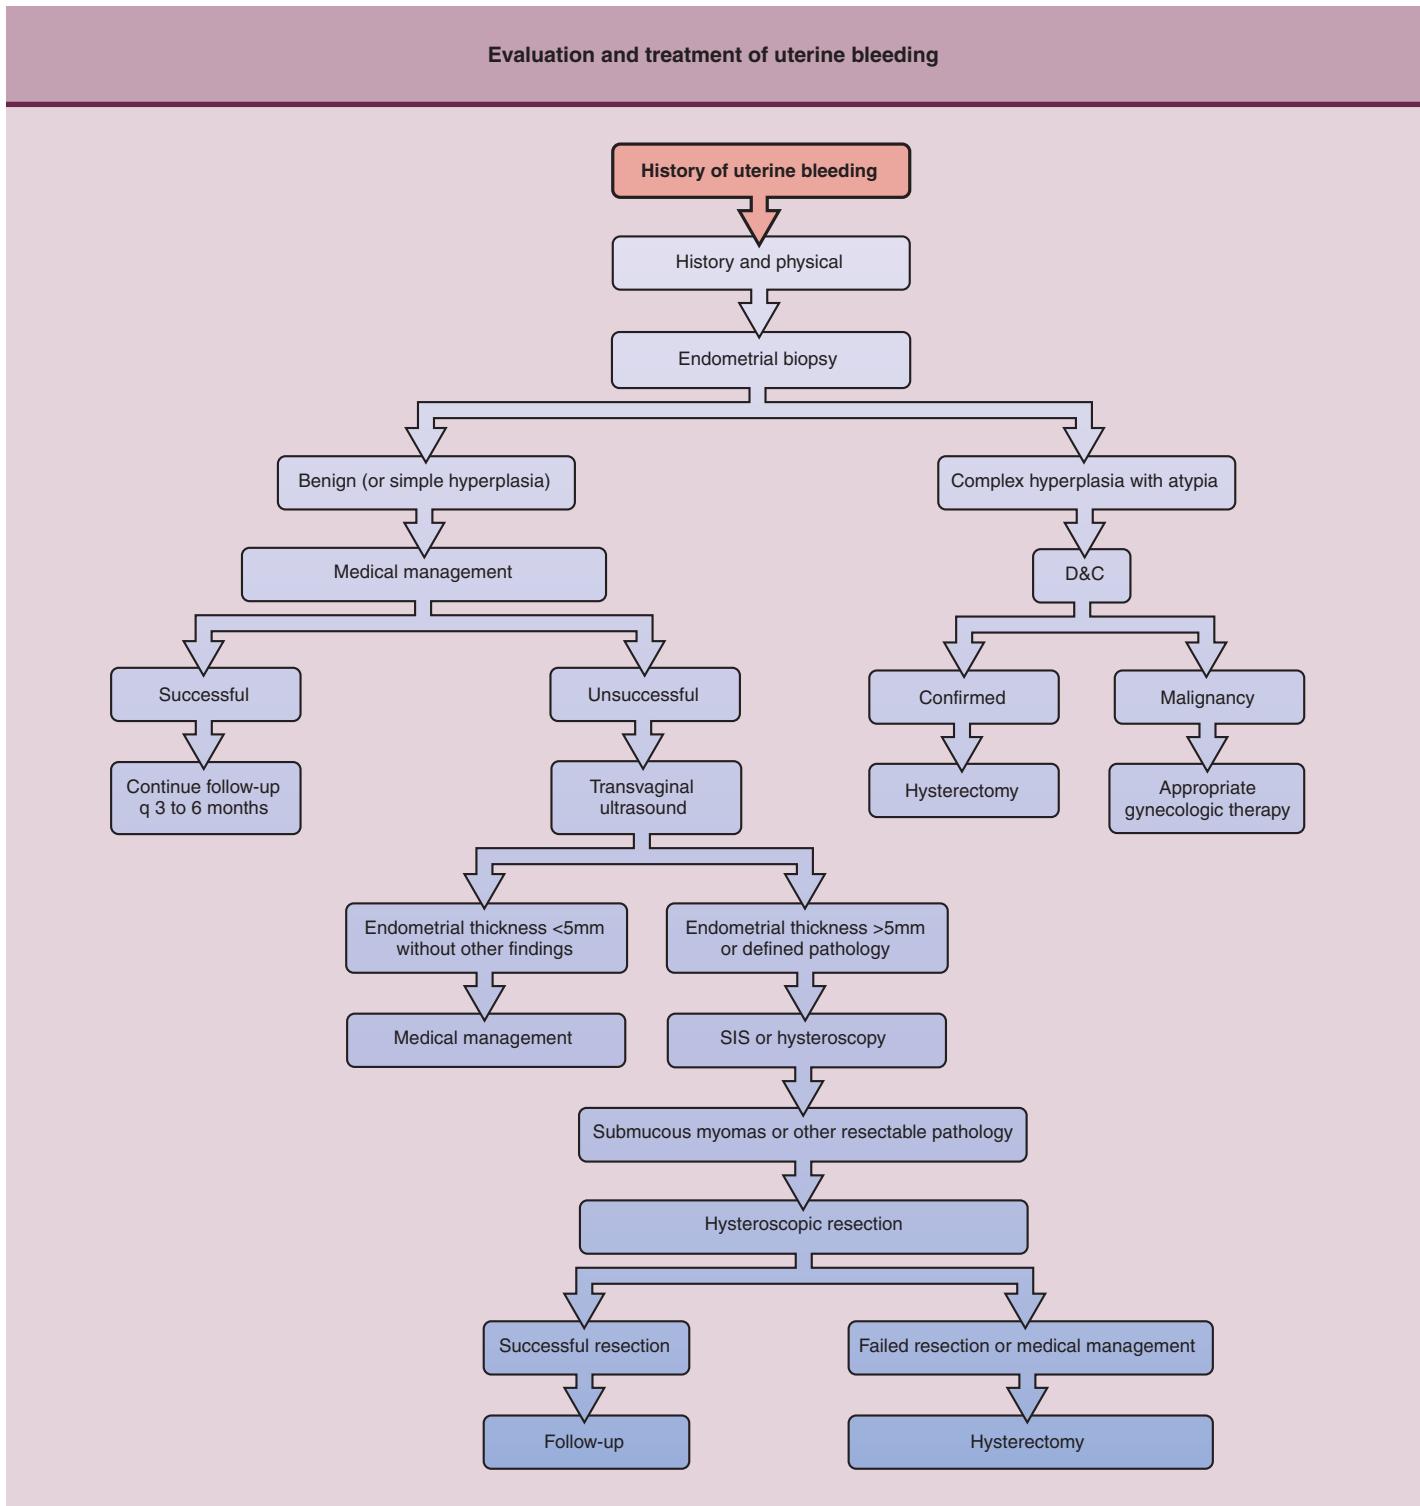

#### Cyclical formulations

Low estrogen dose ( $\leq 35 \mu\text{g}$ ) combination oral contraceptives  
Weekly transdermal contraceptive patch: 150 µg norelgestromin/20 µg ethinyl estradiol daily (Ortho Evra)  
Three-week contraceptive vaginal ring: ~120 µg etonogestrel/15 µg ethinyl estradiol per day (NuvaRing)  
Three-month depot medroxyprogesterone acetate injection: 150 mg per injection (Depo-Provera) plus oral or transdermal estradiol  
Levonorgestrel intrauterine device (Mirena) plus oral estrogen

#### High progestin dose combination menopausal formulations

Norethindrone acetate 0.5 mg/estradiol 1 mg (Activella)  
Norethindrone acetate 1 mg/ethinyl estradiol 5 µg (femhrt)

From Kaunitz AM: Gynecologic problems of the perimenopause: evaluation and treatment. Obstet Gynecol Clin North Am 2002;29:455-473.

**Figure 61-7 Algorithm for evaluation and treatment of uterine bleeding.** SIS, saline-infused sonography.

regimen may then be continued for menopausal therapy if indicated.

### Progestin Therapy

Cyclic oral progestin therapy has been long utilized for treatment of dysfunctional uterine bleeding. Table 61-8 lists doses

that may be used for 12 to 14 days per month and yield good results. Cyclic progestins are especially useful in the obese patient who exhibits excess estrogen from peripheral aromatization. Endometrial protection should be documented by biopsy. Use of danazol, while successful in reducing menstrual flow, is limited by significant side effects of hirsutism, weight gain, and acne.

Table 61-8 Oral Cyclic Progestin-only Regimens for Treatment of Abnormal Uterine Bleeding in Perimenopausal Women		
Progestin	Tablet Strength	Daily Dose*
Medroxyprogesterone acetate	2.5, 5, 10 mg	5–10 mg
Norethindrone acetate	5 mg	2.5–5 mg†
Norethindrone	0.35 mg	0.7–1 mg‡
Danazol	50, 100, 200 mg	200 mg

\*Administered for 12–14 days each month.

### Intrauterine Systems

A levonorgestrel-containing intrauterine system (IUS) has been available in the United States for a number of years. Several older studies and a Cochrane review<sup>27</sup> have established that the IUS is as effective in menstrual control as norethindrone and allows some women considering surgical therapy to continue medical therapy of dysfunctional uterine bleeding. Hurskainen et al<sup>28</sup> established that the IUS resulted in patient satisfaction and allowed hysterectomy to be avoided in a study group. Hubacher and Grimes<sup>29</sup> reviewed the literature of non-contraceptive benefits of IUSs and concluded that the levonorgestrel intrauterine system may treat a variety of gynecologic disorders, including menorrhagia and anemia. Use of non-hormonal IUSs was associated with a decrease in endometrial cancer.

### SURGICAL MANAGEMENT OF ABNORMAL UTERINE BLEEDING

Hysterectomy is the second most common surgical procedure performed in reproductive age women in the United States, most commonly for leiomyomata. Utilization of laparoscope-assisted vaginal hysterectomy (LAVH), laparoscopic subtotal hysterectomy, and laparoscopic total hysterectomy have supplemented the standard options of vaginal or transabdominal hysterectomy. When hysterectomy is indicated for medically unresponsive bleeding, the surgeon should utilize the procedure best indicated by his or her experience, the disease process, and the patient's clinical circumstances.

### Endometrial Ablation

Various laser-focused endometrial ablation techniques have gradually been replaced by thermal balloon ablation and other types of thermal ablation including bipolar, microwave, and cryoablation. These techniques have a shorter learning curve and reasonable rates of decreased uterine bleeding and amenorrhea. Several issues should be kept in mind when choosing these techniques. First, malignancy should be ruled out by endometrial sampling prior to use. Second, the techniques do not adequately treat intrauterine pathology such as polyps. Therefore, it is wise to evaluate the endometrial cavity with hysteroscopy or SIS and

remove the lesion prior to therapy. Third, pretreatment with danazol or a gonadotropin-releasing hormone (GnRH) analog should be considered although Lissak and colleagues<sup>30</sup> noted no difference in response between immediate and delayed therapy.

### OTHER BENEFITS OF ORAL CONTRACEPTIVES FOR PERIMENOPAUSAL WOMEN

#### Contraception

The most obvious benefit of OCs to perimenopausal women is birth control. Although fertility significantly decreases in perimenopause, ovulation frequently continues. Data suggest that 80% of women aged 40 to 49 may potentially conceive. Data from the National Survey of Family Growth showed that 51% of pregnancies occurring in women 40 years of age or older were unintended and 65% of those resulted in abortion.<sup>31</sup> Women over age 35 can use OCs or transdermal contraceptives provided they do not smoke or have other cardiovascular risk factors (Table 61-9).<sup>32</sup> Most authors recommend use of lower dose OCs in perimenopausal women; however, the major difference in risk of venous thromboembolic events appears to occur between 50 µg EE pills and those containing 30 to 35 µg. Until 1995, the conventional wisdom held that risk of thrombosis in OCs was related to the estrogen component and the progestin component was not thought to affect clinical thrombosis. In 1995, three papers reported an increase in thrombosis associated with two new progestins (desogestrel and gestodene). Follow-up studies reported both increased and unchanged rates of thromboembolism. Two recent reviews of third-generation progestins concluded that the risk of venous thromboembolism was higher than second-generation products.<sup>33,34</sup> For a complete discussion of general oral contraceptive risks and benefits, see Chapter 58.

#### Fracture Prevention

Bone mass peaks in females at approximately age 22. After age 40, bone loss may approach 1% per year and increase to 3% to 5% per year in postmenopausal women. Women who take OCs have been shown to preserve bone mass, and a study by Michaelsson of women in their 40s who took OCs showed a decreased risk of hip fracture of 30% compared with those who had never used OCs (Table 61-10).<sup>35</sup>

### Lipid Profile

Table 61-11<sup>36</sup> shows the results of a recent study of triphasic OCs on the lipid profile of a group of perimenopausal women. Whether these results have significant clinical implications for the average perimenopausal female is unknown. It appears, however, that OCs do not have an unfavorable effect in the clinically low-risk individual.

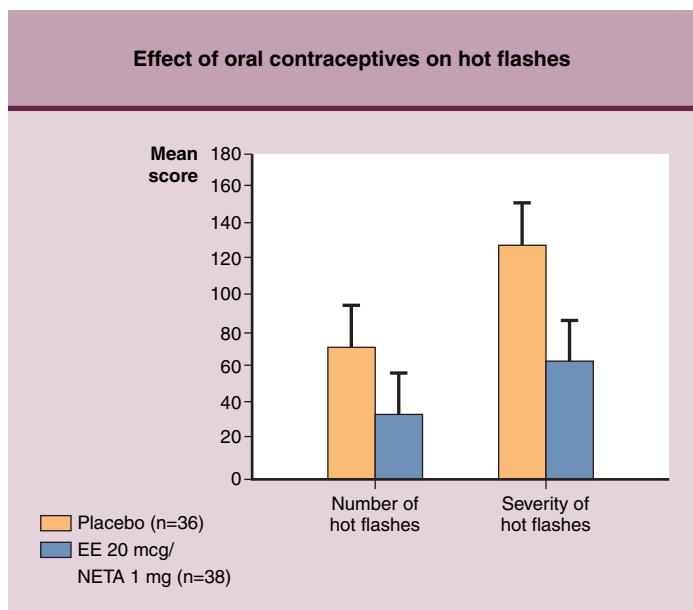

### Vasomotor Symptoms

Approximately 85% of perimenopausal women experience vasomotor instability with marked variation in frequency, duration, and intensity.<sup>37</sup> Studies reviewing treatment of hot flashes and other perimenopausal symptomatology are difficult to perform secondary to a 30% placebo effect. However, placebo-controlled,

Contraception 1999;59:161–166. © 1999, Elsevier Science; and Kaunitz AM: Oral contraceptive use in perimenopause. Am J Obstet Gynecol 2001;185:S32–S37.

**Figure 61-8** Oral contraceptives decrease the number and severity of hot flashes in perimenopausal women in a randomized, double-blind, placebo-controlled, six-cycle trial. EE, ethinyl estradiol; NETA, norethindrone acetate. (Adapted with permission from Casper RF, Dodin S, Reid RL, and Study Investigators: The effect of 20 µg ethinyl estradiol/1 mg norethindrone acetate [Minestrin], a low-dose oral contraceptive, on vaginal bleeding patterns, hot flashes, and quality of life in symptomatic perimenopausal women. Menopause 1997;4:139–147.)

double-blind, randomized studies of OCs have shown approximately 50% fewer hot flashes in the treatment group (Fig. 61-8).<sup>38</sup> Not only was the frequency of hot flashes decreased but the severity also was decreased by 50% compared with placebo. However, because of the significant placebo effect, the differences were not statistically significant.

### Endometrial and Ovarian Cancer

OCs have been shown to decrease the incidence of both endometrial and ovarian cancer presumably owing to progestin action on the endometrium and prevention of ovulation. Endometrial and ovarian cancer is reduced by 40% in a variety of studies. In addition, the effect appears to continue for 15 years following one or more years' use. Perhaps more importantly, the effect appears applicable to women with a family history of breast and ovarian cancer.<sup>39</sup>

### Miscellaneous Benefits

The incidence of pregnancy is obviously reduced in perimenopausal women taking OCs; likewise, the incidence of ectopic pregnancy is decreased. In addition, OCs have been shown to reduce the incidence of ovarian cysts.

### Pelvic Inflammatory Disease

Older studies indicated that women on OCs may be at increased risk for cervical *Chlamydia* infection. However, other studies indicate that the incidence of pelvic inflammatory disease (PID) and the clinical and laparoscopic severity of PID are reduced

## Reproductive Endocrinology and Infertility

by 40% to 60% in patients taking OCs. The mechanism may be the effect of progestins on cervical mucus or modification of the immune response. Perimenopausal women taking OCs have shorter and lighter menses. In addition, endometrial atrophy affected by contraceptive pills and decreased uterine contractility may decrease movement of bacteria into the upper genital tract. While in vitro studies indicate that progestins may inhibit the growth of gonorrhea, animal studies indicate that estrogen and progestin may facilitate the ascent of *Chlamydia trachomatis* into the upper tract. Ness et al<sup>40</sup> appear to have confirmed this hypothesis in an animal model. A summary of oral contraceptive benefits is shown in Table 61-12.<sup>5</sup>

### Vasomotor Symptoms and Sleep Disturbances

Vasomotor symptoms, including hot flashes (hot flushes) and night sweats, are reported by women of all ages. While common in the postmenopausal period, hot flash occurrences become more frequent during perimenopause, peak about the time of the last menstrual period, and decline after menopause, as reported in the MWHS.<sup>4</sup> Women who had long perimenopausal transitions reported more prominent hot flashes than women who had short transitions to menopause.

The "hot flash" describes a sudden onset of erythema affecting the upper body, chest, and head, accompanied by a feeling of intense body heat and sweating. Hot flashes may be frequent or rare and vary from several seconds to one hour in duration. They are most disturbing when occurring at night and cause marked lack of sleep and subsequent problems in daily functioning secondary to fatigue. A cool environment may mitigate the effects of hot flashes.

Hot flashes are not confined to postmenopausal women. In the MWHS, the incidence was 10% in premenopausal women; 37% to 50% in perimenopausal women, 50% at about the time of the last menstrual flow; and 20% to 62% in postmenopausal women. By 4 years after menopause, the incidence had decreased to 20%.

The physiology of hot flashes is incompletely understood. They are most commonly related to decreased or fluctuating estrogen levels encountered in the peri- and postmenopausal time period. However, not all hot flashes are due to estrogen deficiency. Other conditions such as diabetes and thyroid disease that first manifest in the perimenopausal age group also may mimic hot flashes. A differential diagnosis of hot flashes is listed in Table 61-13.<sup>10</sup>

From Kaunitz AM: Gynecologic problems of the perimenopause: evaluation and treatment. Obstet Gynecol Clin North Am 2002;29:455-473.

Estrogen and progestins in combination (for women with a uterus) or estrogen alone has long shown reasonable efficacy in relief of hot flashes in postmenopausal women. However, use of standard hormone therapy for perimenopausal women is controversial. Shulman and Harari<sup>41</sup> studied 22 consecutive menstruating perimenopausal women with vasomotor symptoms in an open-label observational study over 12 months. All patients received estradiol 0.025 mg/day administered through a transdermal weekly patch for 12 months. The authors administered unopposed estrogen feeling that in women who continue to menstruate, unopposed estrogen is unlikely to prove a risk to the endometrium. Forty-five percent of patients reported complete relief and an additional 27% moderate relief of symptoms in this study. Other authors recommend periodic administration of progestin if exogenous estrogen is used in perimenopausal women, menstruating or not (see Chapter 60).

**Table 61-12**

#### Benefits of Oral Contraceptive Use in Perimenopausal Women

- Effective contraception (if needed)
- High bone density/fewer fractures
- Prevention of ovarian and endometrial cancers
- Reduction in vasomotor symptoms
- Treatment of acne
- Treatment of irregular menses/dysfunctional uterine bleeding, menorrhagia, and/or dysmenorrhea

From Kaunitz AM: Oral contraceptive use in perimenopause. Am J Obstet Gynecol 2001;185:S32-S37.

### Sexual Dysfunction and Vulvovaginal Changes

Sexual dysfunction, most often vulvovaginal dryness secondary to decreased estrogen or decreased libido, is common in perimenopause. In addition, irregular menses, hot flashes, and sleep disturbances have an adverse effect on sexuality at this time. Weight gain and emotional issues about body image, marital relations, and social relations also are common. Nachtigall<sup>37</sup> and others have written extensively regarding physiologic changes in perimenopause that may adversely affect sexual function.

Vulvovaginal dryness, irritation, and dyspareunia are common. Even though estradiol levels may be elevated, vaginal dryness (75%) and decreased vaginal lubrication are frequently reported. Kaunitz<sup>42</sup> summarized recommendations in this regard and a recent meta-analysis<sup>43</sup> has shown that vaginal low-dose estrogen is as effective as systemic estrogen in relief of symptoms. Compared with systemic estrogen, local therapy may even be more effective<sup>44</sup> for relief of vaginal symptoms. Vaginal creams are often not well accepted secondary to soiling of bed linens and clothing. However, estradiol vaginal tablets and rings are efficacious.<sup>45,46</sup> Many women begin experiencing increasing urinary incontinence in this age range, whether overflow, urge, or mixed incontinence. Until recently, both oral and vaginal estrogen have been recommended for improvement of these symptoms. Both older and current studies, e.g., the heart and estrogen progestin replacement study HERS,<sup>47</sup> found no improvement in urinary incontinence associated with systemic hormone therapy.

### OSTEOPOROSIS IN PERIMENOPAUSAL WOMEN

More than 60 years ago it was recognized that postmenopausal women developed vertebral fractures leading to pain, disfigurement, and dysfunction. It is now estimated that the annual cost of osteoporosis in the United States exceeds \$14 billion and affects 28 million persons. The morbidity and mortality associated with a hip fracture are significant, and only 15% of those affected women return to their previous lifestyle. Females exhibit maximal bone mass in their early 20s, with maintenance and remodeling until approximately the time of menopause. Perimenopause and associated symptoms give gynecologists the opportunity to be effective in screening and treatment of this significant disease.

Risk factors for osteoporosis are listed in Table 61-14<sup>48</sup> (see Chapter 1). Women at risk for osteoporosis should be screened when they exhibit signs of estrogen deficiency or if they are at high risk by other criteria. If osteopenia or osteoporosis are detected, therapy should be initiated in the same fashion as for the postmenopausal female.

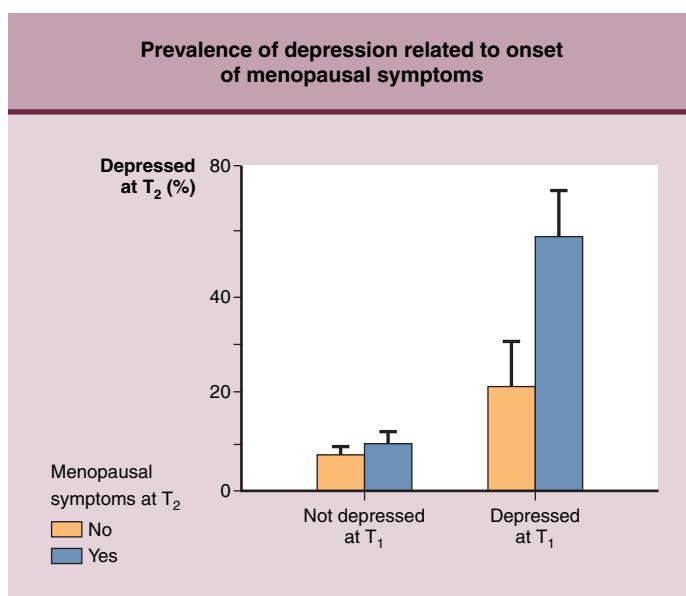

Table 61-14 Risk Factors for Osteoporosis

### DEPRESSION IN PERIMENOPAUSAL WOMEN

The perimenopausal period is often associated with depression. Granted, it is a time of physiologic and hormonal change, but also it is a time of peak performance in careers with accompanying job stress and of balancing career aspirations with family and possibly caregiving to aging parents. Any of the foregoing may cause enough turmoil to elicit depression in a susceptible individual. However, contrary to popular assumptions, while depression is more common in women at all ages than in men, the perimenopausal and menopausal time period is not itself a major risk factor for depression. In fact, most studies indicate that a history of previous depression is the strongest predictor of future depression. In the MWHS,<sup>4</sup> a diagnosis of depression at study entry was the strongest predictor of depression at the close of the study 25 months later. The MWHS noted that the highest incidence of depression occurred in those who remained perimenopausal throughout the period of observation (Fig. 61-9).<sup>4</sup> Increased depression appeared to be related to the continued presence of menopausal symptoms rather than the menopausal status per se (Fig. 61-10).<sup>4</sup> Therefore, the physician should be aware of the possibility of depression in perimenopausal females, especially those who have had symptoms for a longer period of time and those with a previous history of depression (Table 61-15).

Depressive-type symptoms coinciding with the onset of perimenopausal symptoms in the patient without a history of previous depression should raise suspicion of hormone-related episodes. In these persons, a trial of hormone therapy may be considered.

**Figure 61-9 An increased prevalence of depression was related to the onset of menopausal symptoms.** Study subjects were evaluated for depression at the beginning of the study (T<sub>1</sub>) and again 27 months later (T<sub>2</sub>). (From Avis NE, Brambilla D, McKinlay SM, Vass K: A longitudinal analysis of the association between menopause and depression: results from the Massachusetts Women's Health Study. Ann Epidemiol 1994;4:217.)

**Figure 61-10 Previous depression is the greatest predictor of future depression.** Women at different stages in the menopausal transition were evaluated for depression at the beginning of the study (T<sub>1</sub>) and again 27 months later (T<sub>2</sub>). This illustration reports the rate of depression among women at premenopausal, perimenopausal, and postmenopausal stages. For women across all stages, those who were depressed at the beginning of the study (T<sub>1</sub>) had higher rates of depression 27 months later (T<sub>2</sub>). For women who were not depressed at T<sub>1</sub>, rates of depression increased slightly among women who moved from the premenopausal stage into the perimenopausal stage and were highest for women who remained at the perimenopausal stage for at least 27 months. In the same group, depression began to decrease as women became postmenopausal and was lowest among those who were postmenopausal for at least 27 months. (From Avis NE, Brambilla D, McKinlay SM, Vass K: A longitudinal analysis of the association between menopause and depression: results from the Massachusetts Women's Health Study. Ann Epidemiol 1994;4:217.)

It is unclear whether there is a relationship between hormones and changes in neurotransmitters that may be related to depression. However, estrogens have been shown to potentiate the efficacy of fluoxetine therapy for depression.

In addition to exogenous job and family-related stress, women may encounter self-image stress during perimenopause.

**Table 61-16**  
**American Psychiatric Association Criteria\* for Diagnosis of Major Depression**

- Depressed mood most of the day, nearly every day
- Diminished interest in most activities most of the day, nearly every day
- Significant weight loss or gain
- Insomnia or hypersomnia
- Psychomotor agitation or retardation
- Fatigue
- Feelings of worthlessness or guilt
- Indecisiveness
- Recurrent thoughts of death or suicide

\* At least 5% of the preceding criteria, including either of the first two most of the time for at least 2 weeks.

From Association of Professors of Gynecology and Obstetrics: Managing the Perimenopause. APGO Educational Series on Women's Health Issues. Washington, DC, APGO, 2001, pp 1-20.

Realization of the end of reproductive years and the “empty nest syndrome” may be particularly troublesome to some individuals. It is therefore incumbent upon the physician to inquire about the preceding issues in a caring and sensitive fashion to ascertain whether a significant potential for depression exists and if it requires therapy. The American Psychiatric Association has established criteria for diagnosis of major depression (Table 61-16).

## FERTILITY IN PERIMENOPAUSAL WOMEN

Secondary to changes in career orientation, marriage, and the aging “baby boom” generation, the proportion of older primiparous women (>35 years) is expected to exceed 25% in Western countries in 2005. Although uncommon, spontaneous pregnancies occur even into the fifth and sixth decade of life. How old is old then in relation to fertility? In the United States, it is estimated that rates of infertility are 10% at 20 to 29 years of age, 25% at 30 to 39 years of age, and 50% over 40 years of age. The estimated rate of a spontaneous pregnancy is 2% at age 42 and almost zero after 45 years. The implantation rate also drops from 20% at age 30 to less than 4% at age 40, as do birth rates. Age 41 is generally considered the time when fertility stops, and menopause occurs approximately 10 years after loss of conception potential. The percentage of women who do not succeed in conceiving after 1 years’ time increase from 5% at less than 25 years of age to 30% at more than 35 years of age.

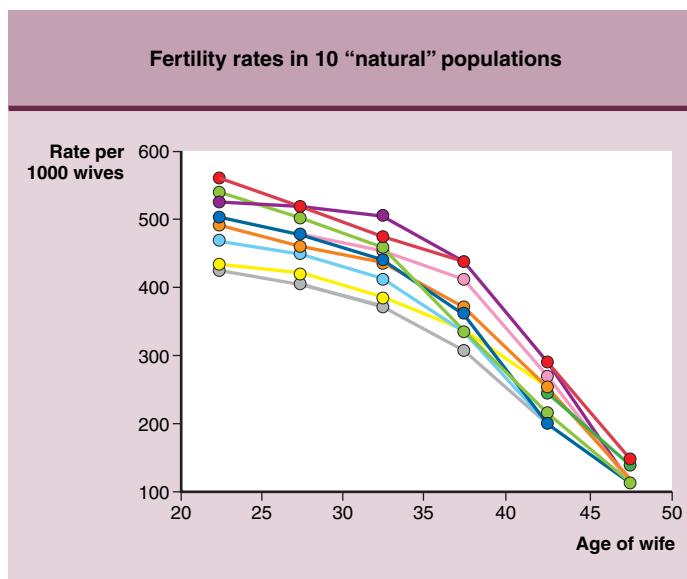

Fertility has been studied in several stable, fertile populations, most notably the Hutterites (Fig. 61-11 and Table 61-17).<sup>49,50</sup> In this population, the height of fertility was between 18 and 30, but fertility was present in 86% of women at age 36, 66% at age 40, and 13% at age 45.

As previously indicated, ovarian reserve decreases with advancing age from 4 to 7 million oocytes at 20 weeks of gestation to 400,000 at birth. The pool of follicles declines exponentially, and from age 35 forward, accelerated loss occurs so that by age 38 a woman may have only 25,000 follicles; at age 40, 1500; at age 45, 5000; and in the early 50s, only a few hundred. Furthermore, polymorphisms of genes and a decrease

**Figure 61-11 Fertility rates in 10 "natural" populations.** (Reprinted with permission from Menken J, Trussell J, Larsen U: Age and infertility. Science 1986;233:1389–1394. ©1986 American Association for the Advancement of Science.)

in the quality of oocytes may occur, as indicated by the increased number of oocyte aneuploidies noted in women greater than 37 years of age undergoing in vitro fertilization (IVF). Therefore, in the perimenopausal woman, oocyte aneuploidies reduce the chance of successful fertilization, implantation, and development. Interestingly, juvenile and adult mouse ovaries possess mitotically active germ cells that, based on rates of oocyte degeneration (atresia) and clearance, are needed to continuously replenish the follicle pool. These data tentatively established the existence of proliferative germ cells that sustain oocytes and follicle production in the postnatal mammalian ovary. These data are contrary to the basic doctrine of mammalian development that has been accepted for many years.<sup>51</sup>

By most epidemiologic data, the probability of pregnancy in perimenopause is low and the spontaneous abortion rate in clinically recognized pregnancies increases from 10% before age 30 to 34% at age 40, and to 50% to 75% at after age 45 years.

From the American Society for Reproductive Medicine; and Klein J, Sauer MV: Assessing fertility in women of advanced reproductive age. Am J Obstet Gynecol 2001;185:758–770.

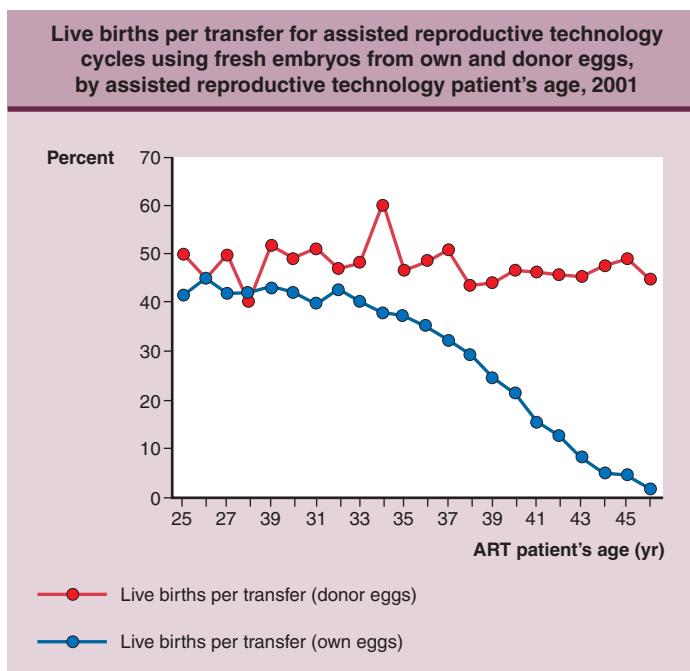

In addition, some fetuses are noted to have chromosomal anomalies.

After age 40 the likelihood of a successful response to assisted reproductive technology decreases and most women are considered to have a poor prognosis for successful fertility. In couples undergoing IVF/embryo transfer therapy, implantation, clinical pregnancy, and live birth rates drop with advancing age. The quoted implantation rate is less than 6% after age 40, and the live birth rate is less than 3.5% after age 45 and 8% between ages 40 and 45 (Fig. 61-12).<sup>52</sup>

Oocyte donation was used initially in women with inherited defects but now has been applied to those wishing to extend child-bearing potential into later years. These pregnancies have a significantly higher success rate than conventional IVF (Fig. 61-13). For example, in the United States in 1999 (the last year for which such data are available), 5844 donor oocyte cycles resulted in a live birth rate of 41.1%, whereas in women undergoing IVF, the rate was 9.7%. In the United States more than 70% of all assisted reproductive technology cycles at age 46 involve donor eggs. If oocytes are donated by young women to older women, implantation and pregnancy rates are normal in the recipients regardless of age. Therefore, the limiting factor appears to be largely the condition of oocytes and not necessarily the uterus of the woman. However, pregnancies after donation incur a higher risk of obstetric complications including vaginal bleeding (12% to 50%), pregnancy-induced hypertension (16% to 40%), premature rupture of membranes (6%), and premature labor (13% to 56%).<sup>53</sup> The interested reader is referred to the Klein and Sauer<sup>50</sup> review of this material.

## HEALTH MAINTENANCE AND SCREENING

Evaluation and treatment of the patient's problems are obviously the most important task in caring for the perimenopausal woman. However, equally important is screening for pathophysiologic conditions that may not be apparent to the patient and encouraging health maintenance. The current epidemic of overweight and obesity associated with "metabolic syndrome," diabetes, and heart disease promise to have a major impact on health care in the next 20 to 50 years in the United States. Therefore, it is incumbent upon the gynecologist to perform proper health screening and make recommendations for prevention or correction of conditions that may compromise the patient in the future.

At the time of the annual well-woman examination, the patient should be asked about smoking, alcohol intake, diet and exercise habits, and stress. A review of personal and family history of chronic and inheritable diseases should be obtained. Standard health screening and laboratory testing appropriate for that age group should be performed (Table 61-18).<sup>54</sup> In addition, the physician should screen for signs of depression.

## LIFESTYLE INTERVENTION: CARDIOVASCULAR DISEASE

Patients need to understand the physiologic consequences of aging and loss of estrogen in the menopausal transition. Despite the new data regarding lack of cardiovascular protection by hormone therapies in older women, younger females (i.e., those who are still menstruating) continue to have low relative rates of apparent cardiovascular disease. Therefore, screening for risk factors of elevated serum lipids, lack of exercise, and improper nutrition is important. Proper nutrition serves to maintain desirable body weight and reduces predisposition to insulin resistance, impaired insulin secretion, hyperglycemia, and reduced pulmonary function. General recommendations should include taking adequate calcium and minerals, increasing fiber intake, limiting alcohol and caffeine, and avoiding high-fat foods. Absorption of dietary calcium is more efficient than from supplements; however, if dietary screening indicates low calcium intake, supplements of 1000 mg/day for women under 51 years and 1200 mg/day for those over 51 years are recommended by the National Osteoporosis Foundation. Calcium, whether from diet or supplements, is best absorbed when taken in amounts of 500 mg or less. Calcium carbonate is best absorbed when taken with food, while calcium citrate may be taken at any time.

Older women, especially those in northern climates where activities take place indoors for much of the year, should be encouraged to add supplements containing vitamin D to their diet. Skin has a decreased ability to synthesize the active form of vitamin D as aging occurs, and lack of exposure to sunlight, especially during the winter, compounds the problem. There is no clear evidence that addition of vitamin D is beneficial in younger, perimenopausal women; however, screening for the recommended daily allowance of 400 IU is encouraged. While vitamin D doses of 400 to 800 IU/day are desirable, women should not consume over 800 IU/day.

## HORMONE THERAPY

Beginning in 1998 with the publication of the HERS and estrogen replacement atherosclerosis (ERA) studies and culminating with data from the Women's Health Initiative (WHI), researchers and patient attitudes regarding the use of hormone replacement therapy have dramatically changed. Hormone therapy (HT), as it is now called, recognizes that according to current convention, a hormone is not being replaced, as is done with the thyroid. Hormones in the form of OCs and conventional hormone therapy have a place in management of the perimenopausal female.<sup>55</sup>

The goals of hormone therapy for perimenopausal and postmenopausal women differ and as do the agents utilized. One major goal in perimenopausal women is to control menstrual irregularity and menorrhagia or metrorrhagia due to hormonal causes. However, many of these same women are also affected by common menopausal symptoms such as irritability, hot flashes, and night sweats. In addition, at least some concern must be given to the inevitable onset of cardiovascular disease, increased vulvovaginal symptoms, and osteoporosis common after hormone production ceases.

If the patient does not have any of the standard contraindications (smoking, history of deep venous thrombosis, etc), it is generally accepted that she may use OCs containing equal to or less than 35 µg EE for menstrual irregularity and dysfunctional bleeding. The obvious advantage of these agents is gonadotropin suppression and contraception.

The use of standard HT is more controversial. Since the standard dose of HT is approximately 25% of the amount of estrogen in a 20 µg contraceptive, some authors argue that hormone levels may continue to fluctuate and result in further bleeding. In addition, an Association of Professors in Gynecology and Obstetrics (APGO)<sup>2</sup> publication states that use of progesterone alone may fail to control menstrual irregularity, since it may not fully suppress FSH and estradiol fluctuation. In addition, the data from the WHI have resulted in a dramatic decrease in HT utilization of all types. Women are now reluctant to begin HT secondary to concern about breast cancer, stroke, and heart disease. Even the long-touted potential of HT to decrease Alzheimer's disease and dementia has been seriously questioned by the WHI.

OCs may be reasonably utilized for those who meet criteria until menopause is established. At that time, the decision must be made whether to change to standard HT or to stop therapy. APGO<sup>2</sup> advocates continuation of OCs until approximately age 50 to 52. OCs may be arbitrarily stopped at that time and the patient followed or transferred to HT. Use of gonadotropin measurements (FSH) to determine the proper timing is controversial. In the past some have advocated day 3 or 7 of the pill-free week to obtain an FSH level. A consistent level of FSH equal to or greater than 20 mIU/mL indicates that menopause has occurred, especially if LH is consistently elevated also. Nevertheless, other authors have utilized HT in perimenopause for therapy of vasomotor symptoms with good results.<sup>41</sup>

There appears to be agreement among most organizations regarding indications of HT. Recommendations from a recent North American Menopause Society (NAMS)<sup>48</sup> statement on use of HT in peri- and postmenopausal women is summarized in Table 61-19. The currently understood risks and benefits of

**Table 61-19**  
North American Menopause Society Recommendations for  
Estrogen and Progesterone in Peri- and Postmenopausal Women

Treatment of moderate to severe menopausal symptoms
Treatment of vulvovaginal atrophy
Progestins for endometrial protection in women with a uterus
No hormone therapy for primary or secondary prevention of coronary heart disease
Progesterins may be associated with increased risk of breast cancer
Hormone therapy is effective for prevention of osteoporosis, but other agents should be considered
Hormone therapy is not recommended for prevention of dementia after age 65
Data from WHI and HERS should be extrapolated with caution to women younger than age 50 who initiate hormone therapy
Use of hormone therapy should be limited to shortest duration consistent with treatment goals of the individual woman
Lower than standard dose of hormone therapy should be considered

From Estrogen and progestogen use in peri- and postmenopausal women: September 2003 position statement of the North American Menopause Society. *Menopause* 2003;10:497-506.

HT in the postmenopausal woman are discussed in detail in Chapter 60.

## KEY POINTS

- Polycystic ovary syndrome (PCOS) is the most common endocrine disorder in reproductive-aged women.
- PCOS is a lifelong disease beginning in fetal life and extending into the postmenopausal period.
- Hyperinsulinemia is the pivotal factor in the pathogenesis.
- PCOS is an inherited disorder that follows an autosomal dominant inheritance pattern although the gene or genes involved are unknown.
- Hyperandrogenemia with or without hyperandrogenism along with oligomenorrhea are the hallmark features of PCOS.
- Anovulation resulting in infertility is a common presentation.
- Obesity worsens metabolic abnormalities such as hyperinsulinemia and hyperandrogenemia.
- Diabetes, lipid disorders, heart disease, and endometrial cancer are metabolic sequelae of PCOS.
- Insulin-sensitizing agents have dramatically changed the management of PCOS. Metformin, an insulin-sensitizing agent, is now the first choice for the treatment of anovulation in PCOS. Weight loss and exercise are the best long-term therapy to decrease the metabolic sequelae of PCOS.

PCOS is a lifelong, multisystem genetic disorder. Although manifestations of PCOS may be present at birth, they are traditionally first noticed in puberty as menstrual irregularities and weight gain. PCOS evolves throughout life into a series of disorders characterized by insulin resistance, premature adrenarche, infertility, hyperandrogenemia, dyslipidemia, and can be related to heart disease, diabetes mellitus, endometrial hyperplasia, and cancer. However, PCOS is best known and most extensively studied as a cause of anovulatory infertility in reproductive-aged women. Patients with PCOS represent a heterogeneous population with different subtypes of the disease. These women have various symptoms depending on their age and the manifestations of the disease. Therefore, numerous diagnostic criteria are used in the literature to detect women with PCOS. Although various short-term symptomatic therapies are available, the best long-term management strategies have not been established. Taken together, all these factors make PCOS a challenging disorder to diagnose, treat, and study.

## EPIDEMIOLOGY, RISK FACTORS, AND PATHOGENESIS

PCOS is most extensively studied as an endocrine disorder of reproductive-aged women. Most studies reporting the prevalence

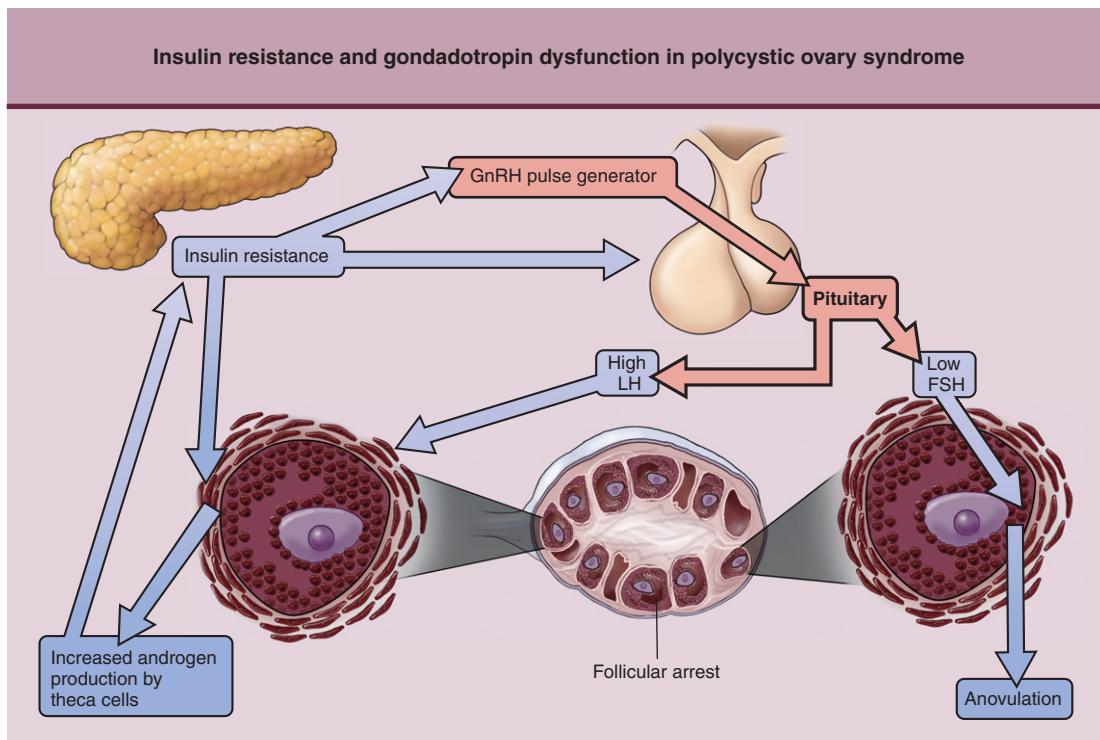

of PCOS are not reliable because of the various diagnostic criteria used for patient selection in each study. However, three well-designed studies have found similar results in different reproductive-aged patient populations.<sup>1–3</sup> The first examined unselected white and African American women who were being evaluated for employment at a large institution and found that 4.7% of whites and 3.4% of blacks had PCOS as defined by 1990 National Institutes of Health (NIH) consensus criteria.<sup>1</sup> Two other studies using similar methods reported a prevalence of 6.8% and 6.5%, respectively, in unselected populations from the Greek island of Lesbos and from Spain.<sup>2,3</sup> In the United States, it is estimated that PCOS afflicts approximately 3 million reproductive-aged women.<sup>4</sup> PCOS is therefore the most common endocrine disorder in the reproductive-aged woman.

Although the principal molecular defect that causes PCOS is still unknown, insulin resistance seems pivotal. Dysfunctional gonadotropin metabolism and excessive androgen production are now believed to be downstream consequences of insulin resistance.

### Insulin Resistance

An association between insulin resistance and hirsutism has been known for decades. The first report describing diabetes in bearded women appeared in 1921 by Achard and Thiers.<sup>5</sup> Burghen et al described the association of hyperinsulinemia with PCOS in 1980.<sup>6</sup> These investigators demonstrated that obese PCOS patients had elevated glucose and insulin levels on a 3-hour glucose tolerance test (GTT) compared with the obese non-PCOS controls. Almost a decade later another study reported that not only obese but also nonobese or lean PCOS patients had greater insulin resistance than weight-matched controls.<sup>7</sup> Now it is generally accepted that 50% to 80% of women with PCOS have at least some insulin resistance. A correlation between serum insulin and androgen levels has been reconfirmed in many studies.

There is compelling evidence that hyperinsulinemia precedes the hyperandrogenism. Suppression of androgens does not restore normal insulin sensitivity.<sup>8,9</sup> Conversely, androgen administration does not produce insulin resistance of the same magnitude as seen in PCOS.<sup>10</sup> Several mechanisms are implicated in insulin-augmented androgen production in the ovary and adrenal gland. Insulin induces pituitary luteinizing hormone (LH) secretion and LH-stimulated androgen synthesis in the ovarian theca cells.<sup>11</sup> Insulin also affects ovarian androgen production directly.<sup>12</sup> Suppression of insulin levels reduces circulating androgens.<sup>13</sup> Adrenal steroidogenesis is also augmented by insulin through increased sensitivity to adrenocorticotropic hormone (ACTH).<sup>14</sup> These findings support the pivotal role of insulin resistance in PCOS (Fig. 62-1).

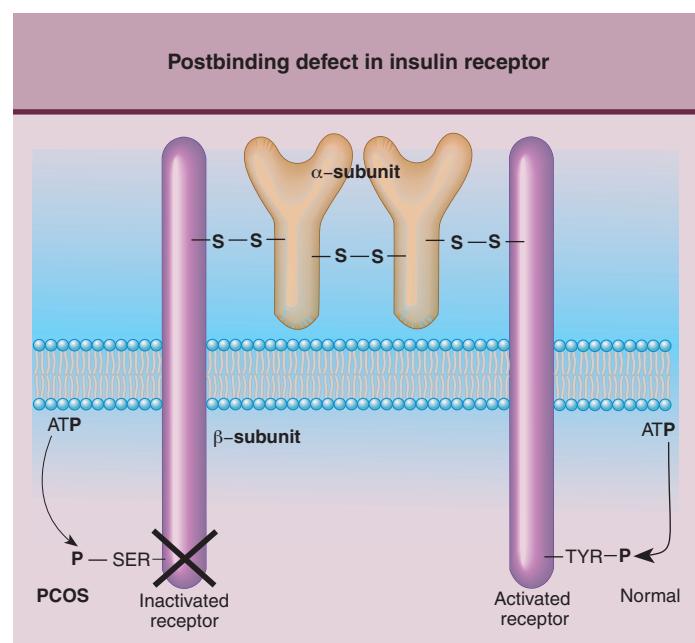

**Figure 62-1** Insulin resistance results in increased luteinizing hormone (LH) and decreased follicle-stimulating hormone (FSH) secretion. Gonadotropin dysfunction leads to follicular arrest and increased androgen production.

The underlying mechanism of insulin resistance is unknown. Insulin receptor number or binding affinity has been shown to be normal in PCOS. No mutations have been identified in the insulin receptor gene. One explanation for the insulin resistance in PCOS is decreased insulin receptor (INSR) tyrosine auto-phosphorylation along with increased serine phosphorylation.<sup>15</sup> INSR has been shown to be inactivated when serine residues are phosphorylated rather than tyrosine residues (Fig. 62-2). This finding suggests a postbinding defect in insulin receptor signaling. Suppressed insulin receptor substrate-1-associated kinase activity has also been reported in some PCOS patients with decreased skeletal muscle glucose uptake compared with matched controls.<sup>16</sup> All these findings are consistent with an obesity-independent insulin receptor-signaling defect. However, obesity increasingly fuels insulin resistance and in turn hyper-androgenemia. Weight loss alone can improve insulin sensitivity and may result in resumption of regular cycles. However, not all PCOS patients have insulin resistance. Furthermore, many women with type 2 diabetes do not have PCOS. Therefore, hyperinsulinemia alone also is an insufficient explanation for the development of PCOS.

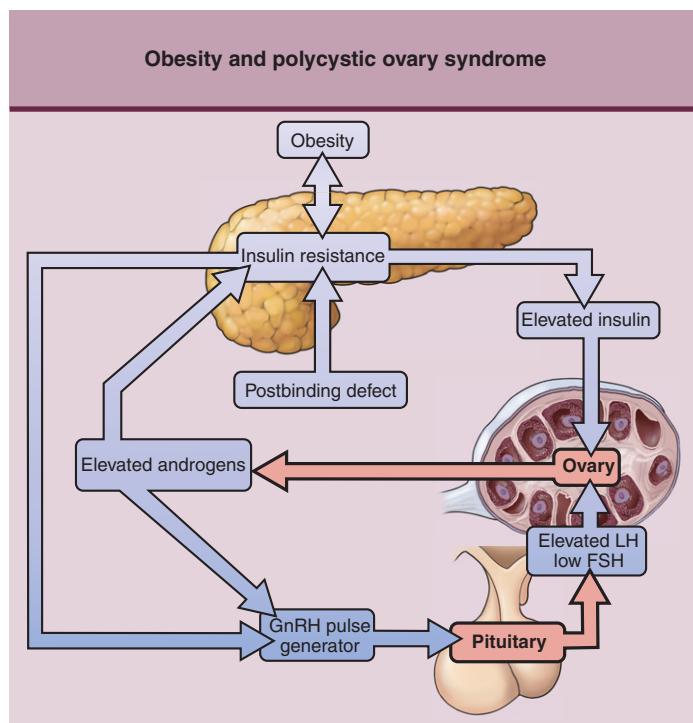

#### Dysfunctional Gonadotropin Metabolism

Both lean and obese women with PCOS have overall increased LH secretion. Elevated 24-hour levels of LH, increased LH pulse frequency, and greater pulse amplitude are normally characteristic of these women.<sup>17</sup> However, single-sample basal concentrations of LH are highly variable. The elevated LH of PCOS is probably not causative but rather a result of another underlying pathology. Thus, in one transgenic mouse system, pituitary LH secretion was extremely sensitive to exogenous

gonadotropin-releasing hormone (GnRH) stimulation when the *INSR* gene was knocked out in the central nervous system.<sup>18</sup> The same animals were also obese and had elevated triglyceride and insulin levels. These findings strongly suggest that elevated LH levels in PCOS may be secondary to insulin resistance.

**Figure 62-2** Increased insulin receptor serine phosphorylation results in a postbinding defect leading to insulin resistance.

**Figure 62-3** Insulin resistance aggravated by obesity impairs the hypothalamic-pituitary-ovarian axis, resulting in anovulation.

Both lean and obese women with PCOS have overtly decreased follicle-stimulating hormone (FSH) secretion. One could thus argue that insufficient levels of FSH might cause an arrest in follicle maturation and result in decreased aromatase activity in granulosa cells. Thus, low E<sub>2</sub> and elevated androgen production might be expected. However, follicles in polycystic ovaries are responsive to exogenous FSH, and clomiphene induces FSH secretion sufficiently to enable mature follicle development.<sup>4</sup> Therefore, the suppressed FSH is most likely a secondary phenomenon in PCOS (Fig. 62-3).

### Excessive Androgen Production

Increased androgen production and its manifestations are hallmark features of PCOS.

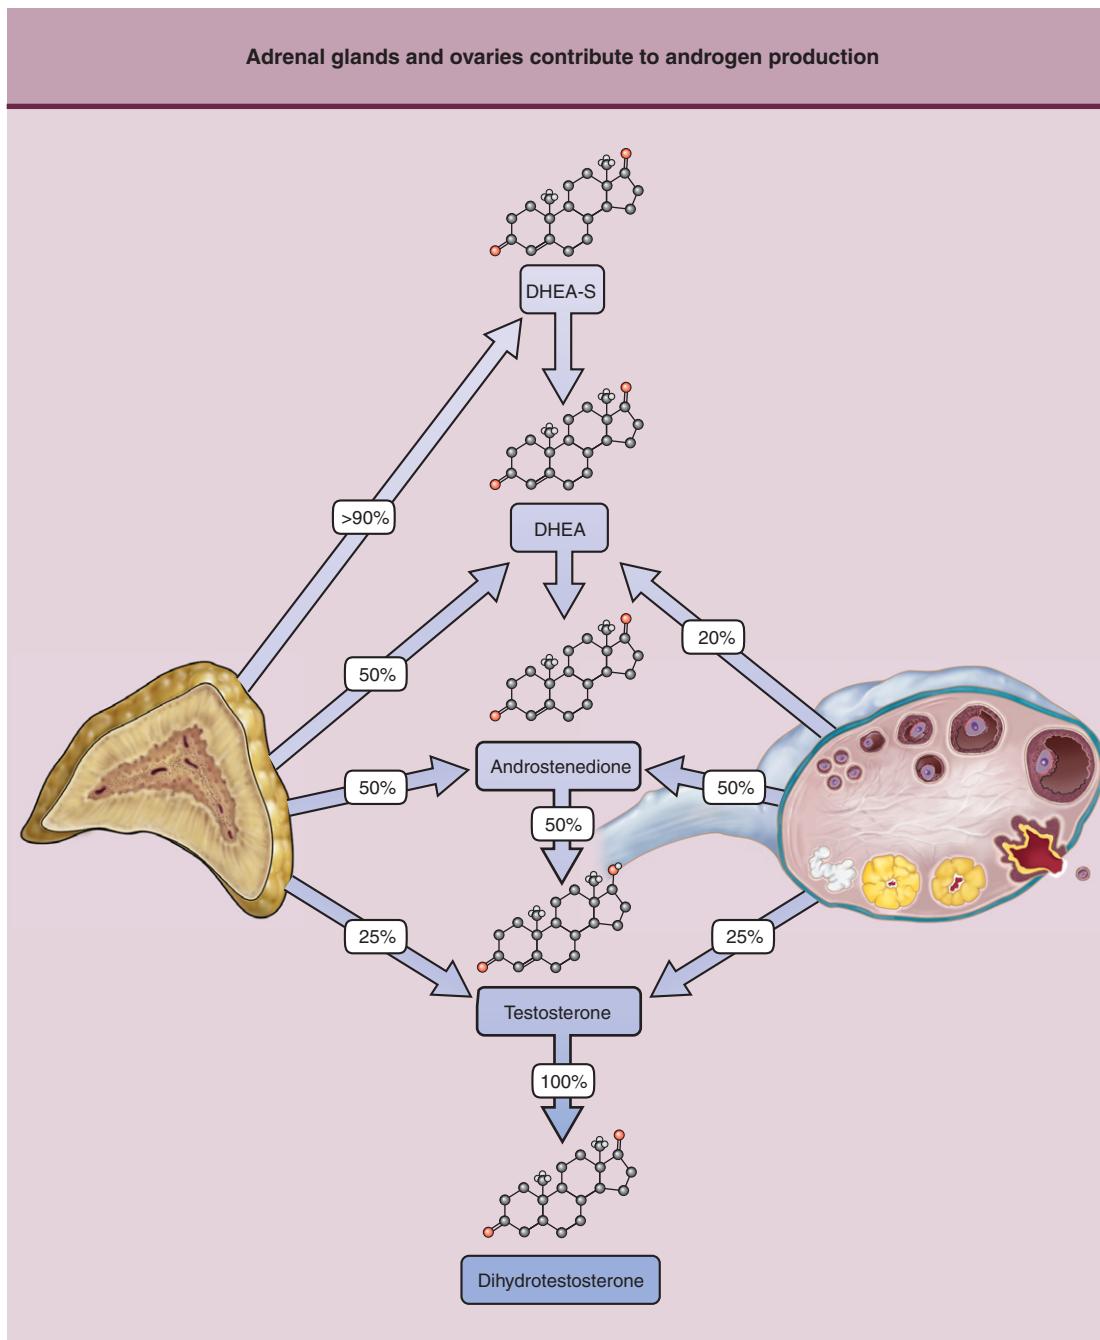

In normal women, adrenal glands and ovaries both contribute to circulating androgens. Dehydroepiandrosterone (DHEA) and androstenedione are the major androgen products of the ovary. Adrenals and ovaries equally contribute to androstenedione production, whereas one half of circulating DHEA is secreted by adrenals and about 20% comes from the ovary. The remaining 30% is produced in peripheral tissues from dehydroepiandrosterone sulfate (DHEAS) intracellularly.<sup>19</sup> DHEAS is almost exclusively produced by the adrenal gland and is converted in peripheral tissues to biologically active androgens. Thus, one half of testosterone arises from peripheral conversion of androstenedione and the other half is secreted equally by the ovary and the adrenal (Fig. 62-4). Testosterone is converted by the intracellular 5 $\alpha$ -reductase in androgen responsive tissues to form intracellular dihydrotestosterone (DHT), the most potent androgen. Androstenedione and DHEAS are weak androgens with no receptors and are frequently considered "prehormones."

Androstenedione and testosterone are biosynthesized in the theca cells and converted to estrone and estradiol in the granulosa cells by aromatase (Fig. 62-5).

The majority (69% to 79%) of testosterone molecules in serum are bound to sex hormone-binding globulin (SHBG) which is a  $\beta$ -globulin. Approximately 20% to 30% of testosterone is albumin-bound, and 1% is found free in serum. This small unbound, or free, portion constitutes the biologically active hormone. Free testosterone levels are determined by the amount of androgen production and the circulating levels of SHBG. Hyperthyroidism, pregnancy, and estrogens increase SHBG levels, whereas corticoids, androgens, progestins, growth hormone, insulin, and insulin-like growth factor-1 (IGF-1) decrease SHBG. Thus, insulin increases the bioavailability of testosterone. Androgen production including testosterone, DHEA, and DHEAS declines significantly with age. Free testosterone levels also decrease in older women as the percentage of free testosterone does not change with age. Six cytochrome P-450 (CYP) enzymes are involved in steroidogenesis including members of the CYP11, CYP17, CYP19, and CYP21 enzyme families. CYP11A, or cholesterol side-chain cleavage enzyme, participates in the conversion of cholesterol to pregnenolone. CYP17A (P450c17) possesses 17 $\alpha$ -hydroxylase and 17,20-lyase activities, which catalyze 17 $\alpha$ -hydroxylation of pregnenolone and progesterone and oxidation of their side chains (Fig. 62-6). CYP21A or 21-hydroxylase participates in the biosynthesis of glucocorticoids and mineralocorticoids from progesterone and 17-hydroxyprogesterone. Another important steroidogenic enzyme is 3 $\beta$ -hydroxysteroid dehydrogenase, which belongs to the short-chain dehydrogenase/reductase enzyme family. This enzyme catalyzes the conversion of pregnenolone and DHEA to progesterone and androstenedione, respectively.

In women with PCOS, production rates of androgens are approximately four-fold increased over normal controls.<sup>20</sup> Thus, clinical hyperandrogenism is a major component of PCOS. Approximately 80% of PCOS diagnosed by NIH consensus criteria demonstrates elevated androgen levels. Hyperandrogenemia is directly accountable for the traditional signs and symptoms of PCOS: hirsutism, acne, and anovulation. Major sources of androgen excess in PCOS are the ovary, primarily theca cells, and the zona reticularis of the adrenal cortex. It is well documented in vitro that isolated theca cells from women with PCOS produce significantly higher levels of DHEA, androstenedione, and 17-hydroxyprogesterone at baseline and in response to LH or forskolin compared with control theca cells.<sup>21</sup> Theca cells from PCOS patients also exhibit increased activity of steroidogenic enzymes such as CYP11A, CYP17, and 3 $\beta$ -hydroxysteroid dehydrogenase after forskolin stimulation.<sup>21</sup> Therefore, increased steroidogenic enzyme activity is in part responsible for ovarian hyperandrogenism. Persistence of increased enzyme activity in long-term cultured theca cells suggests an intrinsic defect in theca cells that may contribute to the pathogenesis of PCOS.

Adrenal androgen production is also increased in many women with PCOS. One proposed mechanism is an increase in cortisol clearance that leads to compensatory stimulation of ACTH. This, in turn, induces excessive androgen production by the reticularis zone of the adrenal gland. Cortisol is inactivated in an irreversible fashion by 5 $\alpha$ -reductase and 5 $\beta$ -reductase.

**Figure 62-4 The adrenal gland and ovary contribute to androgen production.**

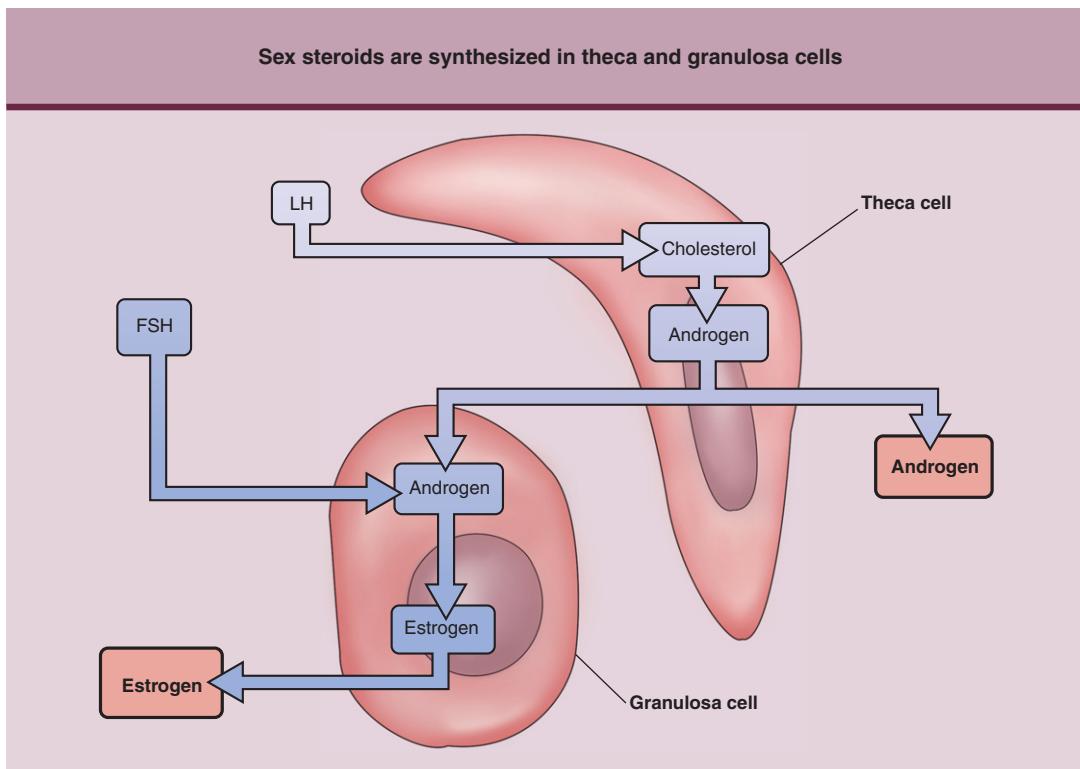

Women with PCOS have higher levels of urinary 5 $\alpha$ -cortisol metabolites compared with controls.<sup>22</sup> It is known that androgens augment the enzymatic activity of 5 $\alpha$ -reductase, thereby inducing the inactivation of cortisol. Additionally, the activity of 11 $\beta$ -hydroxysteroid dehydrogenase-1, the enzyme that converts inactive cortisone into active cortisol, has been shown to be reduced in women with PCOS.<sup>23</sup> This may also contribute to the increased ACTH stimulation and augmented androgen production by the zona reticularis.

Insulin resistance has been reported following exogenous testosterone administration and in other hyperandrogenemic disorders such as nonclassical congenital adrenal hyperplasia

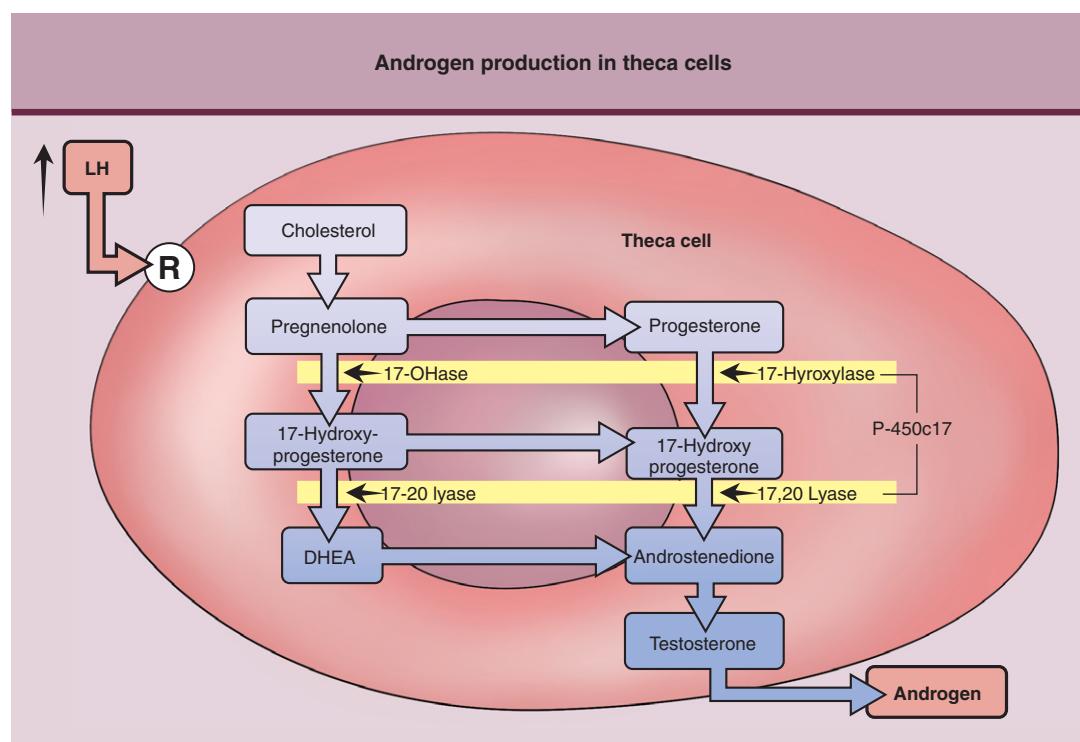

(CAH).<sup>24</sup> However, insulin resistance probably is not caused by hyperandrogenemia in PCOS, since suppressing androgens does not completely restore normal insulin sensitivity.<sup>8,9</sup> Furthermore, insulin resistance produced by androgen administration does not have the same magnitude as that seen in PCOS.<sup>10</sup>

#### Anovulation in Polycystic Ovary Syndrome

Dysfunctional gonadotropin metabolism, characterized by increased LH and suppressed FSH, leads to follicular arrest and anovulation. Hyperandrogenemia and steady mid-follicular levels of estradiol also contribute to anovulation through potentiation of dysfunctional gonadotropin secretion. Hyperinsulinemia also

**Figure 62-5** Androgens produced by theca cells under the control of luteinizing hormone (LH) are aromatized to estrogens in granulosa cells and by peripheral conversion. Follicle-stimulating hormone (FSH) stimulates follicular maturation and granulosa cell growth.

**Figure 62-6** Androgens are produced in theca cells from cholesterol following steroidogenic pathways.

## Reproductive Endocrinology and Infertility

triggers increased LH pulse amplitude and pulse frequency in response to GnRH stimulation. It also sensitizes granulosa cells to LH. Granulosa cells from women with PCOS are more responsive to LH than granulosa cells from size-matched follicles obtained from normal women.<sup>25</sup> This hyperresponsiveness to LH has been suggested as a possible major mechanism for anovulation. Hyperandrogenemia may further aggravate the effects of hyperinsulinemia and elevated LH secretion.

### **Polycystic Ovary Syndrome as an Inherited Disorder**

PCOS is an inherited disorder. Pedigree studies have consistently suggested an autosomal dominant inheritance pattern with elevated androgen levels in about 50% of sisters of women with PCOS. Only a few studies suggested X-linked or polygenic inheritance. One well-designed, controlled study showed that approximately 22% of sisters of women with PCOS also had PCOS as defined by hyperandrogenemia and oligomenorrhea, and another 24% of these sisters had hyperandrogenemia alone.<sup>26</sup> The segregation ratio for overall hyperandrogenemia was 0.46, which is consistent with an autosomal dominant inheritance. The risk of hyperandrogenemia in sisters of PCOS women was approximately three-fold increased compared with controls in this study. However, androgen levels are also highly heritable independent of PCOS.<sup>27</sup> Moreover, a large twin study of PCOS failed to support a strong genetic component.<sup>28</sup> The male phenotype expected from these genetic studies has been also elusive. A recent study showed that male-pattern balding score did not differ between controls and male relatives of PCOS patients.<sup>29</sup> However, a higher incidence of insulin resistance and impaired glucose tolerance has been found among male and female relatives of women with PCOS.<sup>30</sup> Thus, pancreatic  $\beta$ -cell dysfunction may be a heritable phenotype.

Familial aggregations of PCOS led investigators long ago to search for candidate genes. Logically, the genes involved in steroid hormone biosynthesis, carbohydrate metabolism, and gonadotropin action and regulation were investigated. Therefore, early studies focused on CYP11A, CYP17, and CYP21, which are important enzymes in steroidogenesis. Although initial studies suggested an association between these genes and PCOS, later studies did not confirm the initial findings. Follistatin, a glycoprotein, suppresses pituitary FSH production. This glycoprotein's locus, thought to be associated with PCOS in an early study,<sup>31</sup> was not linked to PCOS as shown by later studies.<sup>32</sup> Neither overexpression nor granulosa cell-specific inactivation of follistatin in mice resulted in features similar to those of PCOS.<sup>33,34</sup> A variable number tandem repeat (VNTR) locus, upstream of the insulin gene, regulates insulin expression. Thus, Waterworth et al suggested an association between alleles of this locus and PCOS.<sup>35</sup> Further studies, however, failed to confirm this linkage.<sup>31</sup> Insulin receptor gene mutations cause insulin resistance similarly to PCOS. However, several studies did not find changes in the sequence of the insulin receptor gene in PCOS patients. Tucci et al reported a significant association between PCOS and an insulin receptor gene marker D19S884.<sup>36</sup> This marker is about 1 Mbp telomeric to the *INSR* gene. The authors concluded that the susceptibility gene may be the *INSR* itself or a closely related gene. Unfortunately, a later study failed to confirm an association between marker D19S884 and PCOS in women from Spain and Italy.<sup>37</sup> Microarray technology can

detect differential expressions of up to 45,000 genes. With this new technique, Wood et al compared gene expression profiles of normal and PCOS theca cells using oligonucleotide microarray chips.<sup>38</sup> These investigators identified approximately 400 genes that were either up- or down-regulated in PCOS theca cells. Genes that are involved in retinoic acid synthesis, such as retinol dehydrogenase and aldehyde dehydrogenase, and genes that encode transcription factors, such as GATA6, were selected by the authors as candidate genes that might have an impact on theca cell steroidogenesis. These genes need to be investigated by further studies. This study will help researchers focus on a number of new genes that may be involved in PCOS.

### **CLINICAL FEATURES**

PCOS is a lifelong disease which traditionally manifests in puberty with premature adrenarche, obesity, and menstrual irregularity. Sequelae later in life include infertility, diabetes mellitus, cardiovascular disease, and gynecologic cancers (Fig. 62-7).

In reproductive-aged women, the main features of PCOS are oligomenorrhea, hirsutism, acne, obesity, and infertility. None of these features is pervasive and universal except oligomenorrhea, which is a diagnostic criterion by 1990 NIH consensus. Reproductive-aged women with PCOS usually come in for one of the following three reasons: (1) symptoms of androgen excess, (2) menstrual irregularity, and/or (3) infertility.

#### **Androgen Excess**

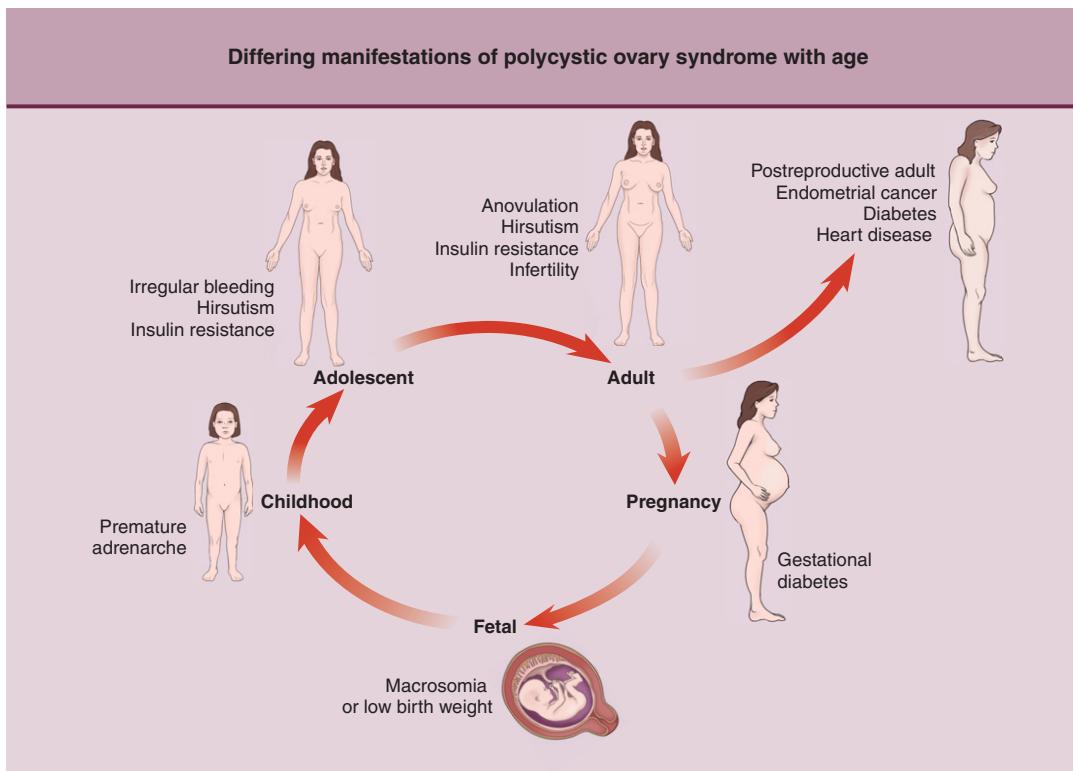

Hirsutism is subjective, and not every woman with elevated androgen levels is hirsute. Hair growth depends on the number of hair follicles and  $5\alpha$ -reductase activity. For instance, hirsutism is milder in Asian women. It is considered normal in some Mediterranean women. The number of hair follicles, thickness, and pigmentation of individual hairs in the hormone-dependent areas such as upper lip, chin, chest, back, upper abdomen, thighs, and arms are increased in hirsutism. Acne and seborrhea are the other common signs of androgen excess in PCOS. Male pattern baldness and clitoromegaly are infrequently encountered.

#### **Menstrual Irregularity**

Erratic ovulation with breakthrough bleeding results in oligomenorrhea in many women with PCOS. The onset of oligomenorrhea is usually peripubertal and continues through the first two decades of reproductive life. However, menstrual regularity improves after age 30, and the majority of women with PCOS have regular cycles by age 40.<sup>39</sup> Regular menstrual cycles commonly return between ages 35 and 43. This phenomenon may be related to the decline of the follicle cohort and decreased ovarian androgen production with age. These women do not necessarily have gynecologic or reproductive problems after age 35, and diabetes and heart disease are diagnosed later in life (Fig. 62-8).

#### **Infertility**

Anovulation is the underlying mechanism for infertility in women with PCOS in reproductive years. Thus, PCOS accounts for 75% of anovulatory infertility.<sup>40</sup> Although the precise mechanism of anovulation in PCOS has not been determined, inadequate FSH stimulation and tonic levels of LH are believed to impair follicle

**Figure 62-7** Polycystic ovary syndrome (PCOS) is a lifelong disease with differing manifestations evolving over the different stages of a woman's life.

maturity and ovulation. Although women with PCOS may ovulate incidentally and become pregnant spontaneously, they frequently require ovulation induction. Ovulation induction, however, is challenging in these women because many do not respond predictably to ovulation induction agents. Unfortunately, when they do respond, ovarian hyperstimulation and multiple gestation often occur.

#### Other Clinical Features

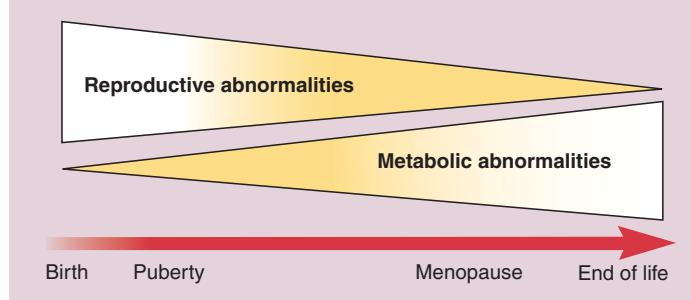

Other clinical features of PCOS include obesity, acanthosis nigricans, and morphologic appearance of polycystic ovaries on

ultrasound. Although many women with PCOS are obese, they may be lean with wide variability among patient populations. Approximately 30% to 60% of women with PCOS have a body mass index (BMI) greater than 30. These obese women frequently have central or android body fat distribution. The prevalence of abdominal body fat distribution is also higher in lean PCOS patients, which contributes to their increased risk for metabolic abnormalities. Obesity fuels androgen production and hyperinsulinemia and decreases SHBG production, resulting in elevated free testosterone.

Acanthosis nigricans is an abnormal thickening of the epidermis associated with hyperpigmentation and hyperkeratosis. It is usually encountered in severe insulin resistance and type 2 diabetes along with HAIR-AN syndrome. Hyperandrogenism (HA), insulin resistance (IR) and acanthosis nigricans (AN) is considered a subtype of PCOS and commonly caused by mutations in the *INSR* gene.<sup>41</sup>

One of the most controversial features of PCOS is the ultrasound morphology of polycystic ovaries. The typical polycystic ovary is defined ultrasonographically by more than 12 subcapsular follicles measuring 2 to 9 mm and hyperechogenic stroma representing stromal hyperplasia. About 20% of women with normal menstrual cycles and no hirsutism have this morphology on ultrasound, whereas only 70% of women with hirsutism and oligomenorrhea have such ultrasound findings. Therefore ultrasound findings alone are not diagnostic, although it is commonly used as a diagnostic criterion in Europe. PCOS most likely represents a heterogeneous disorder with different subtypes. Therefore, patients have differing degrees of metabolic and gonadotropin abnormalities.

#### Significance of reproductive and metabolic abnormalities with age

**Figure 62-8** Reproductive abnormalities of polycystic ovary syndrome decrease with advancing age, whereas metabolic abnormalities such as diabetes and heart disease become more significant.

### **Polycystic Ovary Syndrome in Adolescence**

There is increasing evidence that PCOS manifests before birth and continues throughout life. Some studies report a significant relationship between low birth weight and development of PCOS later in life,<sup>42</sup> whereas others show an association between high birth weight and PCOS.<sup>42</sup> These findings suggest a U-shaped relationship between birth weight and PCOS caused by different subtypes of the disease. Peripubertal girls with pubarche before age 8, obesity, and irregular cycles are at risk for PCOS and so should be followed closely. Clinical features of PCOS in adolescent girls are similar to those of adult women. These adolescent girls have obesity, irregular cycles secondary to anovulation, and hirsutism and acne as a result of hyperandrogenemia. Another clinical feature that has recently been linked to adolescent PCOS is premature pubarche or adrenarche, which is defined as pubic hair development before the age of 8 years. Girls with premature pubarche have been shown to develop insulin resistance and hyperandrogenemia during puberty.<sup>43</sup> Therefore, premature pubarche has been proposed as an early marker of PCOS. Insulin resistance and obesity seem to precede hyperandrogenemia, which is usually seen after menarche. Acanthosis nigricans is also a common finding in pubertal girls with obesity and insulin resistance. Pubertal physiologic anovulation has been challenged. Some investigators suggest that oligomenorrhea in adolescence may be an early sign of PCOS rather than a physiologic maturation process. Treatment of these girls with insulin-sensitizing agents is controversial at this time, although initial studies showed improved metabolic parameters in treated girls.

### **Diabetes Mellitus**

Insulin resistance combined with the worsening effect of accompanying obesity makes PCOS a major risk factor for type 2 diabetes in adolescents and premenopausal women. Several studies reported increased prevalence of type 2 diabetes in women with PCOS. About 15% of PCOS patients develop diabetes, based on current evidence.<sup>44</sup> The Nurses' Health Study II investigated the relative risk of diabetes among women with a cycle length greater than 40 days, between ages 18 and 22 years, who were followed prospectively for over 8 years.<sup>45</sup> The total number of women who participated in this study was 101,703 of whom 7.6% had a cycle length greater than 40 days or too irregular to estimate. The relative risk (RR) of diabetes was 2.08 (95% confidence interval [CI] 1.62–2.66) among oligomenorrheic women, and this risk was further increased by high BMI (RR 3.86, 95% CI 2.33–6.38). In this study, hirsutism and/or severe acne during teenage years and family history of diabetes were also important predictors for the development of type 2 diabetes. Similarly, the incidence of PCOS among women with type 2 diabetes has been shown to be higher than in the general population, although these studies are small and used ultrasound appearance as a diagnostic marker.

### **Cardiovascular Disease**

The association between lipid abnormalities and PCOS has been known since the mid-1980s. Several studies have shown that women with PCOS have higher levels of low-density lipoprotein (LDL) and triglycerides, and lower levels of high-density lipoprotein (HDL) compared with weight-matched controls.

LDL and HDL are good predictors of coronary heart disease. Small LDL particles are strongly associated with coronary heart disease, and PCOS patients have significantly smaller LDL particle size than regularly cycling women.<sup>46</sup> LDL particle size is associated with SHBG levels, which are inversely correlated with insulin levels. In the light of these findings, women with PCOS seem to be more likely to have coronary artery abnormalities. Several studies support this conclusion. For instance, women with PCOS are more likely to have coronary artery calcification than age- and weight-matched controls.<sup>47</sup> Women with extensive coronary artery disease on coronary angiography are also more likely to have PCOS on ultrasound.<sup>48</sup> These women are at greater risk for developing hypertension than are age-matched controls.<sup>49</sup> Syndrome X, or metabolic syndrome, which is associated with atherosclerosis and CHD, is characterized by hypertension, hypertriglyceridemia, low HDL, insulin resistance, and obesity. Approximately 45% of women with PCOS demonstrate features of the metabolic syndrome at a relatively young age.<sup>50</sup> Surprisingly, it is not clear whether cardiovascular events are more common in women with PCOS. One study found no increase in the death rate due to the circulatory disease among women with PCOS.<sup>51</sup> This study, however, lacked controls and the diagnosis was made based on ovarian wedge resection. A prospective cohort study with large numbers is necessary to answer whether cardiovascular events are associated with PCOS.

### **Gynecologic Cancers**

Several studies suggest an association between PCOS and gynecologic cancers. The first report suggesting an association between endometrial cancer and PCOS was published in 1949, 14 years after the classical description by Stein and Leventhal in 1935. However, no controlled studies have appeared since the first report. Most studies that examined the relationship between PCOS and a variety of cancers lack control groups and suffer from poor study design and inconsistent diagnostic criteria.

Although the risk of endometrial cancer is increased with exposure to unopposed estrogens, the association between PCOS and endometrial cancer is not clear. Six studies show an increased risk of endometrial cancer. However, all these studies were retrospective and most lacked control groups. Probably the most frequently cited study by Couplam et al found an RR of 3.1 (95% CI 1.1–7.3) for the development of endometrial carcinoma in women with a diagnosis of chronic anovulation.<sup>52</sup> Escobedo et al reported an increased risk of endometrial cancer in women with ovarian factor infertility,<sup>53</sup> whereas Dahlgren et al showed a significant relationship between endometrial cancer and such variables as hirsutism, parity, BMI, diabetes mellitus, and smoking.<sup>54</sup> Gallup and Stock found that about 31% of endometrial cancer patients who are younger than 40 years of age had polycystic ovaries and tended to be more overweight than older patients.<sup>55</sup> Two recent studies evaluated women with infertility. One was a retrospective cohort study by Wild et al, which found the odds ratio for endometrial cancer in women with PCOS to be 5.3.<sup>56</sup> The other study was also retrospective and looked at endometrial biopsy findings in infertile women.<sup>57</sup> Four of 2573 endometrial biopsy specimens from women with PCOS showed endometrial cancer. However, all these studies used stigmata of PCOS rather than an actual diagnosis. Therefore,

their results cannot be extrapolated to all women with PCOS. Nonetheless, they suggest that the incidence of clinical features of PCOS is higher in younger women with endometrial cancer although these patients are only a small number of all women with endometrial cancer. Moreover, PCOS may not be an independent risk factor, and specific endocrine or metabolic abnormalities occurring as a result of PCOS, such as obesity, may play a more important role in the development of endometrial cancer. Although a few studies failed to find an association between PCOS and endometrial cancer, intuitively it seems likely that these women are at risk for endometrial cancer because of the stimulatory effects of unopposed estrogen secretion in PCOS. Moreover, there is strong evidence that risk of premalignant atypical endometrial hyperplasia is increased in PCOS. Thus, women with PCOS should be counseled for a probable increased risk of endometrial cancer.

Risk for breast cancer may also be increased in PCOS. However, evidence linking the two is circumstantial. PCOS carries potential risk factors for postmenopausal breast cancer including obesity, infertility, and elevated androgen levels. However, the evidence is not strong. Two studies from the same group of investigators found an increased risk for breast cancer in women with elevated androgen and estrogen levels.<sup>58,59</sup> However, four large population-based studies failed to show this association.<sup>60-62</sup> This is in line with findings from the Women's Health Initiative (WHI), because breast cancer risk did not increase in the estrogen-only arm of this study.<sup>63</sup> It seems that progesterone is necessary for estrogens to increase breast cancer risk, and progesterone levels are significantly low in women with PCOS. Currently, there is not enough evidence to suggest an association between breast cancer and PCOS. A subset of women with PCOS may be at risk for breast cancer, since elevated hormone levels and obesity may act in a complex manner in breast cancer. Further studies are needed to resolve this issue.

The risk for ovarian cancer does not appear increased. Intuitively, women with PCOS would be protected against ovarian cancer owing to the elimination of uninterrupted ovulation, which is one of the risk factors for ovarian cancer. However, a retrospective case-control study suggests that PCOS patients may be at increased risk for epithelial ovarian cancer.<sup>64</sup> In this study, history of PCOS was determined by self-report. Endocrine testing, ultrasound scanning, or medical record review were not performed to confirm the diagnosis. The adjusted odds ratio for ovarian cancer was 2.4 (95% CI 1.0–5.9). Animal data also suggest that increased LH may be associated with ovarian tumorigenesis.<sup>65</sup> Overexpression of LH in transgenic mice leads to infertility, polycystic ovaries, and granulosa cell tumors. However, LH levels in these animals were 12 to 14 times greater than in controls, which is much higher than LH levels encountered in women with PCOS. Further studies are necessary, but evidence linking the two is lacking.

## DIAGNOSIS

The most commonly used diagnostic criteria are based on the 1990 NIH/National Institute of Child Health and Human Development (NICHD) consensus: (1) chronic anovulation, (2) clinical and/or biochemical signs of hyperandrogenism, and (3) exclusion of other etiologies such as congenital nonclassical

**Table 62-1**  
**Diagnostic Criteria for Polycystic Ovary Syndrome\***

1. Oligo- or anovulation
2. Clinical and/or biochemical signs of hyperandrogenism
3. Polycystic ovaries
4. Exclusion of other etiologies such as congenital adrenal hyperplasia, androgen-secreting tumors, and Cushing's syndrome

ASRM, American Society for Reproductive Medicine; ESHRE, European Society of Human Reproduction and Embryology.

\*The presence of two of the first three criteria is sufficient for diagnosis.

Rotterdam ESHRE/ASRM-Sponsored PCOS Consensus Workshop Group: Revised 2003 consensus on diagnostic criteria and long-term health risks related to polycystic ovary syndrome. *Fertil Steril* 2004;81:19–25. Copyright 2004. Reprinted with permission from the American Society for Reproductive Medicine.

adrenal hyperplasia, Cushing's syndrome, androgen-secreting tumors, and hyperprolactinemia. The presence of polycystic ovaries on ultrasound is not one of the NIH consensus criteria. These criteria were revised by the Rotterdam European Society of Human Reproduction and Embryology (ESHRE)/American Society for Reproductive Medicine (ASRM)-sponsored PCOS consensus workshop group in 2004.<sup>66</sup> New criteria include (1) oligo-ovulation or anovulation, (2) clinical and/or biochemical signs of hyperandrogenism, (3) polycystic ovaries, and (4) exclusion of other etiologies. The presence of two of the first three criteria is sufficient for diagnosis when other etiologies are ruled out (Table 62-1). This workshop combined European and North American diagnostic approaches; however, it may not diminish the use of different diagnostic criteria in the literature, which may be partly responsible for divergent findings in various studies. Another point that should be emphasized is that neither obesity nor insulin resistance is necessary for diagnosis by either consensus.

## History

History is essential in establishing the diagnosis. A long-standing history of oligomenorrhea (cycles >35 days) indicates chronic anovulation. Hair growth and skin changes such as acne are consistent with hyperandrogenism. Onset, severity, and rapidity of these symptoms are crucial for the exclusion of other etiologies. Thus, rapidly progressing, severe androgen excess should suggest an androgen-secreting tumor. Severe hyperandrogenism in postmenopausal women or women with a recent history of regular cycles is also suggestive of a tumor. If the onset of androgen excess coincides with puberty, PCOS and nonclassical CAH are likely diagnoses. A history of galactorrhea is consistent with hyperprolactinemia in women with oligomenorrhea. Regular cycles and normal testosterone levels in a woman with hair growth are indicative of idiopathic hirsutism.

## Physical Examination

Physical examination is paramount. Classical findings of PCOS are hirsutism and central obesity. The Ferriman-Gallwey score may be useful to quantify hirsutism objectively, but it is most beneficial to determine response to treatment. (The Ferriman-Gallwey scoring system consists of five grades based on densities and areas involved for each of nine hormonal sites including upper lip, chin, chest, upper back, lower back, upper abdomen, lower abdomen, arm, and thigh.) Seborrhea, acne, and alopecia

## Reproductive Endocrinology and Infertility

may also be seen. Virilization defined as clitoromegaly, deepening of the voice, and temporal balding is rarely encountered in PCOS. Virilization suggests an androgen-secreting tumor, although a severe variant of PCOS, hyperthecosis, may cause clitoromegaly. A palpable ovarian mass in a woman with virilization implies an androgen-secreting tumor. Signs of insulin resistance such as acanthosis nigricans are consistent with PCOS. Hyperprolactinemia is strongly suspected when galactorrhea is detected during the physical examination. Centripetal obesity, moon face, hirsutism, purple striae, and plethora indicate Cushing's syndrome.

### Laboratory Testing

The goal of laboratory testing is exclusion of other etiologies. It is not essential to rule in the diagnosis of PCOS. High levels of total testosterone, above 200 ng/dL, are usually encountered in the presence of an androgen-secreting tumor. A mildly elevated total testosterone level in the serum is consistent with PCOS. Basal LH levels are highly variable and may be elevated in PCOS. Thus, LH/FSH ratio may be reversed to 2:1. However, this finding is only supportive and not required for the diagnosis. The FSH level may be helpful to rule out hypergonadotropic or hypogonadotropic hypogonadism. Serum prolactin (PRL) and thyroid-stimulating hormone (TSH) levels should be obtained on all patients with oligomenorrhea to rule out hyperprolactinemia and thyroid disorders. Androgen levels including total testosterone, DHEA and DHEAS may be elevated in women with hyperprolactinemia. Conversely, mildly increased PRL levels may be found in PCOS. Hypothyroidism reduces the levels of SHBG and thus may cause hyperandrogenism. A morning serum 17-hydroxyprogesterone level is helpful to rule out nonclassical CAH especially in women of Ashkenazi Jewish, Hispanic, and central European descent. If the 17-hydroxyprogesterone level is elevated, an ACTH stimulation test should be performed to diagnose nonclassical CAH. However, the clinical importance of a nonclassical CAH diagnosis is debatable. Women with this disorder respond well to antiandrogen therapy and ovulatory agents that are standard therapies for PCOS. However, this is an autosomal recessive disorder, and patients should be counseled appropriately. These women also have a theoretic risk for adrenal insufficiency in case of surgery and trauma, although this has never been reported.<sup>67</sup> A serum cortisol level immediately following a 1-mg dexamethasone suppression test is a helpful screening method if Cushing's syndrome is suspected. When an adrenal tumor is suspected, DHEAS levels may be highly elevated, which is an indication for adrenal imaging. Although the presence of insulin resistance is not required for diagnosis, insulin resistance and glucose intolerance should be assessed in obese women with PCOS. Although indices calculated using fasting glucose and insulin such as the homeostasis model assessment (HOMA), quantitative insulin sensitivity check index (QUICKI), and the fasting glucose to insulin ratio (G/I) may be helpful in determining insulin resistance, no clinical tests are validated for accurate detection of insulin resistance. The 2-hour glucose level after a 75-g oral glucose load is preferred to determine glucose intolerance over the fasting plasma glucose level. A 2-hour glucose level between 140 and 199 mg/dL indicates impaired glucose tolerance, and a level above 199 mg/dL is diagnostic for type 2 diabetes mellitus. A fasting lipid profile also

**Table 62-2**  
**Diagnostic Evaluation for Polycystic Ovary Syndrome**

Tests Performed Routinely	Excluded Disorder
TSH PRL FSH LH	Hypo- or hyperthyroidism Hyperprolactinemia Premature ovarian failure Increased in PCOS—too variable to be useful
Tests Performed Based on Presentation and History	Excluded Disorder
17-Hydroxyprogesterone	Nonclassical congenital adrenal hyperplasia
Total testosterone	Androgen-secreting tumors
DHEAS	Adrenal adenoma
Dexamethasone suppression test	Cushing's syndrome
DHEAS, dehydroepiandrosterone sulfate; FSH, follicle-stimulating hormone; LH, luteinizing hormone; PRL, prolactin; TSH, thyroid-stimulating hormone.	

may be obtained. Assessment of glucose intolerance and lipid levels is crucial for patient counseling and long-term management in obese women with PCOS.

Routine measurement of TSH, PRL, and FSH levels is recommended in women with oligomenorrhea and hyperandrogenism. Other laboratory tests including 17-hydroxyprogesterone, total testosterone, DHEAS, and the dexamethasone suppression test should be performed to exclude nonclassical CAH, androgen-secreting tumors, and Cushing's syndrome if the clinical presentation is suggestive or the prevalence in the patient's ethnic background is high (Table 62-2).

### Imaging Studies

Imaging of ovaries and adrenals should be performed when a tumor is suspected. Transvaginal ultrasound is the preferred method to rule out an adnexal mass. Typically, polycystic ovaries appear enlarged with 12 or more subcapsular follicles measuring less than 10 mm around dense hyperechoic stroma. However, some women with PCOS do not have these findings, whereas normal women may have polycystic ovaries on ultrasound. Therefore, ultrasound findings are not diagnostic. Abdominal CT or MRI should be performed if an adrenal tumor is suspected.

## TREATMENT

### Treatment of Infertility

Traditionally, clomiphene citrate (CC) has been the first-line agent followed by gonadotropin stimulation when CC is unsuccessful. Overall understanding about the role of insulin resistance has dramatically changed this tradition, and insulin sensitizers, for example, metformin are now used as first-line agents by many clinicians. However, it is always prudent to recommend weight loss and exercise to reduce insulin resistance and resume ovulation (Table 62-3).

### Weight Loss and Exercise

Obesity and PCOS have synergistic negative impact on insulin resistance and hyperandrogenemia. Studies on weight loss have

**Table 62-3**  
**Treatment of Polycystic Ovary Syndrome**

Therapy	Benefit
Weight loss: diet and exercise	Prevention of long-term sequelae such as diabetes, resumption of ovarian function
Insulin-sensitizing agents	Resumption of ovulation, prevention of long-term sequelae, possible improvement of hirsutism
Clomiphene citrate	Ovulation induction
Gonadotropins	Ovulation induction
Oral contraceptive pills	Suppression of hyperandrogenism, prevention of endometrial hyperplasia and cancer
Progestin	Prevention of endometrial hyperplasia and cancer
Spirolactone, flutamide, finasteride, cyproterone acetate, GnRH analogs	Suppression of hyperandrogenism
GnRH, gonadotropin-releasing hormone.	

consistently showed an improvement in insulin resistance, hyperandrogenemia, menstrual irregularity, and anovulation. As little as 5% loss of the starting weight causes a significant decrease in insulin resistance, as defined by reduction in insulin levels after fasting and in response to 75 g oral glucose.<sup>68</sup> This decline in insulin is accompanied by an increase in SHBG levels and a decrease in free testosterone, which may lead to improvement of hirsutism. Weight loss also restores reproductive function as indicated by regular cycles, increased pregnancy rates, and greater efficacy of ovulation induction agents. Improved pregnancy outcome after weight loss is perhaps the most important benefit.<sup>69</sup> Spontaneous ovulation may resume in up to 90% of obese women after 10% decline in BMI.<sup>70</sup>

Weight loss is an effective therapy with no side effects. Therefore, all patients should be strongly encouraged to lose weight. However, in today's clinical environment this is difficult to achieve even though patients are strongly driven to conceive. This is in part because effective medical treatment options are available, and weight loss is more arduous and may take longer.

#### **Insulin-Sensitizing Agents**

The strong association between hyperinsulinemia and PCOS has led to use of insulin-sensitizing agents such as metformin, thiazolidinediones, and D-chiro-inositol as ovulation induction agents. Of these medications, metformin is the most extensively studied.

#### **Metformin**

The first reported use of metformin for the management of PCOS, by Velazquez et al, appeared in 1994.<sup>71</sup> Metformin is a biguanide that is a well-established oral antidiabetic agent. Interestingly, biguanide compounds are also used as chemical sanitizers in swimming pools and as topical antiseptics such as contact lens cleansing solutions. Metformin decreases hepatic glucose production and increases peripheral glucose uptake by

muscle and adipose tissue. The molecular mechanism of metformin action is still unknown, although the drug was developed in the 1950s. Metformin does not stimulate insulin secretion, but it does decrease fasting plasma insulin levels and improves insulin-mediated glucose metabolism, that is, insulin sensitivity. Therefore, it does not cause hypoglycemia. The most frequently used dose is 500 mg orally three times a day. Some investigators also used an oral 850 mg, twice-a-day regimen. The optimal dose range for ovulation induction has not been studied formally. Seven randomized, controlled studies investigated the efficacy of metformin on ovulation induction. Moghetti et al showed improved menstrual regularity and ovulation along with reduced hyperinsulinemia and hyperandrogenemia.<sup>72</sup> In this study, 50% of patients started having regular cycles. Vandermolen et al showed that addition of metformin to CC increased ovulation and pregnancy rates in CC-resistant patients compared with placebo (75% vs. 27% and 55% vs. 7%, respectively).<sup>73</sup> Nestler et al found that 34% of women who were placed on CC ovulated spontaneously, as opposed to 4% of women in the placebo group.<sup>74</sup> When metformin was combined with CC in women unresponsive to CC, the ovulation rate increased to 90% compared with 2% in the CC-plus-placebo group. The area under the insulin curve after an oral GTT also decreased significantly in the metformin group compared with placebo. Ng et al failed to find a significant improvement in ovulation rate with metformin treatment in a small randomized study.<sup>75</sup> There were only 10 patients in each metformin and placebo group, which limits the reliability of their findings. Kocak et al found that metformin therapy decreased hyperandrogenism and insulin resistance and improved ovulation rates in 56 CC-resistant patients who were randomized to receive metformin or placebo.<sup>76</sup> Fleming et al conducted the largest randomized, controlled trial to date.<sup>77</sup> They reported that metformin treatment improved ovulation frequency (23% in the metformin group vs. 13% in the placebo group,  $P < 0.05$ ) and HDL levels in their 94 randomized patients. Treatment efficacy was inversely correlated with BMI. Sturrock et al also investigated the efficacy of metformin treatment on ovulation rates in their randomized, placebo-controlled, double-blind, cross-over study in 19 patients.<sup>78</sup> These patients did not benefit from metformin therapy. In summary, the majority of the randomized, controlled trials reported higher ovulation rates and improved insulin resistance with metformin therapy. Small randomized, controlled trials that failed to confirm the beneficial effects of metformin probably suffered from a subset of patients who were not insulin resistant. A large, multicenter, randomized, controlled study comparing metformin with CC or CC plus metformin is currently under way. The authors routinely use metformin as the first-line agent in ovulatory dysfunction with PCOS and have achieved a 42% pregnancy rate in our case series.<sup>79</sup> This was the first study to report pregnancy as an endpoint.

Beneficial effects of metformin use during pregnancy such as decreased first trimester spontaneous abortion rate and decreased gestational diabetes prevalence have been suggested by retrospective or no-control trials. Randomized, controlled studies are needed to determine the effects of metformin on pregnancy outcome.

Side effects of metformin include diarrhea, nausea, vomiting, abdominal bloating, flatulence, and anorexia. Approximately

## Reproductive Endocrinology and Infertility

30% more women experienced these symptoms compared with women who received placebo. Some investigators suggest starting with 500 mg daily and increasing the dose by 500 mg increments every week up to maximum of 2.5 g daily to reduce side effects. Hepatotoxicity is uncommon. Cessation of the therapy is warranted if liver function tests are found to be elevated. The most serious but rare side effect of metformin is lactic acidosis, which is fatal in 50% of the patients in whom it develops. The risk factors for lactic acidosis are not the usual circumstances of PCOS: impaired renal function, chronic liver and lung disease, and older age. Intravascular administration of radiocontrast media can also induce reduction in renal function and result in accumulation of metformin and lactic acidosis in patients with elevated serum creatinine, since metformin is excreted unchanged through the kidneys.

### Thiazolidinediones

Thiazolidinediones improve insulin resistance and decrease insulin levels presumably through binding to the peroxisome proliferator activator receptor gamma (PPAR $\gamma$ ). Troglitazone, pioglitazone, and rosiglitazone are the three commercially available thiazolidinediones. Troglitazone is the most extensively studied therapeutic agent of the three. However, it was withdrawn from the market in March 2000 owing to reports of idiosyncratic hepatic injury. There are limited data on the effects of pioglitazone and rosiglitazone in inducing ovulation. These agents are also associated with embryotoxicity in animal studies.

### Clomiphene Citrate

CC is an orally active nonsteroidal agent that contains a mixture of two isomers: zucloclomiphene and enclomiphene. Its structure is similar to estrogens and it has mixed estrogen agonist and antagonist effects. In animal models, CC acts as an estrogen antagonist in the presence of estrogen and is a weak estrogen agonist in the absence of estrogen. The main mechanism of its action is thought to be its antagonistic effects on the hypothalamic-pituitary axis and stimulation of GnRH secretion. CC also has antiestrogenic effects on the uterus, cervix, and vagina.

The initial dose of CC is 50 mg daily for 5 days between cycle days 3 and 7 or 5 and 9. The ovulatory LH surge usually occurs 7 days after the last pill. Approximately 75% of pregnancies occur in the first three treatment cycles, and 50% of patients conceive at the 50 mg dose.<sup>80</sup> If ovulation does not occur at the starting dose, dosage is increased by 50-mg increments up to 200 to 250 mg daily. It has been reported that 15% of patients who require higher doses of 150 and 200 mg become pregnant. However, doses above 100 mg have antiestrogenic effects and may not be efficient at producing pregnancy. If patients do not conceive within the first 6 months after the initiation of CC, prolongation of treatment does not improve the outcome. It is not possible to predict which patients will respond to CC. High BMI and elevated levels of androgens and PRL are associated with CC resistance. Dexamethasone may help women with high levels of androgens. The usual dose of dexamethasone is 0.5 mg at bedtime every day in addition to CC at the starting dose of 50 mg. Patients with elevated PRL levels may benefit from bromocriptine, a dopamine agonist that directly inhibits PRL secretion by the pituitary. The initial dose is 2.5 mg at bedtime. Some anovulatory women with normal PRL levels who did

not become pregnant with CC treatment may benefit from bromocriptine although this is controversial. Weight loss and insulin-sensitizing agents are the choice of treatment for hyperinsulinemic women with high BMI.

Side effects of CC are hot flashes, nausea and vomiting, headache, breast discomfort, abdominal bloating, hair changes, and visual symptoms. These side effects are not dose-dependent. Hot flashes are the most common side effect and are seen in about 10% of patients. They are thought to be due to the antiestrogenic effect of CC on the hypothalamic-pituitary axis. Visual symptoms including visual spots or flashes and blurry vision are considered a reason to discontinue CC. Liver function tests should be checked in women with symptoms or a history of liver disease.

### Gonadotropins

When the previously mentioned treatment options fail, the next step is to administer gonadotropins. However, anovulatory women with PCOS are prone to ovarian hyperstimulation syndrome (OHSS) and multiple pregnancies as a result of gonadotropin treatment. Many investigators have looked at the optimal ovulation induction protocols with gonadotropins including the type of the gonadotropins, dosing, and length of the treatment. Low-dose, step-up gonadotropin therapy with small starting doses for 14 days and a small incremental dose change thereafter has the highest pregnancy rates and lowest OHSS and multiple pregnancy rates.<sup>81</sup> Routine addition of GnRH agonists or antagonists is not recommended. However, addition of insulin-sensitizing agents may moderate hyperstimulation and is recommended by some investigators.

### Aromatase Inhibitors

Aromatase inhibitors have recently been suggested as an ovulation induction agent. They suppress the conversion of androgens to estrogens and thus decrease the negative feedback of estrogens on the hypothalamic-pituitary axis, similarly to CC. However, the current data are derived from only small preliminary studies.<sup>82,83</sup>

### D-Chiro-inositol

An initial randomized, controlled pharmaceutical-supported study reported that D-chiro-inositol was effective in improving insulin resistance and ovulatory function in 22 women with PCOS. However, phase II clinical trials failed to show this benefit.<sup>84</sup>

### Corticosteroids

Women with high serum androgen levels are likely resistant to CC. Women with elevated serum DHEAS levels may benefit from the addition of dexamethasone. In one randomized, controlled study in anovulatory, CC-resistant women with normal DHEAS levels, the addition of 2 mg dexamethasone to CC increased the ovulation rate compared with CC plus placebo (80% vs. 20%, respectively).<sup>85</sup> Although it is believed that a decline in adrenal androgen production improves responsiveness to CC, corticosteroids may also have direct effects on follicle development, cytokines such as IGF-1, and the hypothalamic-pituitary-ovarian axis. Dexamethasone treatment, 0.5 to 2 mg at bedtime, in addition to CC may be considered in CC-resistant women. However, prolonged use of dexamethasone in excess of

0.5 mg/day may induce iatrogenic Cushing's syndrome and is no longer recommended. The addition of metformin is now preferred by most clinicians.

#### **Combination Therapy with Insulin-sensitizing Agents**

Metformin in combination with other ovulation induction agents may improve pregnancy rates. When CC was used in conjunction with metformin in women who are unresponsive to either drug alone, pregnancy rates improved and ovulation was achieved at lower doses of CC.<sup>86</sup> Metformin also appears to suppress hyperresponsiveness of the ovary to FSH. However, randomized studies with sufficient power are needed in order to make definitive conclusions.

#### **Surgery**

Ovarian wedge resection for ovulation induction was first developed by Stein and Leventhal. It was abandoned years later because of the risk of postoperative peritubal and paraovarian adhesion formation although many patients resumed ovulation after wedge resection. With the advent of laparoscopy, a less invasive technique, laparoscopic ovarian drilling, has emerged. This technique employs puncturing of the ovary using electrocautery or laser. The ovary is usually punctured at 5 to 10 different places, which are approximately 10 mm deep and 1 mm in diameter. The purpose of ovarian drilling is similar to that of wedge resection: removal or destruction of hormone-producing tissue. Thus, it results in decreased testosterone and inhibin levels, leading to a rise in FSH and resumption of normal folliculogenesis. A randomized, controlled study comparing ovarian drilling to FSH for ovulation induction showed that ovarian drilling alone yielded lower pregnancy rates compared with recombinant FSH alone (37% vs. 75%, respectively).<sup>87</sup> Addition of FSH injections to ovarian drilling improved pregnancy rates to be similar to those of FSH alone. One advantage of ovarian drilling was the reduced rate of multiple pregnancy (rate ratio 0.11, CI 0.01–0.88). This procedure may be considered for patients who are adverse to risk of multiple pregnancy or are unresponsive to other conservative therapies.

#### **Treatment of Symptoms Unrelated to Infertility**

The main goal of treatment for women who do not desire fertility is the prevention of long-term sequelae.

#### **Type 2 Diabetes Mellitus**

Three large randomized, controlled studies report that significant reductions in the incidence of diabetes can be obtained through intensive lifestyle changes.<sup>88–90</sup> Diet and exercise in high-risk groups such as people with a first-degree diabetic relative, history of gestational diabetes, or impaired glucose tolerance are beneficial. One randomized, controlled study compared metformin therapy to lifestyle intervention and placebo.<sup>91</sup> Although both metformin and intensive lifestyle intervention reduced type 2 diabetes incidence, metformin was not as effective as lifestyle changes only (31% vs. 58%, respectively). As noted previously, weight loss as low as 5% alone may improve metabolic parameters and measurably decrease diabetes risk. A low-calorie, low-fat diet combined with moderate exercise has been successful. However, extensive one-on-one counseling is needed to reinforce the behavioral changes. Weight loss also facilitates

spontaneous ovulation and the effectiveness of ovulation induction agents.

#### **Cardiovascular Disease**

Because women with PCOS exhibit known risk factors for cardiac disease such as obesity, diabetes, and dyslipidemia, therapies directed toward prevention of these comorbidities may reduce the heart disease risk. Diet and exercise are the mainstay of preventative therapy. Currently, there are insufficient data to recommend insulin-sensitizing agents as a means of cardiovascular protection. However, indirect evidence including decreased cardiovascular events in diabetic patients on metformin and improvement of metabolic parameters such as triglyceride and LDL levels warrants further investigation.

#### **Endometrial Hyperplasia/Cancer**

Although efficacy is unknown, intuitively accepted practice is to induce withdrawal bleeding with a progestin at least four times a year. A well-established prevention method for endometrial cancer is oral contraceptive pills (OCPs). At least a 1-year use of OCPs decreases the risk of endometrial cancer between ages 40 and 55 years by 50%. However, there are concerns about altered carbohydrate metabolism in women on OCPs. Progestins increase plasma insulin and decrease glucose tolerance. However, to date, studies have failed to find a significant relationship between diabetes and currently used combined OCP formulations.<sup>92</sup> Another concern is the increased risk of cardiovascular disease among OCP users. A large study conducted by the World Health Organization (WHO) reported that OCPs increase myocardial infarction risk only in women with known cardiovascular risk factors such as smoking and hypertension.<sup>93</sup> A Dutch study found an increased risk of myocardial infarction in women on second-generation OCPs but not in women on third-generation OCPs.<sup>94</sup> Several other studies in the literature showed increased risk of myocardial infarction only in women who smoke and use OCPs. Randomized, controlled studies are needed to investigate the effects of OCPs on the development of diabetes and heart disease in women with PCOS.

Intuitively, insulin-sensitizing medications may protect the endometrium in women who resume regular cycles on these drugs.

#### **Hirsutism and Acne**

Treatment directed to the suppression of androgen production and its peripheral action may prevent new hair growth and enhance cosmetic removal of existing hairs. Several medications can be used to achieve this goal.

#### **Oral Contraceptive Pills**

The most commonly used medication for hirsutism is OCPs. They suppress LH and FSH secretion, which decreases ovarian androgen production. Estrogens in OCPs also increase SHBG levels, which in turn decreases free testosterone levels. Progestins such as norethindrone may inhibit 5α-reductase activity in the skin. Intuitively, progestins with low androgenic activity including gestodene, desogestrel, and norethindrone acetate are preferred. Therapy should be continued for at least 6 months before an improvement can be expected. The hair growth cycle is approximately 6 months long.

## Reproductive Endocrinology and Infertility

### Spironolactone

Spironolactone is an aldosterone antagonist diuretic. It is also a competitive androgen receptor antagonist and directly inhibits 5 $\alpha$ -reductase activity. Spironolactone is generally accepted as a potent agent for the treatment of hirsutism although there are only a few randomized, controlled trials that investigated the effectiveness of this medication in hirsutism. A review of all randomized, controlled studies in the literature reported that spironolactone treatment achieved significant subjective and objective improvement in hair growth compared with placebo.<sup>95</sup> It was also superior to finasteride and low-dose cyproterone acetate in one randomized, controlled study.<sup>96</sup> The effective dose is usually 200 mg daily. Side effects include metrorrhagia, urticaria, polyuria, nocturia, and dyspepsia. Hyperkalemia is a potential complication of the treatment that can occur in the elderly, persons with diabetes, and women taking a potassium-saving diuretic.

### Flutamide

Flutamide is a nonsteroidal androgen receptor antagonist that is used as adjuvant treatment for prostate cancer. Hair growth is directly inhibited at a starting dose of 250 mg daily. However, in randomized comparison studies, flutamide was not superior to spironolactone or finasteride.<sup>97</sup> Moreover, hepatotoxicity is a rare but potentially serious complication.

### Finasteride

Finasteride is a 5 $\alpha$ -reductase inhibitor; it blocks conversion of testosterone to dihydrotestosterone. Finasteride is approved for the treatment of benign prostate hyperplasia and hair loss in men. The usual dose is 5 mg daily. It has not been shown to be more effective than flutamide or cyproterone acetate.<sup>98</sup> However, the lack of side effects makes finasteride a favorable option for the treatment of hirsutism.

### Cyproterone Acetate

This is a potent progestin that inhibits pituitary LH secretion and thus ovarian androgen production. Cyproterone acetate also blocks the androgen receptors and reduces the activity of skin 5 $\alpha$ -reductase. The most commonly used form is called Diane-35 in Europe and Canada, and Dianette in Great Britain. It contains 2 mg cyproterone acetate and 35  $\mu$ g ethynodiol diacetate and is taken by mouth daily. Another method is the reversed sequential regimen with high-dose cyproterone acetate. In this regimen, 50 or 100 mg cyproterone acetate is given for the first 10 days of the cycle with 30 or 50  $\mu$ g ethynodiol diacetate given for 21 days. However, a dose-ranging study did not find a significant difference in treatment effectiveness among different dose regimens of cyproterone acetate (i.e., 2, 20, and 100 mg) after 6 months of therapy, although higher doses showed an improvement 3 months after the initiation of therapy.<sup>99</sup> When cyproterone acetate is compared with other antiandrogenic medications such as flutamide, spironolactone, and finasteride, no significant difference has been demonstrated.<sup>100</sup> Cyproterone acetate appears to be safe as side effects include headache, mood changes, and decreased libido.

### GnRH Analogs

Long-acting GnRH agonists such as leuprolide and nafarelin have been used for the treatment of hirsutism since the mid-

1980s. They suppress pituitary LH secretion and thus decrease ovarian androgen production. Higher doses of GnRH agonists are required to inhibit androgen secretion compared with estradiol secretion. In a randomized study, OCPs alone were as effective as GnRH agonist alone or GnRH agonist plus OCPs, although women in the latter groups had a faster clinical response.<sup>101</sup> Women taking a GnRH agonist alone had significant bone loss, which was not seen in the other two groups. On the contrary, another randomized study showed that the combination of a GnRH agonist and OCPs resulted in greater improvement of hirsutism compared with GnRH alone or OCPs alone.<sup>102</sup> GnRH agonist therapy is as effective as high-dose cyproterone acetate and its effect lasts longer.<sup>103</sup> However, GnRH agonists are relatively expensive and should be used in conjunction with OCPs to prevent bone loss. Therefore, their use is recommended in women with severe insulin resistance and hyperthecosis that is unresponsive to other medical therapies.

### Insulin-Sensitizing Agents

The efficacy of metformin in hirsutism is not well characterized despite the fact that it reduces serum androgens significantly. There are conflicting studies in the literature some of which cannot be used to evaluate hirsutism because of the short follow-up periods. Some studies showed a significant improvement especially in adolescent girls, whereas others did not find a significant reduction. Large randomized studies with a long follow-up period are needed to establish the efficacy of metformin in hirsutism.

### Other Drugs

Ketoconazole inhibits androgen synthesis through the suppression of the cytochrome P-450 system. The high incidence of side effects such as elevated liver enzymes prevents ketoconazole's widespread use, although it is efficacious in the treatment of hirsutism. Cimetidine is a weak androgen receptor blocker and clinically is not effective. Dexamethasone is used only in women with adrenal enzyme deficiency.

## SUMMARY

PCOS is a lifelong inherited disease that evolves with age. Diagnosis may be challenging, since PCOS is a heterogeneous disorder with various manifestations including reproductive and metabolic abnormalities. Although insulin-sensitizing agents have revolutionized treatment, molecular studies will unveil the pathophysiology of PCOS and allow clinicians to develop new treatment strategies.

# Chapter 63

# Thyroid Function and Disorders

Kristiina Parviainen, MD, Hyagriv N. Simhan, MD, MSCR,  
and Thomas P. Foley, Jr., MD

## KEY POINTS

- Normal thyroid function is essential for optimal reproductive function and pregnancy outcome.
- Failure to diagnose or to appropriately treat hypothyroidism in pregnancy can have significant impact on the neurologic development of the child.
- Most women with pregestational hypothyroidism will require a dosage increase in order to maintain euthyroid status.
- Radioactive iodine ( $^{131}\text{I}$ ) is contraindicated in pregnancy owing to potential for ablation of the fetal thyroid gland.
- Neonatal screening for congenital hypothyroidism is mandatory in the United States.

Thyroid disorders are among the most common endocrine disorders affecting women. Thyroid dysfunction may be associated with menstrual irregularity, infertility, and adverse pregnancy outcomes. It is therefore essential that the clinician be well versed in the diagnosis and treatment of thyroid disorders. Diagnosis in pregnancy is particularly important owing to associated pregnancy complications and potentially significant adverse fetal and neonatal sequelae.

Hypothyroidism, defined as inadequate thyroid hormone production, has an incidence of 2.5% in pregnancy.<sup>1</sup> Risk factors for hypothyroidism include history of thyroid surgery, history of head/neck irradiation, family history of thyroid disorders, drug uses (lithium carbonates, amiodarone, aminoglutethimide, interferon, thalidomide, iodides, and stavudine), and pituitary and hypothalamic disorders. Other high-risk populations are the elderly, postpartum women, and individuals with autoimmune disorders including type 1 diabetes mellitus, adrenal insufficiency, and premature ovarian failure. Increased incidence is also reported among individuals with Down syndrome and Turner's syndrome.<sup>2</sup> Although rare in the United States, iodine deficiency is the foremost cause of hypothyroidism worldwide.<sup>3</sup> Goiters are commonly seen in pregnancy in iodine-deficient regions but rarely in the United States.

Hyperthyroidism, defined as excess production of, release of, or exposure to thyroid hormone, and thyrotoxicosis, caused by hyperfunctioning of the thyroid gland, are much less common in pregnancy with a reported incidence of 0.2%.<sup>1</sup> Ninety-five percent of all hyperthyroidism in pregnancy is due to Graves' disease, which is an autoimmune disease characterized by the presence of thyroid-stimulating immunoglobulins (TSIs). Thyroid-stimulating hormone-binding inhibitory immuno-

globulins (TBIs) also may be present in treated cases and may cause hypothyroidism in mother and fetus.<sup>4</sup> Thyroid crisis or storm resulting from the sudden release of thyroxine from the thyroid gland is a medical emergency, with a 2% incidence in pregnancy among thyrotoxic women.

Postpartum thyroiditis is a diagnosis of particular interest to the obstetrician, with a reported incidence of 5% to 9%.<sup>1</sup> This condition usually presents as transient thyrotoxicosis followed by hypothyroidism that by definition occurs within 1 year of childbirth.

Hashimoto's thyroiditis, or chronic lymphocytic thyroiditis, is an autoimmune disease caused by antibody-dependent cell-mediated cytotoxicity. Affected women usually are euthyroid, though approximately 20% are hypothyroid, and may have diffuse thyromegaly, or goiter. It is the most common cause of acquired hypothyroidism in women.

The incidence of thyroid cancer among pregnant women is 1 per 1000 thyroid nodules detected.<sup>5</sup> Clinicians must therefore be cognizant of this rare but serious condition when evaluating women for possible thyroid pathology.

Congenital hypothyroidism (CH) is the most common treatable cause of mental retardation, with an incidence of 1 in 4000 newborns in iodine-sufficient regions of the world. Most of these cases result from permanent thyroid disease that requires lifelong therapy with thyroid hormone. Approximately 15% of CH may be attributed to genetic causes including inherited disorders that cause defects in thyroid hormone synthesis, metabolism, and rarely thyroid embryogenesis.

## PHYSIOLOGY

The thyroid gland consists of a spherical orientation of follicular cells that surround colloid composed of thyroglobulin, the glycoprotein substrate for synthesis of iodothyronines. Thyroid function is regulated by the hypothalamic-pituitary axis through thyrotropin-releasing hormone (TRH) production by the paraventricular nucleus of the hypothalamus that stimulates the production of thyroid-stimulating hormone (TSH) by the pituitary thyrotrophs.

TSH is a glycoprotein that shares the  $\alpha$  subunit with follicle-stimulating hormone (FSH), luteinizing hormone (LH), and human chorionic gonadotropin (hCG). TSH regulates thyroid gland production of thyroxine ( $T_4$ ) and triiodothyronine ( $T_3$ ). Iodide trapping is mediated by the sodium iodide symporter (NIS) and is the rate-limiting step in thyroid hormone synthesis. The unbound or free  $T_4$  ( $FT_4$ ) circulates in the serum and is converted peripherally to  $T_3$  by monodeiodination.  $T_3$  has

Table 63-1 Thyroid Function, Values in Pregnancy, Hyper- and Hypothyroidism Compared to Healthy Nonpregnant Women					
Condition	TSH	Free T <sub>4</sub>	Total T <sub>4</sub>	Total T <sub>3</sub> *	rT <sub>3</sub> U
Pregnancy	Normal	Normal	Elevated	Elevated	Decreased
Hyperthyroidism	Decreased	Elevated	Elevated	Elevated	Elevated
Hypothyroidism	Elevated	Decreased	Decreased	Normal/decreased	Decreased

rT<sub>3</sub>U, resin T<sub>3</sub> uptake.  
\*Total and free T<sub>3</sub> values may not be elevated when there is coexisting nonthyroidal illness syndrome or low T<sub>3</sub> syndrome.

greater biologic activity than T<sub>4</sub> owing to the increased affinity for nuclear receptors. On binding of T<sub>3</sub> to specific receptors attached to DNA, T<sub>3</sub> stimulates transcription and translation of proteins, which results in an elevated metabolic rate at the cellular level.

Circulating thyroid hormone, dopamine, and somatostatin cause a negative feedback by inhibition on pituitary TSH secretion.

Thyroid function changes in early pregnancy as a consequence of (1) increased iodine uptake by the thyroid gland, (2) increased estrogen-mediated production (twofold increase) and decreased clearance of thyroid binding globulin by the liver, and (3) hCG stimulation of the TSH receptor. These effects cause a mild increase in FT<sub>4</sub> that in turn may cause transient gestational thyrotoxicosis.<sup>6</sup> FT<sub>4</sub> concentrations, however, remain essentially stable during pregnancy provided there is normal thyroid function and adequate iodine substrate. Expected changes in thyroid function values in normal pregnancy as compared with the nonpregnant state are depicted in Table 63-1. Maternal blood levels of iodine are decreased in pregnancy owing to an increase in the glomerular filtration rate, provided that it is not accompanied by an increase in iodine intake. The recommended daily iodine intake in pregnancy is 200 µg.<sup>3</sup>

The thyroid gland develops during the first trimester, whereas maturation of the hypothalamic-pituitary-thyroid feedback system and peripheral action of the thyroid hormones continues throughout fetal life into early postnatal life. The thyroid originates from an outpouching of the anterior pharyngeal floor at the base of the tongue (foramen caecum) and migrates to an anterior midline position by 7 weeks' gestation. Iodine trapping is detected by 10 to 12 weeks and thyroxine production by week 14. Normal adult levels of T<sub>4</sub> are achieved by 36 weeks' gestation,<sup>7</sup> continue to increase until delivery, and remain greater than adult levels during infancy. Serum T<sub>3</sub> levels are low during fetal life compared with adult levels, but surge shortly after birth to concentrations above adult levels in response to the abrupt surge of TSH immediately after birth.<sup>8</sup>

## PATHOLOGY

Graves' disease is the most common cause of thyroid gland hyperfunction, with stimulation of the gland mediated by TSIs. The mechanisms for the immune-mediated autoantibody production are unknown.

Thyroid crisis is a severe and life-threatening form of thyrotoxicosis resulting from release of thyroxine stores. Precipitating events include surgery, trauma, infection, and labor.

Hyperemesis gravidarum is a pregnancy-associated, hCG-mediated condition in which uncontrolled nausea and vomiting leads to weight loss and electrolyte imbalance. These symptoms and the typically depressed TSH level seen with hyperemesis gravidarum can make the distinction from hyperthyroidism difficult.

Molar pregnancy/trophoblastic disease with the associated markedly elevated hCG levels can also cause an hCG-mediated hyperthyroid syndrome. This diagnosis should always be considered when symptoms of thyrotoxicosis appear for the first time in the presence of a positive pregnancy test. Molar pregnancy may also be accompanied by elevated blood pressure and thus mimic preeclampsia.

Most cases of hypothyroidism in the United States are caused by primary dysfunction of the thyroid gland. In Hashimoto's thyroiditis, a diffuse lymphocytic infiltrate and lymphoid follicles fill the thyroid parenchyma. Circulating autoantibodies are also detected in serum.<sup>2</sup> Significant sequelae of unrecognized or inadequately treated severe maternal hypothyroidism include low birth weight, congenital anomalies, stillbirth, and neurologic impairment, including impaired cognitive development, in the progeny of women with mild to moderate hypothyroidism during pregnancy.<sup>9,10</sup>

Postpartum thyroiditis is caused by autoimmune lymphocytic infiltration and inflammation of the thyroid gland. The inflammatory process causes injury to the thyroid follicles, release of preformed T<sub>4</sub> and T<sub>3</sub> contained therein, and mild thyrotoxicosis. A hypothyroid phase ensues during healing and recovery of normal thyroid gland architecture and function.

Fetal hyperthyroidism is caused by transplacental passage of thyroid-stimulating immunoglobulins, which stimulate the fetal thyroid gland to secrete excessive amounts of thyroxine. The incidence of neonatal Graves' disease is approximately one clinically affected infant born to 70 women with Graves' disease. The risk for clinical expression of Graves' disease in the newborn is thought to be related to the maternal titer of TSIs and the binding affinity of TSI for the TSH receptor. However, since exact clinical correlation is yet to be determined, the application of TSI titers to clinical practice remains controversial.<sup>11</sup>

Fetal hypothyroidism can also be seen in women with Graves' disease and/or Hashimoto's thyroiditis through the action of the TBIs that block the fetal TSH receptor.

There are several causes of primary CH. The most common category is thyroid dysgenesis, which includes agenesis or dysgenesis of the fetal thyroid gland, familial disorders of thyroid hormone synthesis, and iodine deficiency. Transient iatrogenic hypothyroidism may also be the consequence of overtreatment with antithyroid drugs. Maternal hypothyroidism secondary to iodine deficiency and compounded by other trace metal deficiencies is the most significant risk factor for congenital hypothyroidism and cretinism worldwide. Less common causes are genetic and developmental defects that affect the embryogenesis of the fetal hypothalamus, pituitary, and thyroid that include inactivating mutations of the genes for the synthesis of hormones, receptors, and transcription factors.<sup>12</sup>

## CLINICAL FEATURES

Since routine laboratory screening is currently not recommended in asymptomatic adults, timely diagnosis requires vigilance on the part of the clinician. The signs and symptoms of hyperthyroidism and those specific for Graves' disease are listed in Tables 63-2 and 63-3, respectively. Proptosis and external ocular muscle palsy are distinguishing features of Graves' disease—a direct result of infiltrating ophthalmopathy—but are present in only 30% of cases. Of note, some of the features of hyperthyroidism including tachycardia, heat intolerance, fatigue, anxiety, emotional lability, nausea, and weight loss are not infrequently seen in early pregnancy, potentially resulting in a delay in diagnosis.

The differential diagnosis for goiter in pregnancy includes Graves' disease, Hashimoto's thyroiditis, iodine deficiency, excessive iodine intake, lymphocytic thyroiditis, thyroid cancer, lymphoma, and iatrogenic hypertrophy secondary to treatment with lithium or thioamides.

**Table 63-2**  
**Clinical Signs and Symptoms of Hyperthyroidism**

- Excessive sweating
- Frequent stools
- Goiter
- Heat intolerance
- Hypertension
- Insomnia
- New-onset atrial fibrillation
- Oligomenorrhea or hypomenorrhea
- Palpitations
- Tachycardia
- Tremors
- Weight loss

**Table 63-3**  
**Clinical Signs and Symptoms Specific to Graves' Disease**

- Dermopathy
- Lid lag
- Lid retraction
- Pretibial myxedema
- Proptosis
- Thyroid acropathy

**Table 63-4**  
**Clinical Signs and Symptoms of Hypothyroidism**

- Carpal tunnel syndrome
- Cold intolerance
- Constipation
- Edema
- Fatigue
- Hair loss
- Hypercholesterolemia
- Insomnia
- Intellectual slowness
- Menorrhagia
- Muscle cramps
- Prolonged relaxation of deep tendon reflexes
- Voice changes
- Weight gain

Thyroid storm is a known complication of hyperthyroidism in pregnancy. The classic signs of thyroid crisis are hyperthermia, tachycardia, hypertension, altered mental status, and diarrhea, but the diagnosis should be considered when any of these signs are present in a patient with known hyperthyroidism.

The clinical features of hypothyroidism are depicted in Table 63-4. The symptoms can be subtle and are often dismissed by the patient and clinician as normal changes of pregnancy.

Most infants with congenital hypothyroidism are asymptomatic at birth. Fetal hypothyroidism is rare among cases of congenital hypothyroidism, since the clinical features are often partially masked in utero by the transplacental passage of maternal thyroxine. Congenital hypothyroidism is associated with an increased incidence of congenital anomalies, including cardiac anomalies. Clinical findings of CH in the newborn include lethargy, slow movement, hoarse cry, constipation, large fontanelles, hypotonia, and prolonged jaundice.<sup>13</sup> Cretinism, the most dramatic form of congenital hypothyroidism, is characterized by mental retardation, small stature, and neurologic disorders.

Fetal hyperthyroidism is characterized by tachycardia, intrauterine growth restriction, and craniosynostosis.<sup>14</sup> Neonatal findings include diffuse goiter, vomiting, diarrhea, poor weight gain, hepatosplenomegaly, thrombocytopenia, hypertension, cardiac arrhythmia, and exophthalmos.

## DIAGNOSIS

Clinical suspicion is the key to diagnosis of thyroid disorders, as it leads to appropriate laboratory tests to confirm or refute the diagnosis. Symptoms of hypothyroidism, hyperthyroidism, or anterior cervical discomfort, for example, warrant further evaluation. TSH is typically the initial test recommended, with current TSH assays demonstrating improved sensitivities at or below 0.01 mU/L. Results from analysis of the National Health and Nutrition Examination Survey (NHANES III) data demonstrate that the normal upper range for TSH in adults in the United States is 2.5 to 3.5 mU/L.<sup>15</sup> In patients with clinical suspicion, monoclonal TSH assay has 98% sensitivity and 92% specificity.<sup>16</sup> It is important to remember, however, that a low TSH value based on older TSH normal range data is found in up

## Reproductive Endocrinology and Infertility

to 15% of normal pregnancies in the first trimester. Furthermore, recent data in pregnant women suggest that the upper limit for TSH and other thyroid function varies with gestational age.<sup>6,17</sup>

A careful examination of the thyroid gland may also suggest the need for additional evaluation. For example, a firm, lumpy, irregularly shaped, enlarged thyroid gland is most often associated with autoimmune/Hashimoto's thyroiditis. A soft, spongy goiter is more commonly seen in patients with Graves' disease, inherited disorders of thyroid hormone synthesis, or iodine deficiency but may also be seen in autoimmune thyroiditis in adolescents and young adults. Serum thyroid antibodies, especially the thyroid peroxidase antibodies (TPOAbs), are the diagnostic test for autoimmune thyroid disease (Hashimoto's thyroiditis), since they are present in 95% of cases. By contrast only 60% of these patients will have positive thyroglobulin antibodies (TGAbs).<sup>15</sup>

Among women with known hypothyroidism prior to pregnancy who receive L-thyroxine therapy, 35% to 62% with autoimmune hypothyroidism will require a dosage increase; and 70% to 100% of athyreotic women with congenital athyreosis, following <sup>131</sup>I ablation therapy or thyroidectomy, require a dosage increase. In fact, some thyroidologists recommend that women with established hypothyroidism receiving L-thyroxine therapy increase their T<sub>4</sub> dose by 30% as soon as they suspect that they are pregnant.<sup>18</sup>

Since the thyroid immunoglobulins are IgG subclass 1 and can therefore readily cross the placenta from mother to fetus, the TSIs can cause fetal and neonatal thyrotoxicosis,<sup>19</sup> whereas the TBIs may affect fetal and neonatal hypothyroidism.<sup>20,21</sup> Most cost-effective TSH receptor antibody (TRAb) assays, however, do not distinguish between a TSH-receptor stimulating immunoglobulin, or antibody (TSI), as seen in active Graves' disease with hyperthyroidism<sup>19</sup> and a TSH-receptor blocking antibody (TBI), as seen in Hashimoto's thyroiditis with hypothyroidism.<sup>21</sup> Therefore, although the potential consequences of the transmission of these antibodies across the placenta to the fetus are significant,<sup>20</sup> the utility of immunoglobulin titers in the clinical surveillance of pregnancy is uncertain. The American College of Obstetricians and Gynecologists (ACOG) 2002 Practice Bulletin on thyroid disease in pregnancy states that testing for TRAb (refers to an assay that measures TSI, TBI, and TBII) titers remains controversial.<sup>11</sup>

Although mild thyroid enlargement is commonly seen in pregnancy, a thyroid nodule should be evaluated in the same manner as in the nonpregnant state. An ultrasound-guided, fine-needle aspiration biopsy of the nodule, serum TSH, and FT<sub>4</sub> are the preferred initial tests to determine whether the nodule is benign or malignant.<sup>22</sup>

Newborn screening programs for hypothyroidism include testing for TSH alone (primary TSH screening), T<sub>4</sub> as the primary test and TSH as a confirmatory test on the lowest percentile of T<sub>4</sub> values (usually the lowest 10%), or TSH and T<sub>4</sub> initially. The screening tests are performed on blood from a heel prick that is applied to a filter paper specimen that is collected from 24 hours to 3 days after delivery. The goal of newborn screening is to detect and treat neonates with primary hypothyroidism (high TSH, low T<sub>4</sub>) as early as possible to prevent impaired intellectual development and neurobehavioral disabilities. Every infant with an abnormal TSH screen should have

a serum TSH to confirm the diagnosis, and a serum FT<sub>4</sub> to assess the degree of hypothyroidism to determine the appropriate dose of L-thyroxine. Therapy should be initiated pending confirmation, and may be discontinued if the test returns normal. Most physicians also obtain an imaging study, most commonly a thyroid ultrasound, to diagnose possible causes such as an absent thyroid gland (athyreosis), small thyroid (hypoplasia), thyroid tissue in another location that is usually in the cervical region (ectopia), or a normal or enlarged thyroid as seen with inherited disorders of thyroid hormone synthesis.

Some programs that include T<sub>4</sub> as a screening test also include further tests to detect central (hypothalamic/pituitary) hypothyroidism with the findings of a low T<sub>4</sub> and a TSH that is not elevated as expected in primary hypothyroidism. These additional tests, however, require recalling approximately 3% of the population for an uncommon group of diseases that occurs in approximately 1 in 20,000 infants in Europe and 1 in 50,000 infants in North America.

### TREATMENT

Hyperthyroidism during pregnancy is typically treated with thioamide drugs (propylthiouracil [PTU] and methimazole [MTZ] in the United States and also carbimazole [CBZ]) in other parts of the world. CBZ is functionally the same as MTZ, since the former is enzymatically converted to MTZ in vivo. Their primary mechanisms of action are competitive inhibition of thyroglobulin iodination and iodothyronine biosynthesis. PTU also inhibits conversion of T<sub>4</sub> to T<sub>3</sub>.<sup>23</sup>

PTU has been traditionally preferred to MTZ in the United States in pregnant women owing to reportedly more limited passage across the placenta, inhibition of conversion of T<sub>4</sub> to T<sub>3</sub>, and the reported link between aplasia cutis and methimazole. There is evidence, however, to suggest that both drugs are safe and effective in pregnancy.<sup>24</sup> The goal of therapy in pregnancy is to achieve control with minimal drug dosage, and the target maternal FT<sub>4</sub> should be in the high-normal range. PTU therapy is prescribed in divided doses, with a reasonable initial regimen being 100 to 150 mg three times daily. Often the dose can be decreased in the third trimester. Possible side effects of PTU therapy (1% to 5% incidence) include rash, itching, fever, hepatitis, bronchospasm, and the most serious complication of agranulocytosis and hepatitis.<sup>25</sup> Both PTU and MTZ are compatible with breastfeeding.<sup>26</sup>

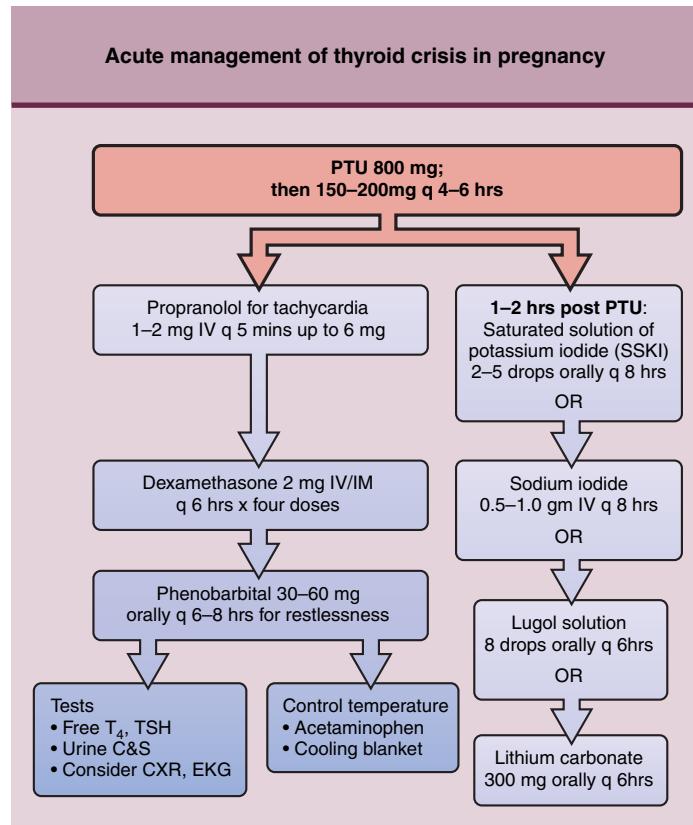

The thioamides are not effective in the treatment of the thyrotoxic phase of postpartum thyroiditis, since this is not caused by an overproduction of thyroid hormone but rather by excessive release from the disrupted thyroid gland.  $\beta$ -Blockers such as metoprolol and atenolol can, however, be utilized in the treatment of symptomatic tachycardia, tremors, and anxiety.

Thyroidectomy is a possible therapeutic option for severe thyrotoxicosis during pregnancy. However, despite considerable advances in anesthesia, thyroidectomy during pregnancy is associated with a higher perioperative complication rate owing to increased vascularity of the thyroid gland. Short-term potassium iodide therapy can be utilized in combination with PTU and  $\beta$ -blockers in the treatment of severe thyrotoxicosis and during the preoperative preparation of the patient to decrease vascularity.<sup>27</sup>

Radioactive iodine treatment, which is the most commonly used therapy for Graves' disease because of its efficacy and cost effectiveness, is *contraindicated* and not a therapeutic option in pregnancy owing to the potential for fetal thyroid ablation. Women who have been treated with radioiodine for hyperthyroidism should avoid pregnancy for 1 year after treatment.<sup>28</sup>

Thyroid crisis is a very rare complication of Graves' disease. It requires prompt treatment with  $\beta$ -blockers (the most important therapeutic modality), sodium iodide infusion, PTU, and hypothermia.  $\beta$ -Blockers are utilized to reverse the hyperadrenergic state and to control the heart rate and thereby to improve cardiac output and also inhibit the peripheral conversion of  $T_4$  to  $T_3$ . PTU may be administered acutely by mouth or nasogastric tube. Sodium iodide is administered intravenously to inhibit thyroid release.<sup>29</sup> Acetaminophen is the drug of choice for treatment of pyrexia because salicylates can displace  $T_3$  and  $T_4$  from TBG.<sup>30</sup> A hypothermic blanket and maintenance of fluid and electrolyte balance and normovolemia are most important. A schematic for treatment of thyroid crisis in pregnancy is depicted in Figure 63-1.<sup>29</sup>

Hypothyroidism in pregnancy should be treated as soon as the diagnosis is made in order to minimize fetal and neonatal sequelae. Thyroxine should be initiated at a dose of 2.0  $\mu\text{g}/\text{kg}$  of pregnancy weight once daily.<sup>31</sup> TSH should be repeated in 2 to 4 weeks and the dose adjusted until the TSH is in the target

**Figure 63-1** Acute management of thyroid crisis in pregnancy.

(From Winkler CL, Davis LD: Endocrine emergencies. In Dildy GA, elfort MA, Saade GR, et al [eds]: Critical Care Obstetrics, 4th ed. Malden, Mass, Blackwell Science, 2004, pp 423–428.)

range. Patients should be informed that iron included in prenatal vitamins and calcium tablets (e.g., Tums) can interfere with thyroxine absorption in the gastrointestinal tract, and thyroid supplement intake should be timed accordingly.

In cases of pregestationally diagnosed hypothyroidism, women should continue to take thyroxine. An increase in thyroxine dose is usually necessary with advancing pregnancy. TSH testing should be repeated 2 to 4 weeks after a dose change and every 8 to 12 weeks thereafter in women who are euthyroid at initial assessment.

Postpartum thyroiditis requires treatment only if symptomatic. The transient hyperthyroid phase is treated with  $\beta$ -blockers and the hypothyroid phase with thyroxine replacement.

Women who have thyroid carcinoma are treated surgically, optimally in the second trimester. Delay until the postpartum period is also an acceptable option in cases of well-differentiated papillary and selected cases of follicular thyroid carcinoma without evidence of extrathyroidal extension or distant metastasis.<sup>5</sup>

## CLINICAL COURSE AND PROGRESSION

Diagnosis and appropriate treatment of pregestational hypothyroidism are essential for optimal pregnancy outcome for mother and child. Programs that ensure adequate maternal iodine intake are crucial in the effort to reduce the incidence of fetal hypothyroidism and cretinism worldwide.<sup>3</sup> In iodine-sufficient populations, undiagnosed or inadequately treated maternal hypothyroidism during pregnancy has been associated with adverse pregnancy outcomes and suboptimal neuropsychological development in the euthyroid children.<sup>8</sup>

Hyperthyroidism in pregnancy is associated with increased risk of preterm labor, spontaneous abortion, low birth weight, preeclampsia, and heart failure. PTU dosing should be adjusted frequently to minimize fetal effects by utilizing the lowest dose that maintains  $T_4/\text{FT}_4$  in the high-normal and TSH in the low-normal range. The dose can often be reduced or therapy discontinued in the third trimester.

Utilizing the minimal dose is important because of the reported association between PTU dose and clinical neonatal hypothyroidism, with 50% incidence of neonatal hypothyroidism in infants of mothers treated with PTU dose greater than 300 mg/day.<sup>24</sup>

The incidence of neonatal Graves' disease is 1% to 5% in newborns of mothers with hyperthyroidism secondary to maternal Graves' disease.<sup>32</sup> The low incidence is thought to be secondary to the combination of stimulatory and inhibitory immunoglobulins that cross the placenta.<sup>33</sup> Findings of neonatal hyperthyroidism include high baseline heart rate, goiter, advanced bone age, and craniosynostosis. With regard to follow-up of the neonate, it is important to remember that thioamides are cleared more rapidly than the stimulatory TSH-receptor antibodies. Furthermore, infants of euthyroid women treated with surgery or radioactive iodine in the past may still be at significant risk for neonatal Graves' disease, since immunoglobulin production may still be present.

As previously mentioned, clinical signs and symptoms of CH can be masked, in part, during the early newborn period by the presence of maternal thyroxine. However, transplacentally acquired maternal thyroxine does not completely normalize

## Reproductive Endocrinology and Infertility

neonatal thyroid function in infants with CH, with the possible exception of very low birth weight (VLBW) infants. If CH is unrecognized and untreated, cretinism can ensue. For this reason, neonatal screening is mandated in the 50 states and the District of Columbia.

### PITFALLS AND CONTROVERSIES

The diagnosis of hyperthyroidism may be difficult to make in early pregnancy as a result of the clinical overlap of signs and symptoms with those of normal early pregnancy and because TSH can be suppressed by hCG-mediated stimulation of the TSH receptor. If the TSH result is depressed in the first trimester, it should be repeated in the second trimester.

Normal values for TSH in pregnancy are rarely provided by commercial laboratories for reference.

The application of antibody titer levels to clinical practice in pregnancy surveillance remains controversial.

Universal screening of women before or during pregnancy, although an attractive idea, is currently not recommended.

# Chapter 64

# Disorders of the Adrenal Gland

Carla P. Roberts, MD, PhD

## KEY POINTS

- The adrenal gland is responsible for the production of cortisol, aldosterone, and the adrenal androgens.
- Exogenous corticosteroids may result in adrenal suppression within a relatively short time frame, so cortisol deficiency states should always be suspected and evaluated.
- Acute adrenal insufficiency is an emergency.
- Chronic adrenal insufficiency can become an emergency in the setting of superimposed stress or illness without adequate corticosteroid replacement.
- Late-onset congenital adrenal hyperplasia may masquerade as polycystic ovary syndrome. This enzymatic deficiency should be ruled out.

## INTRODUCTION

The anatomy of the adrenal glands was described 450 years ago by Bartholomeo Eustacius; however, a functional role for the adrenal glands was not defined until the pioneering work of Thomas Addison in 1855. Table 64-1 demonstrates the remarkable pathway of the history of the adrenal gland that allows us to manipulate and manage the steroidogenic disorders discussed in this chapter. A review of mineralocorticoids, pheochromocytomas, and other disorders of endocrine hypertension is not included in this discussion.

The control of adrenocortical function by a pituitary factor was demonstrated in the 1920s, and this led to the isolation of sheep adrenocorticotrophic hormone (ACTH) in 1943. Such a concept was supported through clinical studies, notably in 1932 by Harvey Cushing, who associated his original clinical observations of 1912 (a “polyglandular syndrome” caused by pituitary basophilism) with adrenal hyperactivity. The neural control of pituitary ACTH secretion by corticotropin-releasing hormone (CRH) was defined by Harris and other workers in the 1940s, but CRH was not characterized and synthesized until 1981 in the laboratory of Wylie Vale.

Located on top of the kidneys, the adrenal glands are triangular shaped and measure approximately a half-inch in height and 3 inches in length. The inner adrenal medulla secretes epinephrine and norepinephrine, which affect blood pressure, heart rate, and sweating. The outer cortex secretes hormones as well as mineralocorticoids (Fig. 64-1). Three main types of hormones are produced by the adrenal cortex: glucocorticoids (cortisol, corticosterone), mineralocorticoids (aldosterone, deoxycorticosterone [DOC]), and sex steroids (mainly andro-

gens). All steroid hormones are derived from the cyclopentanoperhydrophenanthrene structure, that is, three cyclohexane rings and a single cyclopentane ring. Figure 64-2 depicts the steroidogenic pathway found in the adrenal gland. Steroidogenesis in the adrenal gland involves a coordinated action of several enzymes, including a series of cytochrome P-450 enzymes. Most of these enzymes have been cloned and characterized, and mutations in the genes encoding these enzymes result in human disease, so some understanding of the underlying pathways and steroid precursors is required (Table 64-2). Recent studies have confirmed the importance of a 30-kd protein, steroidogenic acute regulatory protein (StAR), in mediating this effect. StAR is induced by an increase in intracellular cyclic adenosine monophosphate after the binding of ACTH to its receptor, providing the first important rate-limiting step in adrenal steroidogenesis.

ACTH is the principal hormone stimulating adrenal glucocorticoid biosynthesis and secretion. ACTH has 39 amino acids but is synthesized within the anterior pituitary as part of a much larger 241-amino acid precursor, pro-opiomelanocortin (POMC). POMC is cleaved in tissue-specific fashion to yield smaller peptide hormones. In the anterior pituitary this results in the secretion of  $\beta$ -lipoprotein and pro-ACTH, the latter being further cleaved to an N-terminal peptide, joining peptide, and ACTH itself (Fig. 64-3). The functions of the N-terminal peptide and  $\beta$ -lipoprotein are unknown, although they have weak steroidogenic activity of their own and may augment the effect of ACTH, particularly on stimulating adrenal growth. The first 24 amino acids of ACTH are common to all species, and synthetic ACTH 1 to 24 (cosyntropin) is available commercially for clinical testing of the hypothalamic-pituitary-adrenal (HPA) axis and assessment of adrenal glucocorticoid reserve. Melanocyte-stimulating hormones ( $\text{MSH-}\alpha$ ,  $\text{-}\beta$ , and  $\text{-}\gamma$ ) are also cleaved products from POMC.

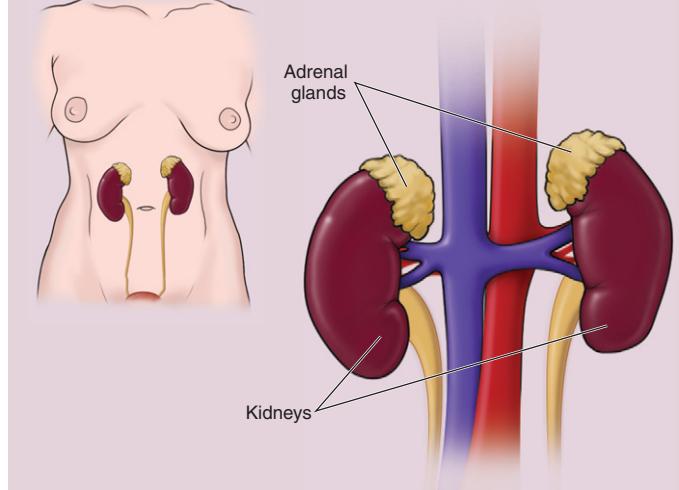

CRH is the principal stimulus for ACTH secretion. The peak response of ACTH to CRH does not differ throughout the day, but it is affected by endogenous function of the HPA axis in that responsiveness is reduced in subjects treated with corticosteroids but increased in subjects with Cushing’s disease. ACTH is secreted in pulsatile fashion with a circadian rhythm so that levels are highest on waking and decline throughout the day, reaching lowest values in the evening. ACTH pulse frequency is higher in normal adult men than in women (on average 18 pulses vs. 10 pulses per 24 hours), and the circadian ACTH rhythm appears to be mediated principally by an increased ACTH pulse amplitude between 5 and 9 AM but also by a reduction in ACTH pulse frequency between 6 and 12 PM. Food ingestion is a further stimulus to ACTH secretion. Circadian rhythm is dependent on both day-night and sleep-wake patterns and is disrupted by alternating day-night shift working patterns and by

**Table 64-1**  
**Milestones in Clinical Adrenal Medicine**

1563	Eustachius describes the adrenals (published by Lancisi in 1714)
1849	Thomas Addison, while searching for the cause of pernicious anemia, “stumbles” on a bronzed appearance associated with the adrenal glands—“melasma suprarenale”
1855	Thomas Addison describes the clinical features and autopsy findings of 11 cases of diseases of the suprarenal capsules, at least 6 of which were tuberculous in origin
1856	In adrenalectomy experiments, Brown-Séquard demonstrates that the adrenal glands are essential for life
1896	William Osler gives an oral glycerine extract derived from pig adrenals and demonstrates clinical benefit in patients with Addison’s disease
1905	Bullock and Sequeria describe patients with congenital adrenal hyperplasia
1929	Liquid extracts of cortical tissue are used to keep adrenalectomized cats alive indefinitely (Swingle and Pfeiffer); subsequently, this extract was used successfully to treat a patient with Addison’s disease (Rowntree and Greene)
1932	Harvey Cushing associates the “polyglandular syndrome” of pituitary basophilism first described by himself in 1912 with hyperactivity of the pituitary-adrenal glands
1936	Concept of stress and its effect upon pituitary-adrenal function described by Selye
1937–1952	Isolation and structural characterization of adrenocortical hormones (Kendall, Reichstein)
1943	Li and colleagues isolate pure adrenocorticotropic hormone from sheep pituitary
1950	Hench, Kendall, and Reichstein share Nobel Prize in Medicine for describing the anti-inflammatory effects of cortisone in patients with rheumatoid arthritis
1953	Isolation and analysis of the structure of aldosterone (Simpson and Tait)
1956	Conn describes primary aldosteronism
1981	Characterization and synthesis of corticotropin-releasing hormone (Vale)
1980–present	The “molecular era”: cloning and functional characterization of steroid receptors, steroidogenic enzymes, and adrenal transcription factors; definition of the molecular basis for human adrenal diseases

From Larsen PR, Kronenberg HM, Melmed S, et al: (eds): Williams Textbook of Endocrinology, 10th ed. Philadelphia, WB Saunders, 2002, p 492.

**Anatomy of the adrenal glands**

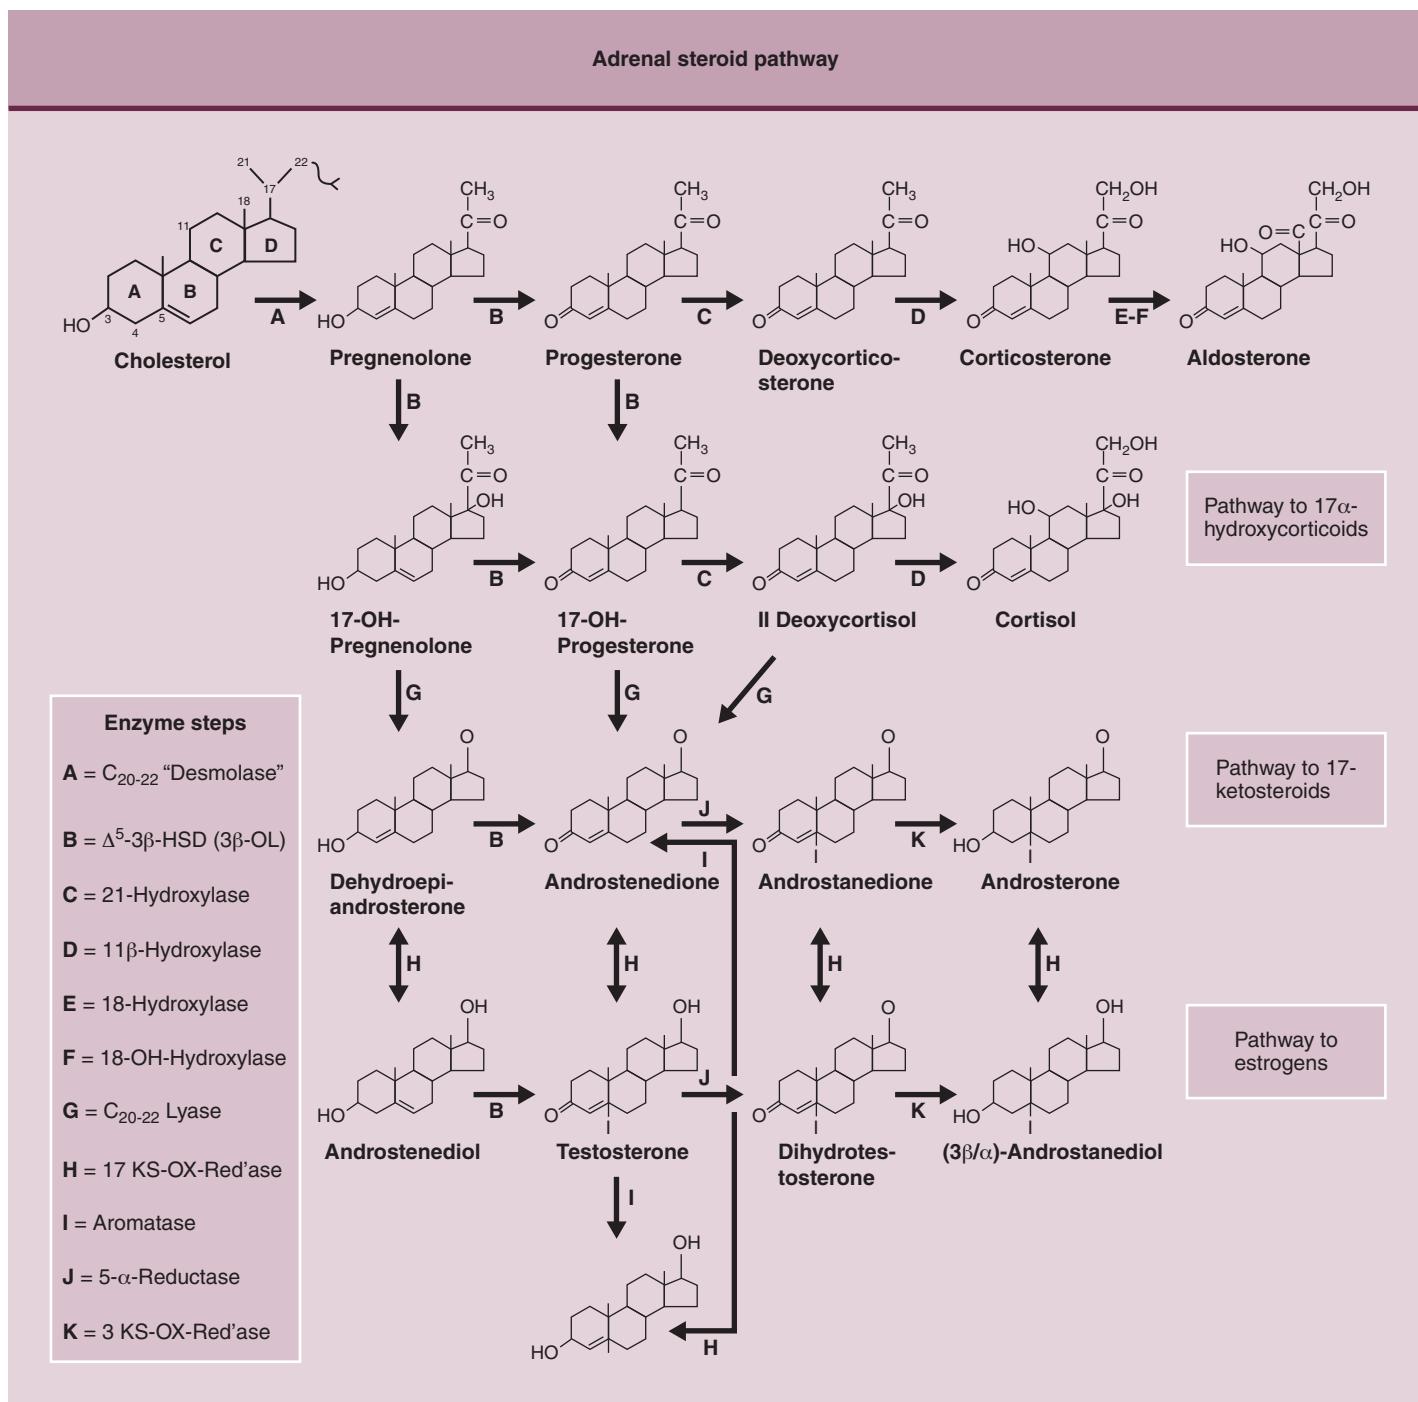

**Figure 64-1 Anatomy of the adrenal glands.** (From A.D.A.M.)

The effects of ACTH on the adrenal include both immediate and chronic effects; the end result is the stimulation of adrenal steroidogenesis and growth. Acutely, steroidogenesis is stimulated through a StAR-mediated increase in cholesterol delivery to the CYP11A1 enzyme in the inner mitochondrial membrane. Chronically (within 24 to 26 hours of exposure), ACTH acts to increase the synthesis of all steroidogenic CYP enzymes (CYP11A1, CYP17, CYP21A2, CYP11B1) in addition to adrenodoxin, effects that are mediated at the transcriptional level. ACTH also increases synthesis of the low-density lipoprotein (LDL) and high-density lipoprotein (HDL) receptors and possibly also 3-hydroxy-3-methylglutaryl coenzyme A reductase, the rate-limiting step in cholesterol biosynthesis. ACTH increases adrenal weight by inducing both hyperplasia and hypertrophy. Adrenal atrophy is a feature of ACTH deficiency.<sup>2</sup>

**Table 64-2**  
**Gene Location for Adrenal Steroidogenic Enzymes**

Enzyme Name	Gene	Chromosome
Cholesterol side-chain cleavage (SCC) (desmolase)	CYP11A1	15q23-q24
3β-Hydroxysteroid dehydrogenase (3β-HSD) (type II isozyme)	HSD3B2	1p13.1
17α-Hydroxylase/17,20 lyase	CYP17	10q24.3
21-Hydroxylase	CYP21A2	6p21.3
11β-Hydroxylase	CYP11B1	8q24.3
Aldosterone synthetase	CYP11B2	8q24.3

In Becker KL, Bilezikian JP, Hung W, et al [eds]: Principles and Practice of Endocrinology and Metabolism, 2nd ed. Philadelphia, JB Lippincott, 1995, p 650.)

### Mineralocorticoid Secretion: Renin-Angiotensin-Aldosterone Axis

Aldosterone is secreted from the zona glomerulosa under the control of angiotensin II, potassium, and to a lesser extent ACTH. Other factors, notably somatostatin, heparin, atrial natriuretic factor, and dopamine, can directly inhibit aldosterone synthesis. The secretion of aldosterone and its intermediary 18-hydroxylated metabolites is restricted to the zona glomerulosa because of the

zona-specific expression of CYP11B2 (aldosterone synthase). Corticosterone and DOC, although synthesized in both the zona fasciculata and the zona glomerulosa, can act as mineralocorticoids; this becomes significant in some clinical diseases, notably, some forms of congenital adrenal hyperplasia (CAH) and adrenal tumors. Similarly, it is now established that cortisol can act as a mineralocorticoid in the setting of impaired metabolism to cortisone carried out by the enzyme 11β-hydroxysteroid

**Figure 64-3 Schematic of pro-opiomelanocortin (POMC).** CLIP, corticotropin-like intermediate lobe peptide;  $\beta$ -END,  $\beta$ -endorphin; JP, joining peptide;  $\beta$ -LPH,  $\beta$ -lipotropin;  $\gamma$ -LPH,  $\gamma$ -lipotropin;  $\alpha$ -MSH,  $\alpha$ -melanocyte-stimulating hormone; SP, signal peptide. (From White PC, Pescovitz OH, Cutler GB: Synthesis and metabolism of corticosteroids. In Becker KL, Bilezikian JP, Hung W, et al [eds]: Principles and Practice of Endocrinology and Metabolism, 2nd ed. Philadelphia, JB Lippincott, 1995, p 1489.)

dehydrogenase (HSD); this is important in patients with hypertension, ectopic ACTH syndrome, and renal disease.

The rate-limiting step in the renin-angiotensin system is the secretion of renin, which is also controlled through a negative feedback loop. Renin is secreted from juxtaglomerular epithelial cells within the macula densa of the renal tubule in response to underlying renal arteriolar pressure, oncotic pressure, and sympathetic drive. Thus, low perfusion pressure or low tubular fluid sodium content, as seen in hemorrhage, renal artery stenosis, dehydration, or salt loss, increases renin secretion. Conversely, secretion is suppressed by a high-salt diet and by factors that increase blood pressure. Autoregulation is therefore maintained because the increase in renin secretion stimulates angiotensin II and aldosterone production; the concomitant increase in blood pressure and renal sodium retention results in feedback inhibition of renin secretion.

Hypokalemia increases and hyperkalemia decreases renin secretion; in addition, potassium exerts a direct effect on the adrenal cortex to increase aldosterone secretion. The sensitivity of the renin-angiotensin system to changes in circulating potassium is high, with changes in potassium concentrations of only 0.1 to 0.5 mmol/L producing marked changes in aldosterone concentrations. Potassium concentrations also determine the sensitivity of the aldosterone response to a given infusion of angiotensin II, with high potassium intake increasing responsiveness.

The effect of ACTH on aldosterone secretion is modest and differs in the acute and chronic situations. An acute bolus of ACTH increases aldosterone secretion, principally by stimulating the early pathways of adrenal steroidogenesis, but circulating levels increase by no more than 10% to 20% above baseline values. ACTH has no effect on *CYP11B2* gene transcription or

enzyme activity. Chronic continual ACTH stimulation has either no effect or an inhibitory effect on aldosterone production, possibly because of receptor down-regulation or suppression of angiotensin II-stimulated secretion because of a mineralocorticoid effect of cortisol, DOC, or corticosterone. Dopamine and atrial natriuretic peptide inhibit aldosterone secretion, as does heparin.

The separate control of glucocorticoid biosynthesis through the HPA axis and mineralocorticoid synthesis through the renin-angiotensin system has important clinical consequences. Patients with primary adrenal failure invariably have both cortisol and aldosterone deficiency, whereas patients with ACTH deficiency related to pituitary disease have glucocorticoid deficiency but normal aldosterone concentrations because the renin-angiotensin system is intact.

### Adrenal Androgen Secretion

Adrenal androgens represent an important component (>50%) of circulating androgens in premenopausal females. In males this contribution is much smaller because of the testicular production of androgens, but adrenal androgen excess even in males may be of clinical significance, notably in patients with CAH. The adult adrenal secretes dehydroepiandrosterone (DHEA) at approximately 4 mg/day, dehydroepiandrosterone sulfate (DHEAS) at 7 to 15 mg/day, androstenedione at 1.5 mg/day, and testosterone at 0.05 mg/day. DHEA is a weak sex steroid but can be converted to androgens and estrogens through the activities of  $3\beta$ -HSD, a superfamily of  $17\beta$ -HSD isozymes, and aromatase, expressed in peripheral target tissues, and this is of clinical importance in many diseases.

ACTH stimulates androgen secretion; DHEA (but not DHEAS because of its increased plasma half-life) and androstenedione demonstrate a similar circadian rhythm to cortisol. However, there are many discrepancies between adrenal androgen and glucocorticoid secretion, which has led to the suggestion of an additional androgen-stimulating hormone. Many putative androgen-stimulating hormones have been proposed including POMC derivatives such as joining peptide, prolactin, and insulin-like growth factor-1 (IGF-1), but conclusive proof is lacking. Adrenal androgen steroidogenesis is dependent on the relative activities of  $3\beta$ -HSD and  $17\alpha$ -hydroxylase and in particular on the  $17,20$ -lyase activity of  $17\alpha$ -hydroxylase. Factors that determine whether 17-hydroxylated substrates, 17-hydroxypregnolone and 17-hydroxyprogesterone (17-OHP), undergo 21-hydroxylation to form glucocorticoid or side-chain cleavage by  $17\alpha$ -hydroxylase to form DHEA and androstenedione are unresolved and seem likely to be important in defining the activity of any putative androgen-stimulating hormone.<sup>3</sup>

### THERAPEUTIC CORTICOSTEROIDS

Since the anti-inflammatory effect of cortisone was first demonstrated in the 1950s, a series of synthetic corticosteroids have been developed for therapeutic purposes. These are used to treat a diverse variety of human diseases and rely principally on their anti-inflammatory and immunologic actions. The main corticosteroids used in clinical practice, together with their relative glucocorticoid and mineralocorticoid potencies, are shown in Table 64-3.

Table 64-3 Potency Equivalents for Synthetic Steroids			
Steroid	Anti-Inflammatory Action	Hypothalamic-Pituitary-Adrenal Suppression	Salt Retention
Cortisol	1	1	1
Prednisolone	3	4	0.75
Methylprednisolone	6.2	4	0.5
Fludrocortisone	12	12	125
Δ <sup>1</sup> Fludrocortisone	14	—	225
Triamcinolone	5	4	0
Dexamethasone	26	17	0

### Chronic Corticosteroid Therapy, Hypothalamic-Pituitary-Adrenal Axis Suppression, and Steroid Withdrawal

The negative feedback control of the HPA axis by endogenous cortisol was discussed earlier. Synthetic corticosteroids similarly suppress the function of the HPA axis through a process that is dependent on both dose and duration of treatment. As a result, sudden cessation of corticosteroid therapy may result in adrenal failure. This may also occur after treatment with high doses of the synthetic progestagen medroxyprogesterone acetate, which possesses glucocorticoid agonist activity. In patients taking any steroid dose for less than 3 weeks, clinically significant suppression of the HPA axis is rarely a problem and patients can withdraw from steroids suddenly with no ill effect. The possible exception is the patient who receives frequent short courses of corticosteroid therapy, for example, patients with recurrent episodes of severe asthma. Conversely, suppression of the HPA axis is invariable in patients taking the equivalent of 15 mg or more of prednisolone per day chronically. In patients taking lower doses of corticosteroid chronically (prednisolone 5 to 15 mg/day or equivalent), suppression of the HPA axis is variable. Defects

in response of the HPA axis to insulin-induced hypoglycemia or exogenous ACTH have been reported in patients taking prednisolone doses as low as 5 mg/day, but clinically significant suppression at these doses is debatable. Alternate-day therapy is associated with less suppression of the HPA axis.

All patients treated chronically with corticosteroids should be treated in a similar fashion to patients with chronic ACTH deficiency; they should carry steroid cards and be offered Steroid Alert bracelets or necklaces. In the event of an intercurrent stress (infection, surgery), supplemental steroid coverage should be given, equivalent to hydrocortisone at 100 to 150 mg/day. If the patient is unable to take drugs orally, parenteral therapy is required.

Recovery from suppression may take 6 to 9 months. CRH secretion returns to normal, and within a few weeks ACTH levels begin to increase and indeed rise above normal values until adrenal steroidogenesis recovers. In the interim, and without replacement therapy, patients may experience symptoms of glucocorticoid deficiency including anorexia, nausea, weight loss, arthralgia, lethargy, skin desquamation, and postural dizziness. To avoid symptoms of glucocorticoid deficiency, steroids should be withdrawn cautiously over a period of months if the clinical course of the underlying disease permits a reduction. The dose should be reduced from a pharmacologic to a physiologic level (equivalent to prednisolone at 7.5 mg/day) over a few weeks. Thereafter doses should be reduced by 1 mg/day prednisolone every 2 to 4 weeks depending on the patient's clinical symptoms. An alternative approach is to change to hydrocortisone at 20 mg/day and reduce the daily dose by 2.5 mg/day every week to 10 mg/day. Nighttime doses should be avoided, since they result in greater suppression of early morning ACTH secretion.<sup>4</sup>

After 2 to 3 months of these reduced doses of corticosteroids, endogenous function of the HPA axis can be assessed through a corticotropin (ACTH, cosyntropin) stimulation test or an insulin-induced hypoglycemia test. A normal response to either of these tests indicates adequacy of function of the HPA axis, and corticosteroid therapy can be safely withdrawn. In patients taking physiologic doses of prednisolone (less than 5 to 7.5 mg/day) or equivalent, a corticotropin stimulation test 12 to 24 hours after having omitted steroid therapy will provide an immediate answer about whether sudden or gradual withdrawal of steroid therapy is indicated (Table 64-4).

Table 64-4 Method to Determine Whether Synthetic Steroid Administration Requires Tapering Before Stopping to Prevent Adrenal Insufficiency				
Dose (mg Prednisolone/day)	≤3 weeks	>3 weeks		
≥7.5 mg	Stop steroid	Reduce rapidly e.g., 2.5 mg every 3–4 days then		
5–7.5 mg	Stop steroid	Reduce by 1 mg every 2–4 wk	or	Convert 5 mg prednisolone to hydrocortisone 20 mg and decrease by 2.5 mg/wk to 10 mg for 2–3 mo
<5 mg	Stop steroid	Reduce by 1 mg every 2–4 wk		Cortrosyn stimulation test or insulin tolerance test Alternatively administer If pass, withdraw steroid If fail, continue steroid tapering

From Larsen PR, Kronenberg HM, Melmed S, et al: (eds): Williams Textbook of Endocrinology, 10th ed. Philadelphia, WB Saunders, 2002, p 508.

## DISORDERS OF GLUCOCORTICOID EXCESS

The first case of glucocorticoid excess was described in 1912 by Cushing. The patient was a 23-year-old woman with obesity, hirsutism, and amenorrhea. Glucocorticoid excess is most prevalent in adults between the ages of 20 and 50; it occurs when too much cortisol is produced in the adrenal glands. It can also be caused by excessive or prolonged use of exogenous steroids.

Prolonged natural production of cortisol can be linked to various sources, the most common of which is a tumor of the pituitary gland. The tumor stimulates overproduction of ACTH, which in turn stimulates growth and activity of the adrenal glands. This pituitary hypersecretion of ACTH accounts for 75% to 85% of all Cushing's cases. The other 15% to 25% are due to adrenocortical tumors. The term *Cushing's syndrome* is used to describe all causes, while Cushing's disease is reserved for cases of pituitary-dependent Cushing's syndrome.

Cushing's sufferers can be identified by their characteristic "moon" facies (round and full) and "buffalo" humps (fat collected between the shoulders). The disorder is marked by many other symptoms, the most common of which are obesity (90%), hypertension (80%), diabetes (80%), weakness (80%), excessive body hair (70%), and menstrual abnormalities/sexual dysfunction (70%).<sup>2</sup>

Cushing's syndrome comprises the symptoms and signs associated with prolonged exposure to inappropriately elevated levels of free plasma glucocorticoids (Table 64-5).

### Cushing's Syndrome

The classical features of Cushing's syndrome of centripetal obesity, moon face, hirsutism, and plethora are well known following Cushing's initial descriptions in 1912. Weight gain and obesity are the most common sign, and at least in adults this is invariably centripetal in nature. Interestingly, generalized obesity is more common in the general population than in patients with Cushing's syndrome except in childhood when glucocorticoid excess may result in generalized obesity. In addition to centripetal obesity, patients develop fat depots over the thoracocervical

spine ("buffalo hump"), in the supraclavicular region, and over the cheeks and temporal regions, giving rise to the rounded moon-like facies. The epidural space is another site of abnormal fat deposition, and this may lead to neurologic deficits.

Gonadal dysfunction is common, with menstrual irregularity in females and loss of libido in both sexes. Hirsutism is frequently found in female patients, as is acne. The most common form of hirsutism is vellus hypertrichosis on the face and should be distinguished from darker terminal differentiated hirsutism, which may occur but usually signifies concomitant androgen excess. Hypogonadism occurs because of a direct inhibitory effect of cortisol on gonadotropin-releasing hormone pulsatility and LH or FSH secretion and is reversible on correction of the hypercortisolism.<sup>3</sup>

Psychiatric abnormalities occur in approximately 50% of patients with Cushing's syndrome regardless of cause. Agitated depression and lethargy are among the most common problems, but paranoia and overt psychosis are also well recognized. Memory and cognitive function may also be affected, and increased irritability may be an early feature. Insomnia is common, and both rapid eye movement and delta wave sleep patterns are reduced. Lowering of plasma cortisol by medical or surgical therapy usually results in a rapid improvement in the psychiatric state.<sup>5</sup>

In childhood the most common presentation is with poor linear growth and weight gain. Many patients with long-standing Cushing's syndrome have lost height because of osteoporotic vertebral collapse. This can be assessed by measuring the patient's height and comparing it with the patient's span; in normal subjects these measurements should be equal. Pathologic fractures, either spontaneous or after minor trauma, are not uncommon. Rib fractures, in contrast to those of the vertebrae, are often painless. The radiographic appearances are typical, with exuberant callus formation at the site of the healing fracture. In addition, aseptic necrosis of the femoral and humeral heads, a recognized feature of high-dose exogenous corticosteroid therapy, can occur in endogenous Cushing's syndrome.

Hypercortisolism results in skin thinning, separation, and exposure of the subcutaneous vascular tissue. On examination, wrinkling of the skin on the dorsum of the hand may be seen resulting in a "cigarette paper" appearance (Liddle's sign). Minimal trauma may result in bruising, which frequently resembles "senile purpura." The plethoric appearance of the patient with Cushing's syndrome is secondary to the thinning of the skin combined with loss of facial subcutaneous fat and is not due to true polycythemia. Acne and papular lesions may occur over the face, chest, and back.

The typical, almost pathognomonic red-purple livid striae greater than 1 cm in diameter are most frequently found on the abdomen but may also be present on the upper thighs, breasts, and arms. They are common in younger patients and less so in those older than 50 years. They must be differentiated from the paler, less pigmented striae that occur postpartum (striae gravidarum) or in association with rapid weight loss. Increased skin pigmentation is rare in Cushing's disease but common in the ectopic ACTH syndrome and arises because of overstimulation of melanocyte receptors by ACTH.

Myopathy and bruising are two of the most discriminatory features of the syndrome. The myopathy of Cushing's syndrome

**Table 64-5**  
Common Signs and Symptoms of Cushing's Syndrome

- Weight gain, particularly around your midsection and upper back
- Severe fatigue
- Muscle weakness
- Rounding of face (moon face)
- Facial flushing
- Fatty pad or hump between shoulders (buffalo hump)
- Thinning of arms and legs
- Pink or purple stretch marks on the skin of abdomen, thighs, breasts, and arms
- Thin and fragile skin that bruises easily
- Slow healing of cuts, insect bites, and infections
- Depression, anxiety, and irritability
- Thicker or more visible body hair (hirsutism)
- Acne
- Irregular or stopped menstrual periods in females
- Erectile dysfunction in males
- High blood pressure

involves the proximal muscles of the lower limb and the shoulder girdle. Complaints of weakness such as inability to climb stairs or get up from a deep chair are relatively uncommon, but testing for proximal myopathy by asking the patient to rise from a crouching position often reveals the problem.

Hypertension is another prominent feature, occurring in up to 75% of cases; even though epidemiologic data show a strong association between blood pressure and obesity, hypertension is more common in patients with Cushing's syndrome than in those with simple obesity. This, together with the established metabolic consequences of the disease (diabetes, hyperlipidemia) is thought to explain the increased cardiovascular mortality in untreated cases. In addition, thromboembolic events may be more common in Cushing's patients.

Infections are more common in patients with Cushing's syndrome. In many instances these are asymptomatic and occur because the normal inflammatory response is suppressed. Reactivation of tuberculosis has been reported and has even been the presenting feature in some cases. Fungal infections of the skin (notably *tinea versicolor*) and nails may occur, as may opportunistic fungal infections. Bowel perforation is more common in patients with extreme hypercortisolism, and the hypercortisolism may mask the usual symptoms and signs of the condition. Wound infections are more common and contribute to poor wound healing.

Glucose intolerance occurs, and overt diabetes mellitus is present in up to one third of patients in some series. Hepatic lipoprotein synthesis is stimulated, and increases in circulating cholesterol and triglycerides may be found. Hypokalemic alkalosis is found in 10% to 15% of patients with Cushing's disease but in more than 95% of patients with ectopic ACTH syndrome. Several factors may contribute to this mineralocorticoid excess state, including corticosterone and DOC excess, but the principal culprit is thought to be cortisol itself. Depending on the prevailing cortisol production rate, cortisol swamps the normal metabolizing enzyme, 11 $\beta$ -HSD type 2 in the kidney, to act as a mineralocorticoid. Hypokalemic alkalosis is more common in ectopic ACTH syndrome because cortisol production rates are higher than in patients with Cushing's disease. This can be diagnosed by documenting an increase in the ratio of urinary cortisol to cortisone metabolites.

Ocular effects include raised intraocular pressure and exophthalmos (increased retro-orbital fat deposition). Cataracts, a well-recognized complication of corticosteroid therapy, seem to be uncommon except as a complication of diabetes.

### Cushing's Disease

When iatrogenic causes are excluded, the most common cause of Cushing's syndrome is Cushing's disease, accounting for approximately 70% of cases (Table 64-6). The adrenal glands in these patients show bilateral adrenocortical hyperplasia with widening of the zona fasciculata and zona reticularis. The hypothalamic theory states that ACTH-secreting adenomas arise because of dysfunctional regulation of corticotrophs through chronic stimulation by CRH, but other studies provide data to support a primary pituitary defect as the cause of the condition. The hypothalamus may have an initiating role, but the overwhelming evidence is that, at presentation, the condition is pituitary dependent. The majority of tumors are small micro-

**Table 64-6**  
**Classification of Causes of Cushing's Syndrome**

<b>ACTH-dependent</b>
Cushing's disease (pituitary-dependent)
Ectopic ACTH syndrome
Ectopic CRH syndrome

Depression
Obesity

ACTH, adrenocorticotrophic hormone; CRH, corticotropin-releasing hormone.  
From Larsen PR, Kronenberg HM, Melmed S, et al: (eds): Williams Textbook of Endocrinology, 10th ed. Philadelphia, WB Saunders, 2002, p 509.

adenomas, but larger macroadenomas occur in up to 10% of cases and usually signify a more invasive tumor.<sup>6</sup> Selective surgical removal of a microadenoma results in cure with a low recurrence rate. However, it is possible, particularly in cases with no identifiable pituitary adenoma, that Cushing's disease may be heterogeneous with different subtypes. A key biochemical hallmark of the disease is a relative resistance of ACTH secretion to normal glucocorticoid feedback inhibition.<sup>7,8</sup>

### Ectopic Adrenocortotropic Hormone Syndrome

In 15% of cases, Cushing's syndrome may be associated with nonpituitary tumors secreting ACTH—the ectopic ACTH syndrome. Clinically, this condition comprises two entities: cases occurring in the setting of highly malignant tumors, such as small cell carcinoma of the bronchus, and more indolent cases occurring in patients with underlying neuroendocrine tumors, such as bronchial carcinoids (Table 64-7). Circulating ACTH concentrations and cortisol secretion rates can be extremely high. As a result, the duration of symptoms from onset to presentation is short (<3 months); patients commonly have characteristic pigmentation, and the metabolic manifestations of glucocorticoid excess are often rapid and progressive. Weight loss, myopathy, and glucose intolerance are prominent signs and symptoms. The association of these features with hypokalemic alkalosis and peripheral edema should alert the clinician to the diagnosis.<sup>9</sup>

### Cortisol-secreting Adrenal Adenoma and Carcinoma

With the exclusion of iatrogenic Cushing's syndrome, adrenal adenomas are responsible for about 10% to 15% of cases and carcinomas for less than 5%. By contrast, in children 65% of cases of Cushing's syndrome have an adrenal etiology (15% adenoma, 50% carcinoma). Onset of clinical features is gradual in patients with adenomas but often rapid in adrenal carcinoma. In addition

<b>Table 64-7</b> <b>Tumors Associated with Ectopic Adrenocorticotrophic Hormone Syndrome</b>	
<b>Tumor Type</b>	<b>Approximate Incidence (%)</b>
Small cell lung carcinoma	50
Non-small cell lung carcinoma	5
Pancreatic tumors (including carcinoids)	10
Thymic tumors (including carcinoids)	5
Lung carcinoids	10
Other carcinoids	2
Medullary carcinoma of thyroid	5
Pheochromocytoma and related tumors	3
Rare carcinomas of prostate, breast, ovary, gallbladder, colon	10

From Larsen PR, Kronenberg HM, Melmed S, et al: (eds): Williams Textbook of Endocrinology, 10th ed. Philadelphia, WB Saunders, 2002, p 513.

to the features of hypercortisolism, patients may complain of loin or abdominal pain and a tumor may be palpable. The tumor may secrete other steroids, such as androgens or mineralocorticoids. Thus, in females, there may be features of virilization, with hirsutism, clitoromegaly, breast atrophy, deepening of the voice, temporal recession, and severe acne. With "pure" cortisol-secreting adenomas, hirsutism is uncommon.

### McCune-Albright Syndrome

In McCune-Albright syndrome, fibrous dysplasia and cutaneous pigmentation may be associated with pituitary, thyroid, adrenal, and gonadal hyperfunction. The most common manifestation is of sexual precocity and GH excess, but Cushing's syndrome has been reported. The underlying abnormality is a somatic mutation in the  $\alpha$  subunit of the stimulatory G protein that is linked to adenyl cyclase. The mutation results in the G protein being constitutively activated, mimicking constant ACTH stimulation at the level of the adrenal. ACTH levels are suppressed, and adrenal adenomas may occur.<sup>10</sup>

### Iatrogenic Cushing's Syndrome

Development of the features of Cushing's syndrome depends on the dose, duration, and potency of the corticosteroid used in clinical practice. ACTH is rarely prescribed but chronically also results in cushingoid features. Some features such as increased intraocular pressure, cataracts, benign intracranial hypertension, aseptic necrosis of the femoral head, osteoporosis, and pancreatitis are more common in iatrogenic than in endogenous Cushing's syndrome, whereas other features, notably hypertension, hirsutism, and oligomenorrhea or amenorrhea, are rarer.

### Pseudo-Cushing's Syndromes

A pseudo-Cushing's state can be defined as some or all of the clinical features of Cushing's syndrome together with some evidence of hypercortisolism. Resolution of the underlying cause results in disappearance of the cushingoid state. Several causes have been described.

### Alcohol

In the original description of this syndrome, urinary and plasma cortisol levels were elevated and not suppressed by dexamethasone. Plasma ACTH has been found to be normal or suppressed. The condition is rare but should be suspected in a patient with an ongoing history of heavy alcohol intake and biochemical or clinical evidence of chronic liver disease. Chronic liver disease of any cause is associated with impaired cortisol metabolism, but in alcoholics this is associated with an increase in cortisol secretion rate rather than concomitant suppression in the presence of impaired metabolism. In some studies, alcohol has directly stimulated cortisol secretion; alternatively, vasopressin levels are elevated in patients with decompensated liver disease and may stimulate the HPA axis. With abstinence from alcohol the biochemical abnormalities rapidly revert to normal.<sup>5</sup>

### Depression

It is well recognized that patients with depression may exhibit the hormonal abnormalities of patients with Cushing's syndrome. These abnormalities are reversible on correction of the psychiatric condition. Conversely, patients with Cushing's syndrome are frequently depressed, and a careful clinical and endocrinologic assessment is required.<sup>5</sup>

### Obesity

Patients with obesity have mildly increased cortisol secretion rates, and the data suggest that this is due to activation of the HPA axis. However, circulating cortisol concentrations are invariably normal and urinary free cortisol concentrations are either normal or only slightly elevated. The stimulus for the increased secretion rate appears to be increased peripheral metabolism and hence clearance of cortisol.<sup>2</sup>

### Diagnosis of Cushing's Syndrome

Diagnosis of Cushing's syndrome is based on medical history, physical examination, and laboratory tests to determine cortisol overproduction. Patients are usually asked to collect a 24-hour urine sample to be screened for high levels of the hormone. In normal subjects, plasma cortisol levels are at their highest first thing in the morning and reach a nadir at about midnight (<50 nmol/L, or 2 µg/dL, in a nonstressed subject). This circadian rhythm is lost in patients with Cushing's syndrome so that in the majority of patients the 9 AM plasma cortisol is normal but nocturnal levels are raised. Random morning plasma cortisol levels are therefore of little value in making the diagnosis, and a midnight cortisol level greater than 200 nmol/L (7 µg/dL) indicates Cushing's syndrome. However, various factors such as stress of venipuncture, intercurrent illness, and admission to the hospital may result in false-positive results. Ideally, patients should be hospitalized for 24 to 48 hours before cortisol is measured at midnight, but some centers have reported discriminant results from measurements of midnight values on an outpatient basis. Salivary cortisol concentrations may offer a sensible alternative in patients who are unable to go to the hospital.

For many years the diagnosis of Cushing's syndrome was based on the measurement of urinary metabolites of cortisol (24-hour urinary 17-hydroxycorticosteroid or 17-oxogenic steroid excretion, depending on the method used). However, the sensitivity and specificity of these methods are poor, and most centers have

replaced these assays with the more sensitive measurement of urinary free cortisol excretion. Urinary free cortisol is an integrated measure of plasma free cortisol; as cortisol secretion increases, the binding capacity of corticosteroid-binding globulin (CBG) is exceeded, resulting in a disproportionate rise in urinary free cortisol. Normal values are less than 220 to 330 nmol (80 to 120 µg) per 24 hours depending on the assay used.

Patients should make two or three complete consecutive collections to account for error in collecting samples and episodic cortisol secretion, notably from adrenal adenomas. Simultaneous creatinine excretion (which differs by no more than 10% on a day-to-day basis) may be used to ensure adequacy of collection. Urinary free cortisol is a useful screening test, but it is accepted that urinary free cortisol may be normal in up to 8% to 15% of patients with Cushing's syndrome. Conversely, moderately elevated results should always be endorsed by further testing before a diagnosis of Cushing's syndrome is made.<sup>2,11,12</sup>

#### **Low-Dose and Overnight Dexamethasone Suppression Tests**

In normal subjects, the administration of a supraphysiologic dose of glucocorticoid results in suppression of ACTH and cortisol secretion. In Cushing's syndrome of any cause there is failure of this suppression when low doses of the synthetic glucocorticoid dexamethasone are given. The overnight test is a useful outpatient screening test. Various doses of dexamethasone have been used, but 1 mg of dexamethasone is usually given at midnight. A normal response is a plasma cortisol of less than 140 nmol/L (5 µg/dL) between 8 and 9 AM the following morning. The outpatient overnight test has high sensitivity (95%) but low specificity, and further investigation is often required.

In the 48-hour low-dose dexamethasone test, plasma cortisol is measured at 9 AM on day 0 and 48 hours later following dexamethasone given at a dose of 0.5 mg every 6 hours for 48 hours. Using a postdexamethasone plasma cortisol concentration of less than 50 nmol/L (2 µg/dL), this test is reported as having a 97% to 100% true-positive rate and a false-positive rate less than 1%. Sensitivity is higher if plasma rather than urinary cortisol is measured.

Certain drugs (phenytoin, rifampin) may increase the metabolic clearance rate of dexamethasone and lead to false-positive results. Simultaneous measurement of plasma dexamethasone may be useful in this case and also detects patients who failed to take the drug.<sup>2,11,12</sup>

#### **Determining the Cause of Cushing's Syndrome**

##### **9 AM Plasma ACTH**

Ideally, ACTH should be measured by a modern, two-site immunoradiometric assay that differentiates ACTH-dependent from ACTH-independent causes. In Cushing's disease, 50% of patients have a 9 AM ACTH within the normal reference range (2 to 12 pmol/L [9 to 54 pg/mL]); in the remainder it is modestly elevated. ACTH levels in the ectopic ACTH syndrome are high (usually > 20 pmol/L [90 pg/mL]) but nevertheless overlap values seen in Cushing's disease in 30% of cases and cannot therefore be used to differentiate these two conditions. The most discriminatory time of day to measure ACTH is actually between 11 PM and 1 AM, when ACTH-cortisol secretion is at the nadir; it has been advocated that ACTH be measured with cortisol in the circadian rhythm studies. A midnight ACTH

result greater than 5 pmol/L (23 pg/mL) in a patient with biochemical hypercortisolism confirms that the underlying disease is ACTH-dependent. The measurement of ACTH precursors (pro-ACTH, POMC) is not routinely available but may be more useful in detecting an ectopic source of ACTH; more data are required on patients with occult tumors causing the syndrome. In patients with adrenal tumors, plasma ACTH is invariably undetectable (<1 pmol/L [4.5 pg/mL]). This can also occur with degradation of ACTH; as a result, nonhemolyzed blood samples should be taken on ice and immediately separated.<sup>2</sup>

##### **Plasma Potassium**

Hypokalemic alkalosis is present in more than 95% of patients with the ectopic ACTH syndrome but is present in fewer than 10% of patients with Cushing's disease. Patients with the ectopic syndrome usually have higher cortisol secretion rates that saturate the renal protective 11β-HSD type 2 enzyme, resulting in cortisol-induced, mineralocorticoid hypertension. In addition, these patients have higher levels of the ACTH-dependent mineralocorticoid DOC.<sup>2,11</sup>

##### **High-Dose Dexamethasone Suppression Test**

The rationale for the high-dose dexamethasone suppression test is that in Cushing's disease there is a resetting of the negative feedback control of ACTH to a higher level than normal. Thus, cortisol levels are not suppressed with low-dose but are suppressed with high-dose dexamethasone. The original test introduced by Liddle was based on giving dexamethasone at 2 mg every 6 hours for 48 hours and demonstrating a greater than 50% fall in urinary 17-hydroxycorticosteroids after dexamethasone. In the modern test, plasma or urinary free cortisol, or both, are measured at 0 and +48 hours and a greater than 50% suppression of plasma cortisol in comparison with the baseline sample defines a positive response. In all cases, response is graded and dependent upon the original cortisol secretion rate; greater suppression is often observed in patients with lower basal cortisol values.

In Cushing's disease about 90% of patients have a positive 48-hour test in comparison with 10% with the ectopic ACTH syndrome. The test has 100% specificity for diagnosing pituitary disease if more than 90% suppression in urinary free cortisol is used. Up to 50% of patients with ectopic ACTH syndrome related to indolent bronchial carcinoid tumors exhibit some suppression after high-dose dexamethasone. Conversely, some patients with Cushing's disease, usually those with large invasive ACTH-secreting pituitary macroadenomas, may show no suppression after high-dose dexamethasone.<sup>2</sup>

##### **Metyrapone Test**

Metyrapone blocks the conversion of 11-deoxycortisol to cortisol and DOC to corticosterone by inhibiting 11β-hydroxylase. This effect lowers plasma cortisol and, through negative feedback control, increases plasma ACTH. This, in turn, stimulates an increase in the secretion of adrenal steroids proximal to the block. When metyrapone is given in doses of 750 mg every 4 hours for 24 hours, patients with Cushing's disease exhibit an exaggerated rise in plasma ACTH with 11-deoxycortisol levels at 24 hours exceeding 1000 nmol/L (35 µg/dL). In most patients with the ectopic ACTH syndrome there is little or no response, but

## Reproductive Endocrinology and Infertility

occasional patients (possibly those producing both ACTH and CRH) have an 11-deoxycortisol response that may be similar to that observed in Cushing's disease.

The metyrapone test was originally used to distinguish patients with Cushing's disease from those with a primary adrenal cause. However, these can be more reliably distinguished by measuring plasma ACTH with subsequent computed tomography (CT) scanning of the adrenals.<sup>2</sup>

### Corticotropin-releasing Hormone Test

CRH is a 41-amino acid peptide identified by Vale in 1981 from ovine hypothalamus. The ovine sequence differs by seven amino acid residues from that of the human but, despite this, is slightly more effective in stimulating the release of ACTH in humans. The test involves the intravenous injection of either ovine or human CRH in a dose of 1 µg/kg body weight or a single dose of 100 µg. The test can be performed in the morning or afternoon, and after basal sampling, blood samples for ACTH and cortisol are taken every 15 minutes for 1 to 2 hours following the administration of CRH.

In normal subjects, CRH produces a rise in ACTH and cortisol (approximately 15% to 20%), but this response is exaggerated in Cushing's disease, where typically an ACTH rise greater than 50% and a cortisol rise greater than 20% over baseline values are seen. No response is seen in the ectopic ACTH syndrome, but false-positive results have been reported. In distinguishing pituitary-dependent Cushing's from the ectopic ACTH syndrome, the response of ACTH and cortisol to CRH has a specificity and sensitivity of approximately 90%. However, with an ACTH test, an increase of 100% or a cortisol rise of 50% over baseline values, a positive response effectively eliminates a diagnosis of ectopic ACTH syndrome, and this is the real benefit of this test. Up to 10% of patients with Cushing's disease do not respond to CRH.<sup>12</sup>

### Inferior Petrosal Sinus Sampling and Selective Venous Catheterization

The most robust test to distinguish Cushing's disease from the ectopic ACTH syndrome is inferior petrosal sinus sampling (IPSS). As blood from each half of the pituitary drains into the ipsilateral inferior petrosal sinus, catheterization and venous sampling of both sinuses simultaneously can distinguish a pituitary from an ectopic source. In virtually all patients with the ectopic ACTH syndrome, the ratio of ACTH concentrations between the inferior petrosal sinus and simultaneously drawn peripheral venous level is less than 1.4:1. In contrast, in Cushing's disease this ratio is elevated at greater than 2.0. However, because of the problem of intermittent ACTH secretion, it is useful to make measurements before and at intervals (e.g., at 2, 5, and 15 minutes) after intravenous injection of 100 µg of synthetic ovine CRH. With this approach, an ACTH petrosal sinus/peripheral ratio greater than 3.0 after CRH has a sensitivity of 97% and specificity of 100% for the diagnosis of Cushing's disease.

IPSS may also be of value in lateralizing a pituitary tumor in a patient in whom imaging techniques have failed to demonstrate a microadenoma. Coadministration of desmopressin with CRH may help in localizing the tumor. However, it should be remembered that many tumors are central and may drain into

both sinuses; current evidence suggests that it would unwise to base the surgical procedure on the results of IPSS studies alone. IPSS is a useful technique for establishing the differential diagnosis of ACTH-dependent Cushing's syndrome. However, it is technically demanding, has been associated with complications (referred aural pain, thrombosis), and is expensive. Rarely, selective catheterization of vascular beds may be required to identify the source of ectopic ACTH secretion, for example, from a small pulmonary carcinoid or thymic tumor.<sup>2</sup>

### Imaging Studies

High-resolution, thin-section, contrast-enhanced imaging using either CT or magnetic resonance imaging (MRI) has revolutionized the investigation of Cushing's syndrome. However, the results of any imaging technique must always be interpreted alongside the biochemical results if mistakes are to be avoided. In imaging the adrenals, asymmetric nodular hyperplasia may lead to a false diagnosis of adrenal adenoma. Because of the presence of pituitary incidentalomas, pituitary CT or MRI scanning may produce false-positive results, particularly for lesions less than 5 mm in diameter.

Pituitary MRI is the investigation of choice when the biochemical tests suggest Cushing's disease, with a sensitivity of 70% and specificity of 87%. About 90% of ACTH-secreting pituitary tumors are microadenomas (i.e., less than 10 mm in diameter). The classical features of a pituitary microadenoma are a hypodense lesion after contrast, associated with deviation of the pituitary stalk and a convex upper surface of the pituitary. With such small tumors it is not surprising that the sensitivity of CT scanning is relatively low (20% to 60%) with a similar specificity.<sup>13</sup>

By contrast, for adrenal imaging, CT rather than MRI is the investigation of choice, offering better spatial resolution, but MRI scanning may provide diagnostic information in patients with suspected adrenal carcinoma. Once again, it is stressed that adrenal incidentalomas are present in up to 5% of normal subjects (see section on Cortisol-secreting Adrenal Adenoma and Carcinoma), and thus adrenal imaging should not be performed unless biochemical investigation suggests a primary adrenal cause (undetectable ACTH concentrations).<sup>14</sup> Adrenal carcinomas are large and often associated with metastatic spread at presentation.

In patients with occult ectopic ACTH syndrome, high-definition CT or MRI scanning of thorax, abdomen, and pelvis with images every 0.5 cm may be required to detect small ACTH-secreting carcinoid tumors.<sup>13</sup>

### Scintigraphy Studies

Scintigraphy is of value in certain patients with primary adrenal pathology. The most commonly used agent is <sup>131</sup>I-labeled 6β-iodomethyl-19-norcholesterol. This is a marker of adrenocortical cholesterol uptake. In patients with adrenal adenomas, the isotope is taken up by the adenoma but not by the contralateral suppressed adrenal. Adrenal scintigraphy is useful for suspected adrenocortical macronodular hyperplasia, for which CT scanning may be misleading by suggesting unilateral pathology, whereas with isotope scanning the bilateral adrenal involvement is identified.

Many neuroendocrine tumors giving rise to the ectopic ACTH syndrome express somatostatin receptors and can be

imaged by administering radiolabeled analogs of somatostatin (most commonly  $^{111}\text{In}$ -labeled octreotide). This technique can detect tumors only a few millimeters in diameter and should be considered for patients with ACTH-dependent Cushing's syndrome in whom pituitary disease has been excluded.<sup>2</sup>

### Treatment of Cushing's Syndrome

#### Adrenal Causes

Adrenal adenomas should be removed by unilateral adrenalectomy, which has a 100% cure rate. With the increasing experience of laparoscopic adrenalectomy, this has become the surgical treatment of choice for unilateral tumors, reducing surgical morbidity and postoperative hospital stay compared with traditional open approaches. After surgery, it may take many months or even years for the contralateral suppressed adrenal to recover. Thus, it is necessary to give slightly suboptimal replacement therapy with dexamethasone at 0.5 mg in the morning, with intermittent measurement of morning plasma cortisol. When the morning plasma cortisol is above 180 nmol/L (6 µg/dL), dexamethasone can be stopped. A subsequent insulin tolerance test may then demonstrate whether the response to stress is normal. In the interim, all patients should carry a Steroid Alert card and increase their dose of replacement therapy in the event of an intercurrent illness.

Adrenal carcinomas have a poor prognosis, and most patients are dead within 2 years of diagnosis. It is usual practice to try to remove the primary tumor even though metastases may be present so as to enhance the response to the adrenolytic agent o,p'-dichlorodiphenyldichloroethane (*o,p'*-DDD, mitotane). Radiotherapy to the tumor bed and to some metastases, such as those in the spine, may be of limited value.

#### Pituitary-Dependent Cushing's Syndrome

The treatment of Cushing's disease has been significantly enhanced through transsphenoidal surgery conducted by an experienced surgeon. Before the selective removal of a pituitary microadenoma, the treatment of choice was bilateral adrenalectomy. This had an appreciable mortality even in the best centers (up to 4%) and significant morbidity. The major risk was the subsequent development of Nelson's syndrome (postadrenalectomy hyperpigmentation with a locally aggressive pituitary tumor), which was attributed to loss of any negative feedback after adrenalectomy. In an attempt to avoid this, pituitary irradiation was often carried out at the time of bilateral adrenalectomy. In addition, these patients required lifelong replacement therapy with hydrocortisone and fludrocortisone. Today, bilateral adrenalectomy is rarely indicated for patients with Cushing's disease but may be performed when pituitary surgery has failed or when the condition has recurred.

The surgical outcome for transsphenoidal hypophysectomy is center-dependent and related to surgical expertise. In optimal centers, cure rates are 80% to 90% for microadenomas and 50% for macroadenomas. Rates for hypopituitarism and permanent diabetes insipidus postoperatively depend on how aggressive the surgeon has been in removing pituitary tissue. The ideal outcome is a cured patient with intact pituitary function, but this may not be possible in a patient with Cushing's disease in whom a pituitary adenoma was not identified preoperatively or during the operation itself.

At the time of surgery, patients should be treated with corticosteroids as for any other potential or confirmed deficit of the HPA axis. Postoperatively, hydrocortisone can be withdrawn to maintenance replacement doses, usually within 3 to 7 days.<sup>7,8</sup>

#### Ectopic Adrenocorticotrophic Hormone Syndrome

Treatment of the ectopic ACTH syndrome depends on the cause. If the tumor can be found and has not spread, then its removal can lead to cure (e.g., bronchial carcinoid or thymoma). However, the prognosis for small cell lung cancer associated with the ectopic ACTH syndrome is poor. The cortisol excess and associated hypokalemic alkalosis and diabetes mellitus can be corrected by medical therapy. The treatment of the small cell tumor itself also, at least initially, produces improvement. Sometimes, if the ectopic source of ACTH cannot be found, it may be necessary to perform bilateral adrenalectomy and then observe the patient carefully before the primary tumor becomes apparent.<sup>9</sup>

#### Medical Treatment

Several drugs have been used in the treatment of Cushing's syndrome. Metyrapone inhibits 11 $\beta$ -hydroxylase and has been most commonly given, often to lower cortisol concentrations prior to definitive therapy or while awaiting benefit from pituitary radiation. The daily dose has to be determined by measuring either plasma or urinary free cortisol. The aim should be to achieve a mean plasma cortisol of about 300 nmol/L (11 µg/dL) during the day or a normal urinary free cortisol. The drug is usually given in doses ranging from 250 mg twice daily to 1.5 g every 6 hours.

Aminoglutethimide is a more toxic drug that, in high doses, blocks earlier enzymes in the steroidogenic pathway and thus affects the secretion of steroids other than cortisol. In doses of 1.5 to 3 g daily (start with 250 mg every 8 hours) it commonly produces nausea, marked lethargy, and a high incidence of skin rash. It is commonly prescribed as combination therapy with metyrapone.<sup>15,16</sup>

Ketoconazole is an imidazole that has been widely used as an antifungal agent but causes abnormal liver function tests in about 15% of patients. Ketoconazole blocks a variety of steroidogenic cytochrome P-450-dependent enzymes and thus lowers plasma cortisol levels. For effective control of Cushing's syndrome, 400 to 800 mg daily has been required.<sup>17</sup>

Mitotane is an adrenolytic drug that is taken up by both normal and malignant adrenal tissue, causing adrenal atrophy and necrosis. Because of its toxicity, it has been used mainly in the management of adrenal carcinoma. Doses of up to 10 to 20 g/day are required to control glucocorticoid excess, although evidence that it causes tumor shrinkage or improves long-term survival is lacking. The drug also produces mineralocorticoid deficiency, and concomitant glucocorticoid and mineralocorticoid replacement therapy may be required. Side effects are common and include fatigue, skin rashes, and gastrointestinal disturbance.<sup>9</sup>

#### Prognosis of Cushing's Syndrome

Studies carried out before the introduction of effective therapy indicated that 50% of patients with untreated Cushing's syndrome died within 5 years, principally from vascular disease.

## Reproductive Endocrinology and Infertility

Even with modern management, an increased prevalence of cardiovascular risk factors persists for many years after an apparent cure. Paradoxically, upon correction of the hypercortisolism, patients may feel worse. Skin desquamation, steroid withdrawal arthropathy, profound lethargy, and mood changes may occur and take several weeks or months to resolve.

Features of Cushing's syndrome disappear over a period of 2 to 12 months. Hypertension and diabetes mellitus improve but, as with other secondary causes, may not resolve completely. The osteopenia of Cushing's syndrome improves rapidly in the first 2 years after treatment but resolves more slowly thereafter. Vertebral fractures and aseptic necrosis are irreversible, and permanent deformity results. Visceral obesity and myopathy are both reversible features. Reproductive and sexual functions return to normal within 6 months provided anterior pituitary function was not compromised.<sup>9</sup>

### DISORDERS OF GLUCOCORTICOID DEFICIENCY

Primary hypoadrenalinism is glucocorticoid deficiency occurring in the setting of adrenal disease; secondary hypoadrenalinism arises from deficiency of ACTH. A major distinction between these two is that mineralocorticoid deficiency invariably accompanies primary hypoadrenalinism but does not occur in secondary hypoadrenalinism because only ACTH is deficient with the latter, the renin-angiotensin-aldosterone axis is intact. A further important cause of adrenal insufficiency where there may be dissociation of glucocorticoid and mineralocorticoid secretion is CAH.

#### Primary Hypoadrenalinism: Addison's Disease

This condition was first described by Thomas Addison in 1855. It is a rare condition with an estimated incidence in the developed world of 0.8 cases per 100,000 and prevalence of 4 to 11 cases per 100,000 population. It is associated with significant morbidity and mortality, but when the diagnosis is made it can be easily treated. The causes of Addison's disease are listed in Table 64-8.

#### Autoimmune Adrenalitis

Autoimmune adrenalitis accounts for over 70% of all cases of Addison's disease. In this condition, the adrenal glands are atrophic, with loss of most of the cortical cells, but the medulla is usually intact. In 75% of cases, adrenal autoantibodies can be detected. Fifty percent of patients with this form of Addison's disease have an associated autoimmune disease (Table 64-9), thyroid disease being the most common. Conversely, only 1% to 2% of patients with more common autoimmune diseases such as insulin-dependent diabetes mellitus and thyrotoxicosis have anti-adrenal autoantibodies and adrenal disease. This figure is higher in patients with autoimmune hypoparathyroidism (16%).

These autoimmune polyendocrine syndromes (APSs) are classified as two distinct variants. APS type I is inherited as an autosomal recessive condition and comprises Addison's disease, chronic mucocutaneous candidiasis, and hypoparathyroidism. Other autoimmune conditions such as pernicious anemia, thyroid disease, chronic active hepatitis, and gonadal failure may occur but are rare. APS II is more common and comprises Addison's disease, autoimmune thyroid disease, diabetes mellitus, and

**Table 64-8**  
**Etiology of Adrenocortical Insufficiency**

#### Primary (Addison's disease)

Autoimmune

Sporadic

Autoimmune polyendocrine syndrome type I: Addison's disease, chronic mucocutaneous candidiasis, hypoparathyroidism, dental enamel hypoplasia, alopecia, primary gonadal failure

Autoimmune polyendocrine syndrome type II (Schmidt's syndrome): Addison's disease, primary hypothyroidism, primary hypogonadism, insulin-dependent diabetes, pernicious anaemia, vitiligo

Infection

Tuberculosis

Fungal infection

Cytomegalovirus

HIV

Metastatic tumor

Infiltrations

Amyloid

Hemochromatosis

Intra-adrenal hemorrhage (Waterhouse-Friderichsen syndrome) after meningococcal septicemia

Adrenoleukodystrophies

Congenital adrenal hypoplasia

DAX-1 mutations

SF-1 mutations

ACTH resistance syndromes

Mutations in MC2-R

Triple A syndrome

Bilateral adrenalectomy

#### Secondary

Exogenous glucocorticoid therapy

Hypopituitarism

Selective removal of ACTH-secreting pituitary adenoma

Pituitary tumors and pituitary surgery, craniopharyngiomas

Pituitary apoplexy

Granulomatous disease: tuberculosis, sarcoid, eosinophilic granuloma

Secondary tumor deposits (breast, bronchus)

Postpartum pituitary infarction (Sheehan's syndrome)

Pituitary irradiation (effect usually delayed for several years)

Isolated ACTH deficiency

Idiopathic

Lymphocytic hypophysitis

POMC processing defect

POMC gene mutations

ACTH, adrenocorticotrophic hormone; HIV, human immunodeficiency virus; POMC, pro-opiomelanocortin.

From Larsen PR, Kronenberg HM, Melmed S, et al: (eds): Williams Textbook of Endocrinology, 10th ed. Philadelphia, WB Saunders, 2002, p 526.

hypogonadism. This condition has an inherited basis with linkage to the human leukocyte antigen (HLA) major histocompatibility complex, notably HLA-DR3 and HLA-DR4. Autoantibodies to 21-hydroxylase are usually present and are predictive of the development of adrenal destruction. Other features may accompany APS I and APS II. Patients with APSs are more likely to be female (70%); however, patients with isolated autoimmune adrenalitis are usually male.<sup>18</sup>

Worldwide, infectious diseases are the most common cause of primary adrenal insufficiency and comprise tuberculosis, fungal infections (histoplasmosis, cryptococcosis), and cytomegalovirus infection. Adrenal failure may also occur in the acquired immunodeficiency syndrome (AIDS). Tuberculous Addison's disease results from hematogenous spread of the infection from

<b>Table 64-9</b> <b>Other Endocrine and Autoimmune Diseases Associated with Autoimmune Adrenitis</b>

elsewhere in the body, and extra-adrenal disease is usually evident.

The adrenals are frequently involved in patients with AIDS; adrenalitis may occur after infection with cytomegalovirus or atypical mycobacterium, and Kaposi's sarcoma may result in a requirement for adrenal replacement. The onset is often insidious, but if tested, over 10% of patients with AIDS demonstrate a subnormal cortisol response following an ACTH stimulation test. Adrenal insufficiency may be precipitated through administration of anti-infectives such as ketoconazole (inhibits cortisol synthesis) or rifampin (increases cortisol metabolism).<sup>18,19</sup>

#### Other Causes of Addison's Disease

With the exception of tuberculosis and autoimmune adrenal failure, other causes of Addison's disease are rare. Adrenal metastases (the most common primary being lung and breast) are often found at postmortem examination, but adrenal insufficiency resulting from these is uncommon, perhaps because over 90% of the adrenal cortex needs to be compromised before symptoms and signs become apparent. Necrosis of the adrenals related to intra-adrenal hemorrhage should be considered in any severely sick patient, particularly those with underlying infection, trauma, or coagulopathy. Intra-adrenal bleeding may be found with any cause of severe septicemia, particularly in children, in whom a common cause is infection with *Pseudomonas aeruginosa*. When Addison's disease is caused by meningococcus, the association with adrenal insufficiency is known as the Waterhouse-Friderichsen syndrome. Adrenal deficiency may also occur with amyloidosis and hemochromatosis.

Adrenal hypoplasia congenita is an X-linked disorder comprising congenital adrenal insufficiency and hypogonadotropic hypogonadism. The condition is caused by mutations in the dose-sensitive sex reversal, adrenal hypoplasia congenita, X-chromosome factor (*DAX-1*) gene, a member of the nuclear receptor family of unknown function that is expressed in the adrenal cortex, gonads, and hypothalamus. Mutations in another transcription factor, steroidogenic factor-1, also results in adrenal insufficiency related to lack of development of a functional

adrenal cortex. The transcriptional regulation of many P-450 steroidogenic enzymes is dependent on steroidogenic factor-1.

#### Secondary Hypoadrenalinism (Adrenocorticotrophic Hormone Deficiency)

Secondary hypoadrenalinism is a common clinical problem and is most often due to sudden cessation of exogenous glucocorticoid therapy. Such therapy suppresses the HPA axis with consequent adrenal atrophy, and this may last for months after glucocorticoid treatment ceases. Adrenal atrophy and subsequent deficiency should be anticipated in any patient who has taken more than the equivalent of 30 mg of hydrocortisone per day orally (7.5 mg/day prednisolone or 0.75 mg/day dexamethasone) for more than 3 weeks. In addition to the magnitude of the dose of glucocorticoid, the timing of administration of the dose may affect the degree of adrenal suppression. Thus, prednisolone in a dose of 5 mg given last thing at night and 2.5 mg in the morning produces more marked suppression of the HPA axis than does 2.5 mg at night and 5 mg in the morning because the larger evening dose blocks the early morning surge of ACTH. Secondary hypoadrenalinism may also occur after failure to give adequate glucocorticoid replacement therapy for intercurrent stress in a patient who has received long-term glucocorticoid therapy.

Other causes of secondary adrenal insufficiency reflect inadequate ACTH production by the anterior pituitary gland. In these patients, other pituitary hormones are deficient in addition to ACTH and there is partial or complete hypopituitarism. Secondary hypoadrenalinism also is observed in patients with Cushing's disease after successful and selective removal of the ACTH-secreting pituitary adenoma. The function of adjacent "normal" pituitary corticotrophs is suppressed and may remain so for many months after surgery.

#### Clinical Features of Adrenal Insufficiency

Patients with primary adrenal failure usually have both glucocorticoid and mineralocorticoid deficiency (Table 64-10). In contrast, those with secondary adrenal insufficiency have an intact renin-angiotensin-aldosterone system. This accounts for differences in salt and water balance in the two groups of patients, which in turn results in different clinical presentations. The most obvious feature that differentiates primary from secondary hypoadrenalinism is skin pigmentation, which is nearly always present in primary adrenal insufficiency (unless of short duration) and absent in secondary insufficiency. The pigmentation is seen in sun-exposed areas rather than old scars, in the axillae, nipples, palmar creases, pressure points, and mucous membranes (buccal, vaginal, vulval, anal). The cause of the pigmentation has long been debated, but it is thought to reflect increased stimulation of the melanocortin-2 receptor by ACTH itself. In autoimmune Addison's disease there may be associated vitiligo.

The clinical features are related to the rate of onset and severity of adrenal deficiency. In many cases, the disease has an insidious onset and a diagnosis is made only when the patient comes in with an acute crisis during an intercurrent illness. Acute adrenal insufficiency or an adrenal or addisonian crisis is a medical emergency manifesting as hypotension and acute circulatory failure (Table 64-11). Anorexia may be an early feature,

**Table 64-10**

which progresses to nausea, vomiting, diarrhea, and sometimes abdominal pain. Fever may be present, and hypoglycemia may occur. Patients presenting acutely with adrenal hemorrhage have hypotension; abdominal, flank, or lower chest pain; anorexia; and vomiting. The condition is difficult to diagnose, but evidence of occult hemorrhage (rapidly falling hemoglobin), progressive hyperkalemia, and shock should alert the clinician to the diagnosis.

Alternatively, the patient may have vague features of chronic adrenal insufficiency—weakness, tiredness, weight loss, nausea, intermittent vomiting, abdominal pain, diarrhea or constipation, general malaise, muscle cramps, arthralgia, and symptoms suggestive of postural hypotension. Salt craving may be a feature, and there may be a low-grade fever. Supine blood pressure is usually normal, but almost invariably there is a fall in blood pressure on standing. Although adrenal androgen secretion is lost, this is clinically more apparent in women, who may complain of loss of axillary and pubic hair. Psychiatric symptoms may occur in long-standing cases and include memory impairment, depression, and psychosis. Patients may be inappropriately diagnosed as suffering from chronic fatigue syndrome or anorexia

**Table 64-11**  
**Clinical Features of Adrenal Crisis**

- Dehydration, hypotension, or shock out of proportion to severity of current illness
- Nausea and vomiting with a history of weight loss and anorexia
- Abdominal pain, so-called acute abdomen
- Unexplained hypoglycemia
- Unexplained fever
- Hyponatremia, hyperkalemia, azotemia, hypercalcemia, or eosinophilia
- Hyperpigmentation or vitiligo
- Other autoimmune endocrine deficiencies, such as hypothyroidism or gonadal failure

Modified from Baxter JD, Tyrrell JB. In Felig P, Baxter JD, Frohman LA (eds): *Endocrinology and Metabolism*, 3rd ed. New York, McGraw-Hill, 1995.

nervosa. These features regress on treatment with replacement corticosteroids.

In secondary adrenal insufficiency associated with hypopituitarism, the presentation may be related to deficiency of hormones other than ACTH, notably, LH or FSH (infertility, oligomenorrhea or amenorrhea, poor libido) and TSH (weight gain, cold intolerance). Fasting hypoglycemia occurs because of loss of the gluconeogenic effects of cortisol. It is rare in adults unless there is concomitant alcohol abuse or additional GH deficiency. However, hypoglycemia is a common presenting feature of ACTH or adrenal insufficiency in childhood. In addition, patients with ACTH deficiency present with malaise, weight loss, and other features of chronic adrenal insufficiency.

### Diagnosis of Primary Adrenal Insufficiency

In established primary adrenal insufficiency, hyponatremia is present in about 90% of cases and hyperkalemia in 65%. The blood urea concentration is usually elevated. Hyperkalemia occurs because of aldosterone deficiency and is therefore usually absent in patients with secondary adrenal failure. Hyponatremia may be depletional in an addisonian crisis, but in addition vasopressin levels are elevated, resulting in increased free water retention. Thus, in secondary adrenal insufficiency there may be a dilutional hyponatremia with normal or low blood urea. Reversible abnormalities in liver transaminases frequently occur. Hypercalcemia occurs in 6% of all cases and may be particularly marked in patients with coexisting thyrotoxicosis. However, free thyroxine concentrations are usually low or normal but TSH values are frequently moderately elevated. This is a direct effect of glucocorticoid deficiency and reverses with replacement therapy. Persistent elevation of TSH in association with positive thyroid autoantibodies suggests concomitant autoimmune thyroid disease.

In primary hypoadrenalinism, mineralocorticoid deficiency usually occurs with elevated plasma renin activity and either low or low normal plasma aldosterone. The investigation of zona glomerulosa activity is frequently neglected in Addison's disease as compared with assessment of zona fasciculata function. In secondary adrenal insufficiency, the renin-angiotensin-aldosterone system is intact.

Clinical suspicion of the diagnosis should be confirmed with definitive diagnostic tests. Basal plasma cortisol and urinary free

cortisol levels are often in the low normal range and cannot be used to exclude the diagnosis. However, a basal cortisol value greater than 400 nmol/L (15 µg/dL) invariably indicates an intact HPA axis. All patients suspected of having adrenal insufficiency should have an ACTH stimulation test, although in patients with an addisonian crisis treatment should be instigated immediately and stimulation tests conducted at a later stage.<sup>20</sup>

The ACTH stimulation test involves intramuscular or intravenous administration of 250 µg of cosyntropin (Cortrosyn), which is made up of the first 24 amino acids of normally secreted ACTH 1 to 39. Plasma cortisol levels are measured at 0 and 30 minutes after ACTH, and a normal response is defined by a peak plasma cortisol level greater than 525 nmol/L (19 µg/dL). Response is unaffected by the time of day of the test, and the test can be performed in patients who have commenced corticosteroid replacement therapy provided this is of short duration and does not include hydrocortisone (which would cross-react in the cortisol assay).

A prolonged ACTH stimulation test, involving the administration of depot or intravenous infusions of cosyntropin for 24 to 48 hours, differentiates primary from secondary hypoadrenalinism. In normal subjects the plasma cortisol at 4 hours is greater than 1000 nmol/L (36 µg/dL), and beyond this time there is no further increase. Patients with secondary hypoadrenalinism show a delayed response with usually a much higher value at 24 and 48 hours than at 4 hours, but in primary hypoadrenalinism there is no response at either time. However, the test is now rarely required if plasma ACTH has been appropriately measured at baseline. In primary adrenal insufficiency, the ACTH level is disproportionately elevated in comparison with plasma cortisol.

Radioimmunoassays to detect autoantibodies such as those against the 21-hydroxylase antigen are available and should be analyzed in patients with primary adrenal failure. In autoimmune Addison's disease, it is also important to look for evidence of other organ-specific autoimmune disease. A CT scan may reveal enlarged or calcified adrenals, suggesting an infective, hemorrhagic, or malignant diagnosis. A chest radiograph, tuberculin testing, and early morning urine samples cultured for *Mycobacterium tuberculosis* should be obtained if tuberculosis is suspected. A CT-guided adrenal biopsy specimen may reveal an underlying diagnosis in patients with suspected malignant deposits in the adrenal. Adrenoleukodystrophy can be diagnosed by measuring circulating levels of very long chain fatty acids. Finally, appropriate investigations, including pituitary MRI scans and an assessment of anterior (pituitary) function, are required for patients suspected of having secondary hypoadrenalinism who are not receiving corticosteroid therapy.<sup>21,22</sup>

### Treatment of Acute Adrenal Insufficiency

Acute adrenal insufficiency is a life-threatening emergency, and treatment should not be delayed for definitive proof of diagnosis (Table 64-12). However, in addition to measurement of plasma electrolytes and blood glucose, appropriate samples for ACTH and cortisol should be taken before corticosteroid therapy is given. If the patient is not critically ill, an acute ACTH stimulation test can be performed.

Intravenous hydrocortisone should be given in a dose of 100 mg every 6 hours. If this is not possible, the intramuscular route should be used. In the shocked patient, 1 L of normal

**Table 64-12**  
**Treatment of Adrenal Crisis**

#### Emergency measures

- Establish intravenous access with a large-gauge needle
- Draw blood for stat serum electrolytes and glucose and routine measurement of plasma cortisol and ACTH  
*Do not wait for laboratory results*
- Infuse 2 to 3 L of 154 mmol/L NaCl (0.9% saline) solution or 50 g/L (5%) dextrose in 154 mmol/L NaCl (0.9% saline) solution as quickly as possible  
Monitor for signs of fluid overload by measuring central or peripheral venous pressure and listening for pulmonary rales  
Reduce infusion rate if indicated
- Inject intravenous hydrocortisone (100 mg immediately and every 6 hr)
- Use supportive measures as needed

#### Subacute measures after stabilization of the patient

- Continue intravenous 154 mmol/L NaCl (0.9% saline) solution at a slower rate for next 24 to 48 hr
- Search for and treat possible infectious precipitating causes of the adrenal crisis
- Perform a short ACTH stimulation test to confirm the diagnosis of adrenal insufficiency, if patient does not have known adrenal insufficiency
- Determine the type of adrenal insufficiency and its cause if not already known
- Taper glucocorticoids to maintenance dosage over 1 to 3 days, if precipitating or complicating illness permits
- Begin mineralocorticoid replacement with fludrocortisone (0.1 mg by mouth daily) when saline infusion is stopped

ACTH, adrenocorticotrophic hormone.

saline should be given intravenously over the first hour. Because of possible hypoglycemia, it is usual to give 5% dextrose saline. Subsequent saline and dextrose therapy depends on biochemical monitoring and the patient's condition. Clinical improvement, especially in the blood pressure, should be seen within 4 to 6 hours if the diagnosis is correct. It is important to recognize and treat any associated condition, such as an infection, which may have precipitated the acute adrenal crisis.

After the first 24 hours the dose of hydrocortisone can be reduced, usually to 50 mg intramuscularly every 6 hours, and then, if the patient can take it by mouth, to oral hydrocortisone, 40 mg in the morning and 20 mg at 6 PM. This can then be rapidly reduced to a more standard replacement dose of 20 mg on wakening and 10 mg at 6 PM.

#### Chronic Replacement Therapy

The aim is to give replacement doses of hydrocortisone to mimic the normal cortisol secretion rate (Table 64-13). Most patients can be maintained with less than 84 µmol/day (30 mg/day; 15 to 25 mg/day in divided doses). Doses are usually given on wakening, with a smaller dose in the late afternoon, but some patients may feel better with dosing three times daily. In primary adrenal failure, cortisol day curves with simultaneous ACTH measurements may provide some insight into the adequacy of replacement therapy, but unfortunately there are no good objective tests in secondary adrenal failure. Decisions about doses of replacement therapy are largely based on crude but nevertheless important endpoints such as weight, well-being, and blood

<b>Table 64-13</b> <b>Chronic Maintenance of Primary Adrenal Insufficiency</b>	
<b>Maintenance therapy</b>	
Glucocorticoid replacement	
Hydrocortisone 15–20 mg on awakening and 5–10 mg in early afternoon	
Monitor clinical symptoms and morning plasma ACTH	
Mineralocorticoid replacement	
Fludrocortisone 0.1 (0.05–0.2) mg orally	
Liberal salt intake	
Monitor lying and standing blood pressure and pulse, edema, serum potassium, and plasma renin activity	
Educate patient about the disease, how to manage minor illnesses and major stresses, and how to inject steroid intramuscularly	
Obtain Medic Alert bracelet/necklace, Emergency Medical Information Card	
<b>Treatment of minor febrile illness or stress</b>	
Increase glucocorticoid dose twofold to threefold for the few days of illness; do not change mineralocorticoid dose	
Tell patient to contact physician if illness worsens or persists for more than 3 days or if vomiting develops	
No extra supplementation is needed for most uncomplicated, outpatient dental procedures under local anesthesia; general anesthesia or intravenous sedation should not be used in the office	
<b>Emergency treatment of severe stress or trauma</b>	
Tell patient to inject contents of prefilled dexamethasone (4-mg) syringe intramuscularly	
Tell patient to get to physician as quickly as possible	
<b>Steroid coverage for illness or surgery in hospital</b>	
For moderate illness, give hydrocortisone 50 mg twice a day orally or intravenously; taper rapidly to maintenance dose as patient recovers	
For severe illness, give hydrocortisone 100 mg intravenously every 8 hr; taper dose to maintenance level by decreasing by half every day and adjust dose according to course of illness	
For minor procedures under local anesthesia and most radiologic studies, no extra supplementation is needed	
For moderately stressful procedures, such as barium enema, endoscopy, or arteriography, give a single 100-mg intravenous dose of hydrocortisone just before the procedure	
For major surgery, give hydrocortisone 100 mg intravenously just before induction of anesthesia and continue every 8 hr for first 24 hr; taper dose rapidly, decreasing by half per day, to maintenance level	
Modified from Baxter JD, Tyrrell JB. In Felig P, Baxter JD, Frohman LA (eds): <i>Endocrinology and Metabolism</i> , 3rd ed. New York, McGraw-Hill, 1995.	

pressure. Bone mineral density may be reduced with conventional hydrocortisone doses of 30 mg/day, highlighting the need to strive for the lowest effective dose.<sup>23</sup>

In primary adrenal failure, mineralocorticoid replacement is usually also required in the form of fludrocortisone (or 9 $\alpha$ -fluorinated hydrocortisone) at 0.05 to 0.2 mg/day. The mineralocorticoid activity of this treatment is about 125 times that of hydrocortisone. After the acute phase has passed, the adequacy of mineralocorticoid replacement should be assessed by measuring electrolytes and supine and erect blood pressure and plasma renin activity; too little fludrocortisone may cause postural hypotension with elevated plasma renin activity, and too much may cause the opposite.<sup>24</sup>

Patients receiving glucocorticoid replacement therapy should be advised to double the daily dose in the event of intercurrent febrile illness, accident, or mental stress such as an important examination. If the patient is vomiting and cannot take medi-

cation by mouth, parenteral hydrocortisone must be given. For minor surgery, 50 to 100 mg of hydrocortisone hemisuccinate is given with the premedication. For major operations, this is then followed by the same regimen as for acute adrenal insufficiency. Pregnancy proceeds normally in patients taking replacement therapy, but daily doses of hydrocortisone are usually increased modestly (5 to 10 mg/day) in the last trimester. During labor, patients should be well hydrated with a saline drip and receive hydrocortisone at 50 mg intramuscularly every 6 hours until delivery. Thereafter, doses can be rapidly tapered off to usual maintenance regimens.

Every patient receiving glucocorticoid therapy should be advised to register for a Medic Alert bracelet or necklace and must carry a Steroid Alert card.

For patients with both primary and secondary adrenal failure, beneficial effects of adrenal androgen replacement therapy with DHEA at 25 to 50 mg/day have been reported. To date, the reported benefit is principally confined to female patients and includes improvement in sexual function and well-being.<sup>25</sup>

### Congenital Adrenal Hyperplasia

These inherited syndromes are caused by deficient adrenal corticosteroid biosynthesis. In each case, there is reduced negative feedback inhibition of cortisol and, depending on the steroidogenic pathway involved, alteration in adrenal mineralocorticoid and androgen secretion (Table 64-14).

### 21-Hydroxylase Deficiency

Ninety percent of cases of CAH are due to 21-hydroxylase deficiency. The incidence varies from 1 in 5000 to 1 in 15,000 live births. The condition arises because of defective conversion of 17 $\alpha$ -hydroxyprogesterone to 11-deoxycortisol. Reduced cortisol biosynthesis results in reduced negative feedback drive and increased ACTH secretion; as a consequence, adrenal androgens are produced in excess (see Fig. 64-2). Seventy-five percent of cases include mineralocorticoid deficiency because of the failure to convert progesterone to DOC in the zona glomerulosa. Clinically, several distinct variants of 21-hydroxylase deficiency have been recognized (Table 64-15).

### Simple Virilizing Form

The enhanced ACTH drive to adrenal androgen secretion in utero leads to virilization of an affected female fetus. Depending on the severity, clitoral enlargement, labial fusion, and development of a urogenital sinus may occur, leading to sexual ambiguity at birth and even inappropriate sex assignment. Rarely, the diagnosis is missed in the neonatal period, especially in boys, who may be phenotypically normal at birth. Such patients may present in early childhood with sexual precocity and pubic hair development. Initially, linear growth is accelerated because of premature androgen excess that, left untreated, stimulates epiphyseal closure and compromises final adult height.

### Salt-Wasting Form

Seventy-five percent of cases in both sexes also have concomitant aldosterone deficiency. In addition to the preceding clinical features, neonates may have a salt-wasting crisis and hypotension in the first week of life. Indeed, this may alert the clinician to the diagnosis in a male, but unfortunately the diag-

nosis is still delayed in many cases and the condition carries a significant neonatal mortality rate.

#### **Late-Onset 21-Hydroxylase Deficiency**

These patients present with premature pubarche or with a phenotype that may masquerade as polycystic ovary syndrome

(PCOS). Indeed, late-onset CAH is a recognized secondary cause of PCOS and appears to be more common than the classical variety. In some series from tertiary referral centers, late-onset 21-hydroxylase deficiency may account for up to 12% of all patients with PCOS, but more realistic prevalence rates are probably 1% to 3%. Females have hirsutism and primary or

## Reproductive Endocrinology and Infertility

secondary amenorrhea or anovulatory infertility. Androgenic alopecia and acne may be other presenting features.

### Heterozygote Deficiency

Salt-wasting, simple virilizing, and late-onset 21-hydroxylase deficiencies are all caused by homozygous or compound heterozygous mutations in the human CYP21A2 gene, whereas in the carrier heterozygote state, only one allele is mutated. The clinical significance of the heterozygote state is uncertain; it does not appear to affect reproductive capability but may cause signs of hyperandrogenism in women.

A diagnosis of 21-hydroxylase deficiency should be considered in any infant with genital ambiguity, salt wasting, or hypotension. Hyponatremia and hyperkalemia with raised plasma renin activity are found in salt wasters. In later life, adrenal androgen excess (DHEAS, androstenedione) is found in patients with sexual precocity or a PCOS-like phenotype. 17-OHP is invariably elevated, and clinically useful nomograms have been developed comparing circulating concentrations of 17-OHP before and 60 minutes after exogenous ACTH. This separates patients with classical and nonclassical 21-hydroxylase deficiency from heterozygote carriers and normal subjects, but there is some overlap between values seen in heterozygotes and normal people. 17-OHP is measured basally and then 60 minutes after 250 µg of cosyntropin. Stimulated values are invariably grossly elevated in patients with classical and nonclassical varieties (in excess of 35 nmol/L [11 µg/dL]). Heterozygote patients usually have stimulated values between 10 and 30 nmol/L (3 to 9 µg/dL). Stimulation tests are not always required to make a diagnosis; for example, a basal 17 $\alpha$ -OHP concentration less than 5 nmol/L in the follicular phase of the menstrual cycle effectively excludes late-onset 21-hydroxylase deficiency. Androgen excess in 21-hydroxylase deficiency is readily suppressed after glucocorticoid administration.

Prenatal diagnosis of 21-hydroxylase deficiency has been advocated because treatment of an affected female may prevent masculinization in utero. 17-OHP can be assayed in amniotic fluid, but the most robust approach is the rapid genotyping of fetal cells obtained by chorionic villus sampling in early gestation. Unlike hydrocortisone, which is inactivated by placental 11 $\beta$ -HSD, maternally administered dexamethasone can cross the placenta to suppress the fetal HPA axis. One approach is to advocate dexamethasone therapy as soon as pregnancy is confirmed in high-risk cases and to continue this until the diagnosis is excluded in the fetus. If the fetus is affected, only those of female sex require dexamethasone therapy during gestation. Therapy must be initiated before 8 to 10 weeks of gestation to be effective. However, because only one in eight patients treated in this way have an affected female fetus, the use of steroid therapy in this setting has been questioned. Dexamethasone can lead to maternal cushingoid effects in pregnancy and may in turn have long-term, deleterious effects on the fetus.

In patients with known 21-hydroxylase deficiency requesting fertility (be they male or female), determination of 17-OHP levels by means of a cosyntropin test in the partner before conception occurs uncovers late-onset or heterozygote cases and provides the endocrinologist or geneticist with some assignment of risk before pregnancy.

### Treatment of Congenital Adrenal Hyperplasia

The treatment strategies have subtle variations depending on the age of the patient. In childhood the overall goal is to replace glucocorticoids and mineralocorticoids, thereby preventing further salt-wasting crises, and also to suppress adrenal androgen secretion so that normal growth and skeletal maturation can proceed. Accurate replacement is essential, since glucocorticoids in excess suppress growth, and inadequate replacement results initially in accelerated linear growth but ultimately in short stature because of premature epiphyseal closure. Response is best monitored through growth velocity and bone age, with biochemical markers (17-OHP, DHEAS, testosterone) being useful adjuncts. Corrective surgery is frequently required (clitoral reduction, vaginoplasty) during childhood. In late childhood and adolescence, appropriate replacement therapy is equally important. Overtreatment may result in obesity and delayed menarche or puberty with sexual infantilism, whereas under-replacement results in sexual precocity. Compliance with regular medication is often an issue through adolescence. Problems in adulthood are related to fertility concerns, hirsutism, and menstrual irregularity in women, obesity and impact of short stature, sexual dysfunction, and psychological problems; counseling is often required in addition to endocrine support.

Usual starting doses of hydrocortisone in childhood are 10 to 25 mg/m<sup>2</sup> per day in divided doses. Reverse-phase therapy may be appropriate, giving the largest dose of hydrocortisone at night to suppress early morning ACTH secretion. Long-acting steroids such as dexamethasone are more effective in this regard, but care should be taken to avoid oversuppression and reduction in linear growth. Fludrocortisone is required for patients with salt wasting (although this may improve spontaneously with age); doses of 0.1 to 0.2 mg/day should be given and blood pressure, electrolytes, and supine-erect plasma renin activity monitored to assess response.

In women with hyperandrogenism and untreated late-onset CAH, there is no evidence that final height is affected. In this setting, glucocorticoid suppression in isolation rarely controls hirsutism and additional antiandrogen therapy is often required (cyproterone acetate, spironolactone, flutamide together with an oral estrogen contraceptive pill). However, ovulation induction rates with gonadotropin therapy are improved after suppression of nocturnal ACTH levels with 0.25 to 0.5 mg of dexamethasone.

### 11 $\beta$ -Hydroxylase Deficiency

11 $\beta$ -Hydroxylase deficiency accounts for 7% of all cases of CAH with an incidence of 1 per 100,000 live births. The condition arises because of mutations in the CYP11B1 gene that result in loss of enzyme activity and a block in the conversion of 11-deoxycortisol to cortisol. There is loss of negative cortisol feedback and enhanced ACTH-mediated adrenal androgen excess. Clinical features are therefore similar to those reported in the simple virilizing form of CAH (virilized female fetus, sexual ambiguity), and again milder cases can present later in childhood or even young adulthood. The principal difference compared with 21-hydroxylase deficiency is hypertension, and this is thought to be secondary to the mineralocorticoid effect of DOC excess.<sup>26,27</sup>

### **17 $\alpha$ -Hydroxylase Deficiency**

Fewer than 150 cases of 17 $\alpha$ -hydroxylase deficiency have been reported. Mutations within the CYP17 gene result in the failure to synthesize cortisol (17 $\alpha$ -hydroxylase activity), adrenal androgens (17,20-lyase activity), and gonadal steroids. Thus, in contrast to 21-hydroxylase and 11-hydroxylase deficiencies, 17 $\alpha$ -hydroxylase deficiency results in adrenal and gonadal insufficiency. Loss of negative feedback results in increased secretion of steroids proximal to the block, and mineralocorticoid synthesis is enhanced.

The diagnosis is usually made at the time of puberty when patients come in with hypertension, hypokalemia, and hypogonadism, the latter occurring because of lack of CYP17 expression within the gonad and impaired gonadal steroidogenesis. As a result, LH and FSH levels are elevated. Female patients (46,XX) have primary amenorrhea with absent sexual characteristics, and males (46,XY) have complete pseudohermaphroditism with female external genitalia but absent uterus and fallopian tubes. The intra-abdominal testes should be removed, and such patients are usually reared as female. Glucocorticoid replacement reverses the DOC-induced suppression of the renin-angiotensin system and lowers blood pressure. Additional sex steroid replacement is required from puberty onward.<sup>26,27</sup>

### **3 $\beta$ -Hydroxysteroid Dehydrogenase Deficiency**

In this rare form of CAH, the secretion of all classes of adrenal and ovarian steroids is impaired because of mutations within the HSD3B2 gene encoding 3 $\beta$ -HSDII. The disorder usually presents in early infancy with adrenal insufficiency. Loss of mineralocorticoid secretion results in salt wasting, although this is absent in 30% to 40% of cases. As with 21-hydroxylase deficiency, absence of salt wasting may delay the presentation until childhood or puberty. The spectrum of genital development is variable in both sexes. In males, because the 3 $\beta$ -HSDII enzyme is also expressed within the gonad, male pseudohermaphroditism may occur, with female external genitalia. In milder cases, hypospadias may be found or even normal male genitalia. In females, genital development can be normal but there is usually evidence of mild virilization, presumably because of enhanced adrenal secretion of DHEA, which is converted peripherally to testosterone. A late-onset form has been described in patients with premature pubarche and a PCOS-like phenotype (hirsutism, oligomenorrhea, amenorrhea).

Because activity of the 3 $\beta$ -HSDI enzyme present in skin and other peripheral tissues is intact, circulating  $\Delta$ 4 steroid levels (progesterone, 17 $\alpha$ -hydroxyprogesterone, androstenedione) may be normal (or even increased). However, a diagnosis is established by demonstrating an increased ratio of  $\Delta$ 5 steroids (pregnenolone, 17 $\alpha$ -hydroxypregnenolone, DHEA) to  $\Delta$ 4 steroids in plasma or urine. ACTH stimulation may be required to detect a late-onset presentation. Treatment is with replacement glucocorticoids, fludrocortisone (if indicated), and sex steroids from puberty onward.

### **Steroidogenic Acute Regulatory Protein Deficiency**

Mutations in the gene encoding StAR result in a failure of transport of cholesterol from the outer to the inner mitochondrial

membrane in steroidogenic tissues; as a result, there is deficiency of all adrenal and gonadal steroid hormones. Presentation is of acute adrenal insufficiency in the neonatal period, and males exhibit pseudohermaphroditism because of absent gonadal steroids. The condition is fatal in infancy in two thirds of cases. The adrenal glands are often massively enlarged and lipid laden; prior to the characterization of StAR, the condition was termed *congenital lipoid hyperplasia* and the candidate gene was thought to be cholesterol side-chain cleavage (CYP11A1). In fact, to date, no mutations have been reported in the CYP11A1 gene; such mutations are thought to be lethal in utero.<sup>28</sup>

## Section 9 Coding and Office Management

# Chapter 65

# Coding Tips for the Busy Physician

Philip N. Eskew, Jr., MD

### KEY POINTS

- Be involved in the coding process.
- Learn to use history templates.
- For “complaint” visits, examine only what is clinically relevant.
- Learn the difference between a consultation and counseling.
- Compare your use of the five established patient visits codes with those used by your partners, then audit each other’s charts.
- Document only what you do, code for only what you documented.

Medicine has changed! Most physicians want to just take care of patients and enjoy the challenge of diagnosing, treating, and modifying behaviors toward an improvement in their patients’ overall health. However, physicians must also learn and participate in the *business* of medicine—coding, documentation, reimbursement, contracting, compliance, and risk management. Physicians are busy and most do not want to learn about coding and documentation, but these basic skills will create a better medical record, improve billings and collections, and decrease their level of anxiety regarding fraud and abuse.

The process of reimbursement for physician services involves utilizing coding and documentation principles. Insurance plans and managed care plans reimburse based on the submission, by the physician, of proper CPT (Current Procedural Terminology) and ICD-9 (International Classification of Diseases, ninth edition) codes.

CPT codes are used to record services provided by the physician. Those services include surgical procedures, hospital care, critical care, and office visits. CPT codes are five-digit numbers that indicate to the insurance company what services were provided to the patient (Example 1). ICD-9 codes are three-, four-, or five-digit numbers used to define the diagnosis for the services provided (Example 2).

### EXAMPLE I

99223 Initial hospital care, per day, for the evaluation and management of a patient, which requires these three key components:

a comprehensive history  
a comprehensive examination  
medical decision making of high complexity

Counseling and/or coordination of care with other providers or agencies are provided consistent with the nature of the problem(s) and the patient’s and/or family’s needs. Usually the problem(s) requiring admission are of high severity. Physicians typically spend 70 minutes at the bedside and on the patient’s hospital floor or unit.

This information is in the CPT book under the listing of the code. Information is also provided under the category heading of Initial Hospital Care.

When the patient is admitted to the hospital as an inpatient in the course of an encounter in another site of service (e.g., hospital emergency department, observation status in a hospital, physician’s office, nursing facility), all evaluation and management services provided by that physician in conjunction with that admission are considered part of the initial hospital care when performed on the same date as the admission. The inpatient care level of service reported by the admitting physician should include the services related to the admission he or she provided in the other sites of service as well as in the inpatient setting.

Evaluation and management services on the same date provided in sites that are related to the admission “observation status” should not be reported separately. For a patient admitted and discharged from observation or inpatient status on the same date, the services should be reported with codes 99234–99236 as appropriate.

### EXAMPLE 2

Diabetes with renal manifestations

Use additional code to identify manifestation, as:

Diabetic:  
Nephropathy NOS (583.81)  
Nephrosis (581.81)  
Intercapillary glomerulosclerosis (581.81)  
Kimmelstiel-Wilson syndrome (581.81)

There is a reminder in the book that a fifth digit is required. Use of a fifth digit makes the code more specific and frequently will provide additional information indicating the severity of the condition.

The following fifth-digit subclassification is for use with category 250:

[Category 250 is diabetes mellitus and excludes gestational diabetes (648.8), hyperglycemia NOS (790.6), neonatal diabetes mellitus (775.1), and nonclinical diabetes (790.2)]  
0 type II (non-insulin-dependent type) (NICCM type) (adult-onset type) or unspecified type, not stated as uncontrolled

## Coding and Office Management

Fifth-digit 0 is for use with type II, adult-onset diabetic patients, even if the patient requires insulin

1 type I (insulin-dependent type) (IDDM) (juvenile type), not stated as uncontrolled

2 type II (non-insulin-dependent type) (NIDDM type) (adult-onset type) or unspecified type, uncontrolled

Fifth-digit 2 is for use with type II, adult-onset diabetic patients, even if the patient requires insulin

3 type I (insulin-dependent type) (IDDM) (juvenile type), uncontrolled

The physician's responsibility does not end with the selection of the proper CPT and ICD-9 codes. All insurance companies require that the documentation on the patient's chart accurately reflect the physician work involved in the patient encounter. Each encounter requires the physician to document the history obtained from the patient, the amount of the physical examination performed, and the medical decision making involved in the encounter.

This process may sound simple, but most physicians have developed short cuts, abbreviated forms, and handwritten notes that do not meet documentation guidelines. In other situations, some physicians will make up a diagnosis that will allow the patient's encounter to be reimbursed by the insurer. This can be dangerous, since the patient's medical history may reflect an inaccurate diagnosis that could affect their ability to obtain health insurance in the future. Far too many physicians have been charged with fraud for falsifying insurance claims with procedures that were not performed or for providing inaccurate documentation to justify the insurance claim.

The history obtained from the patient should begin at the initial visit and require the patient to complete a comprehensive intake history form. Many such forms are available that are comprehensive in nature and meet the requirements for a comprehensive history. It is important for the physician to review the history with the patient and sign the history form in addition to asking for the patient's signature. Several insurance and managed care companies inform the patient that to call the company if they feel the physician has over-charged for the visit, and the company will request the medical records for documentation of the visit. This same comprehensive intake history form can be reviewed by the patient, signed, and dated, and countersigned and dated by the physician the next year.

The patient does not have to fill out a new form each year. However, some physicians ask patients to fill out an interval history form if they return within the year for a visit other than an annual examination. At this visit the interval history form can simply ask the patient what changes in their health, family, or medication status have taken place since the last visit. It is appropriate to put on this form a sentence such as "I apologize for having you fill out this form, but most insurance companies require it." This will make up for the inconvenience and frustration that some patients feel when asked to fill out one more form.

In addition to these forms, the physician must record, either on a form or by dictation or in handwriting, the chief complaint, history of present illness, and any pertinent changes in the patient's history since the last visit, to document the reason for the encounter (Example 3).

**EXAMPLE 3**

Chief Complaint: "I have a pain in my belly."

History of Present Illness: The patient complains of an intense, constant, sharp pain in the upper right quadrant that is only relieved by lying down. This began three days ago.

Example 3 provides the Chief Complaint and six components of the History of Present Illness. A detailed or comprehensive history requires only four components. The eight components are location, severity, duration, timing, quality and context, modifying factors, signs and symptoms.

This form provides a good medical record that can easily be understood by the physician's partner or the insurance company or serve as an excellent source for the physician when the patient returns. Physicians are required to go back to basics—to use the history-taking methods learned in medical school and residency training—in meeting the requirements of today's insurers. Templates are acceptable and can serve as a reminder for the physician but also create a comprehensive history.

Most physicians have their own format for dictation of a complete physical examination. The physician can utilize a check-off form for the physical examination as long as each individual item is individually checked. A physician who prefers dictation to document the physical examination must mention each body area actually examined. Whichever method the physician utilizes, the medical record must contain documentation of the clinically relevant body areas examined relative to the patient's diagnosis.

The key to reimbursement is for the physician to only perform an examination of "clinically relevant" body areas. Performing a comprehensive physical examination will not allow the physician to be reimbursed more when the patient's symptoms require only an abbreviated examination. However, physicians place themselves at risk if they submit a claim for a patient encounter that does not document the physical examination required for that CPT code.

The most difficult area of the patient encounter to document is the medical decision-making component. This requires physicians to document their thought processes regarding how they are managing the patient's diagnosis, which tests they are ordering and why, prescriptions written, procedures planned, and diagnoses considered and ruled out (Example 4). With each patient encounter, the physician should devote a portion of their dictation or written narrative to the documentation of what conditions the patient complains of and what tests or procedures the physician is considering to help with the diagnosis and treatment of the complaint.

**EXAMPLE 4**

Impression: Pneumonia

Labs: CBC

Tests ordered: Chest x-ray

Prescriptions: Antibiotic, expectorant

Plan: Follow-up in 7 days, force fluids, report worsening of symptoms

When a patient is hospitalized, the physician must record the services performed in the hospital—either surgical or medical

care—and submit that information to his or her office billing clerk. Each patient has a hospital face sheet with insurance information on which the physician should record the date(s) of service along with the appropriate CPT and ICD-9 codes for each day of hospitalization.

Consultation services should be carefully documented following the requirements prescribed by CPT. A request for a consultation means that another physician wants your advice or opinion. In some cases, this service can be provided on your own patient (Example 5). During a consultation encounter you may order tests, write prescriptions, or provide therapy. The main requirements are for documentation in the chart of the physician who requested the consultation and documentation of a letter sent to that requesting physician.

### EXAMPLE 5

I was asked to see Mrs. Smith in consultation regarding the status of her hypertension prior to undergoing an abdominal hysterectomy for uterine leiomyomata and persistent menorrhagia.

The relative value units for a consultation are much higher than for a new patient visit, so whenever your opinion or advice is requested, use a consultation code.

Many patients come to your office for their “annual physical.” An age-appropriate comprehensive physical examination should be performed. A review of the patient’s intake history form with the patient will meet the requirements for a comprehensive history. It is appropriate to review the patient’s status with regard to several ongoing clinical conditions, refill or adjust medications, and order appropriate screening tests. It is a general rule that if greater than 50% of that visit is related to performing an “annual examination,” then bill it as an “annual examination.” If the patient comes into the office with a new complaint that requires significant physician work, then the visit should be billed at the appropriate established patient level code. If you discover or suspect a new condition, you may order tests to confirm or rule out the condition as long as greater than 50% of your time is spent performing an “annual examination.”

Each physician should take the time to become involved in the coding and billing portion of his or her practice. This means that the physician should meet regularly (weekly or biweekly) with the insurance or billing person in the office. Discussions as to why claims were questioned, denied, or returned for more information by the insurer will help educate the physician in the documentation phase of the patient encounter. Several medical journals and subscription newsletters regularly publish helpful hints regarding coding, billing, and documentation information. Physicians should read these and share them with office personnel. Attendance at coding postgraduate courses by physicians and office staff are valuable in helping everyone understand the importance of coding and documentation.

How accurately the physician codes each patient encounter can affect the amount of money earned in the practice. Some practices divide the financial profits based on a productivity

principle. Each physician’s productivity is based on the relative value units assigned to each procedure and each office encounter. The relative value unit total for the individual physician’s work determines his or her productivity for that time period (Example 6). If a physician incorrectly records a lower level office visit than is actually documented, the relative value unit total will be affected when profits are split.

### EXAMPLE 6

Medicare Reimbursement Unit for 2005 is \$37.8974			
New Patient Encounters		Established Patient Encounters	
99201	0.97	99211	0.57
99202	1.72	99212	1.02
99203	2.56	99213	1.39
99204	3.62	99214	2.18
99205	4.58	99215	3.17
Outpatient Consultation		Inpatient Consultation	
99241	1.33	99251	0.95
99242	2.43	99252	1.91
99243	3.24	99253	2.61
99244	4.56	99254	3.75
99245	5.90	99255	5.17
New Patient Annual Examination		Established Patient Annual Examination	
99385	3.14	99395	2.57
99386	3.69	99396	2.85
99387	4.00	99397	3.13

Each year CPT and ICD-9 publish a book with updates that add, delete, or edit some codes. The physician and office staff need to obtain the new book each year and review the changes. Several publications summarize these changes in articles or newsletters, and physicians can share this information at their regular office staff or business meetings. The Coding Institute publishes a Coding Alert for each specialty offering helpful hints and explanations for the physician and the office staff. The AMA publishes The CPT Assistant, which has helpful articles answering coding questions.

The practice of medicine now requires the physician to not only learn about new procedures and techniques but also how to document the appropriate amount of history, physical examination, and medical decision making for each patient encounter. The challenge for busy physicians is to assess how well they are doing, educate themselves and their office staff about coding principles, and take steps to improve coding, documentation, and compliance. Perform a self-audit of the office visit codes during the past 2 months for each physician. Compare the bar graphs, and then multiply the total number of each level by the relative value units. This can be an eye-opening experience and the beginning of improved coding, documentation, compliance, and comfort.

# Chapter 66

# Federal Regulations

Joseph Sanfilippo, MD, MBA, and Ira R. Horowitz, MD, MHCM

## HIPAA COMPLIANCE

The Health Insurance Portability and Accountability Act (HIPAA) is federal legislation that was passed in 1996. It provides guidelines for patient privacy in a medical practice focused on three main areas:

- Insurance portability
- Administrative focus
- Privacy and security

HIPAA is designed to establish the minimum necessary standard to make a reasonable effort to limit use, disclosure, and requests for patient information.

The insurance portability segment of HIPAA focuses on the patient's ability to maintain health insurance coverage when one makes a decision to change health plans. It is designed to prevent denial of coverage based on a "preexisting" condition.

The administrative segment is predicated on development of standards for the process of information exchange, especially electronically. This aspect of HIPAA also requires health care professionals to implement policies designed to protect patient privacy and confidentiality.

The privacy and security segment addresses the medical record and the effort to keep patient information private and secure from inappropriate access.

The Health Insurance Portability and Accountability Act applies to all health care professionals. It is our responsibility to comply with HIPAA privacy rules and regulations.

### Minimum Necessary Information

The *minimum necessary* rule is designed to provide patient information on a need-to-know basis and applies to all uses, disclosures, and requests for information by individuals and/or industrial organizations that utilize such information to perform health care-related operations. This would include the following:

- Payment for services
- Administrative purposes
- Request for information from other covered entities for their payment or administrative-related activities
- Research purposes

HIPAA includes all aspects of patient information access: written, verbal, and electronic.

Protected health information includes the following:

- Patient name and address
- Social Security number
- Date of birth
- Medical record number

- Medical history
- Diagnosis
- Plan of management
- Medications

### HIPAA Highlights

- Sign-in sheets should only have patient name and not reason for the visit.
- Patients must sign a document that they want to be reminded about a visit as, for example, "annual examination."
- Be discreet about discussing patient information in public areas.
- Never leave patient charts unattended.
- Close the curtain in semiprivate rooms, and ask visitors to step out.
- Position the computer screen such that patient information cannot be viewed easily.
- Do not keep screen up when the computer is unattended.
- Obtain patient authorization before releasing any information not related to billing or collections.
- When finished with confidential information, place in paper shredder.
- Have appropriate security measures in place when e-mailing personal health information.
- When faxing, do not leave patient information unattended.
- Confirm that the fax was received.

### Implementing HIPAA Regulations

To implement HIPAA regulations:

- Identify an individual in the office responsible for implementation of rules and regulations.
- Limit access to patient information.
- Identify individuals who need access to patient information. This can be stated as an all-encompassing policy regarding medical employees (i.e., all involved in the patient's treatment).
- Establish policies and procedures that limit access to patient's medical information. This can be accomplished by establishing a protocol.
- The Minimum Necessary Standard does not apply to disclosures or requests for treatment purposes. This means you may disclose the entire medical record to another provider or request an entire medical record for treatment purposes without documenting on the patient's chart the specific justification.
- Front desk sign-in sheets as well as calling out of patient's name in the waiting room are permitted. Discretion is required if discussing patient information in an open area.

## Coding and Office Management

- Patients should be escorted to the examination room and not left to find it on their own.
- Leaving the patient's record outside the door of the examination room is permissible. If the patient's name can be identified, it must be placed facing the wall to protect privacy.
- Make use of a Business Associate Agreement (Fig. 66-1).

**Protocol for Implementation of HIPAA**

Identify the individuals who may receive or record information on the patient's chart, which may include the following:

- Nursing staff
- Medical assistants
- Clerical personnel employed by the office

**BUSINESS ASSOCIATE AGREEMENT**

Date: \_\_\_\_\_

Name of Company: \_\_\_\_\_

Representative Name: (Print) \_\_\_\_\_

Reason for Records: \_\_\_\_\_

We are furnishing you and your Company with Patient Confidential Information. Use of Private Patient Information must meet the guidelines of The Health Insurance Portability and Accountability Act (HIPAA).

I (We) understand the information provided is subject to federal privacy regulations (HIPAA 1996 and codified at 45 C.F.R. parts 160 and 164—the Privacy Rule). The purpose of this agreement is to enter into compliance with the Privacy Rule. The information released to you/your company may be used for collection or audit of records, insurance, research, or legal purposes. IT IS YOUR RESPONSIBILITY TO KEEP THESE RECORDS PRIVATE. THE INTENDED PURPOSE IS EXCLUSIVELY AS NOTED ABOVE.

I (We) agree to appropriate safeguards to prevent use or disclosure of the Protected Health Information. All subcontractors and agents that receive the information must agree to the same restrictions.

I am in agreement with the stipulations.

Sincerely,

\_\_\_\_\_  
Representative/Company: \_\_\_\_\_

**Figure 66-1 Business Associate Agreement.**

Specify the type of information that may be accessed, which may include the following:

- History and physical examination information
- Progress notes
- Orders
- Medication sheets
- Phone calls
- E-mails related to the patient
- Medical transcription

List who may receive information and state the purpose, such as a claims processor and/or billing and collection personnel.

Educate office personnel with regard to HIPAA rules and regulations.

Do not leave the photocopier unattended when making a copy of information covered under the protected health information.

Confirm information regarding fax number before sending. Include a cover sheet stating that this is confidential information. Verify that the fax was received.

Develop a plan to monitor implementation and compliance in the practice.

Office redesign is not necessary, but privacy protection must include segregating or locking file cabinets or using a password to gain access to patient information in the case of electronically recorded medical records.

The individual in charge must decide on a case-by-case basis regarding provision of protected information to an individual or corporation. Then only the Minimum Necessary Information may be supplied.

#### **Retention of Records**

All medical records must be retained for a minimum of 6 years to comply with HIPAA regulations.

#### **Release of Protected Information**

To release protected health information when it is not being used for health care-related reasons, (e.g., treatment, payment), proceed as follows.

The following information must be recorded:

- Patient's name
- Reason for requesting information
- Name, agency to receive the information
- Name of practice providing the information
- Patient's consent to release the information, including his or her signature
- Provision of minimal but appropriate amount of information

#### **Research**

If patient information is planned to be used in research, the patient must supply specific consent. This would also hold true for retrospective studies.

#### **Minors**

Minors may provide their own authorization for contraception, pregnancy-related care, venereal disease evaluation and treatment, or other reportable medical conditions.

#### **Posting of Notice of Privacy**

The Notice of Privacy Practices (Fig. 66-2) is to be displayed in an area that patients have ready access to. The waiting room is the ideal location for listing of such information.

#### **Patient Aspect**

Patients are to receive the Notice of Privacy Practices document for their signature. If the practice chooses to communicate via e-mail, a separate consent form should be obtained (Figs. 66-3 and 66-4).

Patients may review their medical records, but a request should be obtained in writing. Ideally it should state the reason the request is being made. Patients may be denied access if the record provides information related to psychotherapy or court proceedings, or if the health care provider makes a judgment call regarding information "not in the patient's best interest" (i.e., knowledge of the information could result in life-threatening circumstances).

Sale of a patient list, as, for example, to a pharmaceutical company is not permitted by HIPAA regulations.

#### **Discussions with Other Health Care Professionals**

Such discussion is permitted, but discretion is advised.

In semiprivate locations appropriate judgment is recommended (e.g., close the curtain, ask family members to step out of the room, be discreet in discussions outside of the patient's room).

#### **Violations of HIPAA**

Violations of HIPAA can result in both civil and criminal penalties. Civil penalties of \$100 per violation, with a cap up to \$25,000 in 1 year, can be imposed. In addition criminal penalties ranging from \$50,000 to \$250,000 as well as imprisonment for up to 10 years can be imposed. Enforcement of HIPAA regulations is under the jurisdiction of the U.S. Department of Health and Human Services, Office for Civil Rights.

#### **Reporting of Complaints**

The Secretary of the U.S. Department of Health and Human Services may be contacted directly.

You are referred to the U.S. Department of Health and Human Services for further information.

HIPAA Federal regulations information can be accessed at:

<http://aspe.hhs.gov/admnsimp/final/PvcTxt01.htm>

The Office for Civil Rights document regarding HIPAA can be accessed at:

<http://www.hhs.gov/ocr/hipaa/privacy.html>

#### **CLINICAL LABORATORY IMPROVEMENT AMENDMENTS OF 1988**

In 1988, Congress passed the Clinical Laboratory Improvement Amendments (CLIA) Act. The initial motivation was to standardize all laboratory testing. One impetus for this amendment was to ensure quality assurance on tests performed for diagnosis, prevention, and treatment. This need was demonstrated in the latter part of 1980, when medical organizations and the media highlighted concerns about "Pap smear mills" with questionably reproducible results. Under CLIA, all laboratories

## HIPAA PRIVACY AWARENESS

**The Health Insurance Portability and Accountability Act (HIPAA) is Federal Legislation concerning the following areas:**

**Insurance  
Administrative Activities  
Privacy and Security**

- There is limited access to your medical records in your office.**
- The appropriate Minimal Information is provided for billing purposes.**
- Your Protected Health Information includes your Name-Address-Social Security Number-Medical Record Number-Date of Birth and Medical Record.**
- Any concerns you have about Violation of HIPAA Privacy can be directed to the United States Department of Health and Human Services, Office for Civil Rights.**

Figure 66-2 Notice of Privacy Practices.

performing analysis on human specimens must be certified by the Secretary of the U.S. Department of Health and Human Services (HHS).

Presently more than 40 tests have been approved for a Certificate of Waiver through CLIA (<http://www.fda.gov/cdrh/clia>). CLIA Laboratory Certification as well as Certificates of Waiver are certified by the U.S. Secretary of HHS, the Centers for Disease Control and Prevention (CDC), and the Food and Drug

Administration (FDA). CMS (the Centers for Medicare and Medicaid Services) administers CLIA certification for the HHS Secretary. To qualify for a Certificate of Waiver, it is imperative that the FDA and CDC deem a laboratory test simple enough that the risk of erroneous results is minimal. An example would be the use of urine pregnancy tests in the office setting. The complete list of CLIA waived procedures as well as manufacturers is located at <http://www.cms.hhs.gov/clia/waivetbl.pdf>.

## PATIENT HIPAA AWARENESS DOCUMENT

The Health Insurance Portability and Accountability Act (HIPAA) is Federal legislation designed to protect the privacy of your health care information. Every effort is made to protect your privacy and the information regarding your medical care.

This means access to your medical records is restricted to those directly involved in your medical care. The minimum appropriate information is provided to individuals involved with billing. We are careful to be discrete and confidential so that others do not hear when talking to you about your medical care. Our workforce is educated with regard to HIPAA and the implementation of it. Privacy and Security are an integral part of how we deal with your medical record.

I consent to obtain notification of visits via mail or other means.

If you request additional information regarding guidelines for release of Protected Health Information, it can be obtained from my health care professional.

NAME: \_\_\_\_\_  
DATE: \_\_\_\_\_

SIGNATURE: \_\_\_\_\_

Figure 66-3 Patient HIPAA Awareness Document.

Currently waived analytes used in laboratory test systems waived laboratories are shown in Figure 66-5 and at <http://www.accessdata.fda.gov/scripts/cdrh/cfdocs/cfClia/analyteswaived.cfm>. The complete list of CLIA-waived procedures as well as manufacturers is located at <http://www.cms.hhs.gov/clia/waivetbl.pdf>. To obtain a CLIA Certificate of Waiver one must complete the form CMS 116, which can be obtained at <http://www.cms.hhs.gov/forms/cms116.pdf>.

In addition to CLIA Certificate of Waivers, it is imperative that obstetricians and gynecologists also apply for the Provider-Performed Microscopy Procedure (PPMP) Laboratory Certification. The PPMP certificate permits a laboratory to have physicians, midlevel practitioners, or dentists perform moderately

complex tests utilizing a microscope. The certificate permits the laboratory to also perform waived tests (Fig. 66-6).

### Quality Problems in Laboratories

Since the inception of the Certificate of Waiver in 1992, as the number of waived tests has grown, the number of Certificate of Waiver laboratories has grown, from 20% to 55% of the total 174,504 laboratories enrolled. In addition, PPMP laboratories make up 22% of all laboratories; this results in a total of 77% of laboratories not having any oversight. These led to a desire to examine the safety of laboratories.

In 2000–2001 several pilot studies were performed to evaluate CLIA Certificate of Waiver and PPMP laboratories. The

**E-MAIL CONSENT FORM**

NAME: \_\_\_\_\_

ADDRESS: \_\_\_\_\_

TELEPHONE NUMBER: \_\_\_\_\_

E-MAIL ADDRESS: \_\_\_\_\_

DATE OF BIRTH: \_\_\_\_\_

I consent to use of e-mail for communication regarding my health care.

I am aware of the Patient Privacy Protected Health Information (HIPAA—Health Insurance Portability and Accountability Act).

I agree to provide my **full name and date of birth with each e-mail** communication for proper identification.

I will clearly **state the reason for the e-mail**:

- Medical question
- Medication question
- Billing question
- Request for appointment

I understand the Internet may not always be secure and thus an unauthorized party may inadvertently obtain information regarding my medical care.

I understand there is no guarantee of privacy but that every effort will be made to protect the privacy of my health care information.

I understand that if it is permitted and I receive information regarding my health care at my place of employment, it may not be as secure compared to my home e-mail.

I agree to use of information regarding my medical record for purposes of reimbursement from insurance-related third parties.

I agree not to use e-mail as the method of communication for an emergency circumstance.

I agree to contact the practice directly if my e-mail is not responded to in a timely manner.

I consent to having a copy of my e-mails incorporated into my medical record.

Any changes in my e-mail address will be conveyed in a timely manner.

I may revoke my consent to communication via e-mail by providing a written statement requesting such.

I agree that no liability on the part of this practice will ensue for anyone inadvertently receiving my e-mail information.

I fully understand the information provided in this consent form and have had all questions answered.

### List of PPMP Procedures

**Q0111**—Wet mounts, including preparations of vaginal, cervical, or skin specimens

**Q0112**—All potassium hydroxide (KOH) preparations

**Q0113**—Pinworm examinations

**Q0114**—Fern test

**Q0115**—Postcoital direct, qualitative examinations of vaginal or cervical mucus

**81015**—Urinalysis; microscopic only

**81000**—Urinalysis, by dipstick or tablet reagent for bilirubin, glucose, hemoglobin, ketones, leukocytes, nitrite, pH, protein, specific gravity, urobilinogen, any number of these constituents; nonautomated, with microscopy

**81001**—Urinalysis, by dipstick or tablet reagent for bilirubin, glucose, hemoglobin, ketones, leukocytes, nitrite, pH, protein, specific gravity, urobilinogen, any number of these constituents; automated, with microscopy (NOTE: May only be used when the laboratory is using an automated dipstick urinalysis instrument approved as waived.)

**81020**—Urinalysis; two or three glass test

**89055**—Fecal leukocyte examination (effective 1 January 2004)

**G0027**—Semen analysis; presence and/or motility of sperm, excluding Huhner

**89190**—Nasal smears for eosinophils

**Figure 66-6 List of PPMP procedures.** (<http://www.cms.hhs.gov/clia/ppmplst.asp>)

following were the results of this pilot study, which examined laboratories in 10 states (Certificate of Waiver laboratories and PPMP laboratories were considered separately):

Quality problems in waived laboratories included the following:

- 32% failed to have current manufacturer's instructions on hand
- 32% didn't perform quality control as required by manufacturer or the CDC
- 16% failed to follow current manufacturer's instructions
- 7% did not perform calibration as required by manufacturer
- 23% had certificate issues (i.e., change of name, director, or address)
- 20% cut occult blood cards and urine dipsticks
- 19% had personnel who were neither trained nor evaluated
- 49% did not follow manufacturer's storage and handling instructions
- 56% were using expired reagents/kits

Quality problems in PPMP laboratories included the following:

- 38% had no quality control (did not evaluate test accuracy 2 times a year)
- 36% had no microscope/centrifuge maintenance
- 28% had no director-approved standard-operating procedure manual
- 25% did not document personnel competency (QA)
- 23% had certificate issues

#### Recommendations

It was felt that in 2002 CMS should have the ability to perform independent inspections of these laboratories (<http://www.cms.hhs.gov/clia/ppmpfr2001.pdf>). On completion of the pilot studies, the following recommendations were made:

- To provide educational programs for all waived laboratories
- For all Certificate of Waiver and PPMP laboratory staff to take educational programs

### **SELF-ASSESSMENT CHECKLIST FOR THE PHYSICIAN'S OFFICE EXEMPT LAB**

Laboratory Name \_\_\_\_\_ Address \_\_\_\_\_  
 Physician/Director \_\_\_\_\_ Lab Contact \_\_\_\_\_ Phone \_\_\_\_\_  
 Tests \_\_\_\_\_

CLIA certificate type: Waiver, PPMP, Compliance, or Accreditation \_\_\_\_\_ and # 29D \_\_\_\_\_

Current State of Nevada Physician's License \_\_\_\_\_

**1. NAC 652.155 (1) THIS PROVISION ONLY APPLIES TO A PHYSICIAN PERFORMING ALL OF THE TESTS – WITHOUT ASSISTANCE – ON HIS OWN PATIENTS.**

Does a Nevada State licensed physician perform and read 100 % of the test (s)?

If "No", proceed below. If "Yes", the rest of the regulations do not apply.

**2. NAC 652.155 (2)(a) APPLIES TO ASSISTANTS PERFORMING WAIVED TESTING FOR A PHYSICIAN'S PRACTICE.**

Are office personnel (other than the physician) performing CLIA Waived tests **only**– for the physician or associates of the physician's private practice? If "Yes", proceed to NAC 652.155 (2)(b).

**Note:** The answer is "No" if an APN or a PA is performing microscopic procedure for KOH and Wet Prep, or if one or more office personnel (other than the physician) is performing non-CLIA waived test, such as tests defined by CLIA as moderate or high complexity tests. The facility needs to apply for a Registered Lab and will not qualify as an Exempt Lab.

**3. NAC 652.155 (2)(b)(1) THE LAB DIRECTOR OR DESIGNEE VERIFIES THAT THE PERSON IS COMPETENT TO PERFORM TESTING**

Documented training for each test performed in the office (*training and competency assessment of all testing personnel for all tests performed must be documented and signed by the lab director or designee*).

**4. NAC 652.155 (2)(b)(2) ENSURES THAT TESTS ARE PERFORMED ACCORDING TO MANUFACTURER'S INSTRUCTIONS**

Step by step procedures are followed. Written procedures available at *bench* (*test manufacturer's package inserts are acceptable*).

Proper storage of reagents/kits: temperatures monitored, maintained and documented room \_\_\_\_\_ refrigerator \_\_\_\_\_ (*daily temperature monitoring logs maintained*)

Expiration dates not exceeded or modified upon opening, when applicable (*No expired reagents/supplies in-use with in-use date noted on the vial or log, or expired modified on the vial or log*)

**5. NAC 652.155 (2)(b)(3) CONTROLS USED FOR VALIDATION AND VERIFICATION**

Positive and negative controls for each day of use (*2 levels of external or internal controls, performed and documented each day of testing, or used per manufacturer's directions*)

**6. SAFETY NAC 652.155 (3)(a) SAFETY CONTROLS**

Written policy prohibits eating, drinking, smoking and storage of food in lab area (*Universal Precautions policies and procedures developed and enforced*)

Proper disposal of bio-hazardous waste

Sharps container appropriate

Eye wash available (*portable or fixed eyewash station*)

Adequate ventilation, temperatures controlled

Proper disinfection of lab areas

**7. NAC 652.155 (3)(b) CERTIFIED OR LICENSED BY STATE AS OFFICE LABORATORY ASSISTANT**

*All non-physician testing personnel (M.A., LPN, RN, APN, PA, CNA) performing testing, must apply for personnel certification as an office laboratory assistant.*

**REVIEW BY DIRECTOR**

Training \_\_\_\_\_ Safety Policy \_\_\_\_\_ Written Procedures/Product Package Inserts \_\_\_\_\_ Control logs \_\_\_\_\_

**This is intended to be used as a tool and is not intended to replace any regulation in  
NAC 652 – Medical Laboratories**

- To survey a percentage of Certificate of Waiver and PPMP laboratories annually
- To develop self-assessment tools for PPMP laboratories
- To provide appropriate information of CLIA requirements to new Certificate of Waiver and PPMP laboratories

Although testing is not mandatory, it is imperative that the directors of the Certificate of Wavier and PPMP laboratories

ensure that all of the clinicians performing these tests have been appropriately tested and evaluated for competency. As a result of the preceding pilot data, CMS will inspect approximately 2% of Certificate of Wavier laboratories. The purpose will be to provide education to Certificate of Wavier laboratories and improve quality of care. Several states have recommended self-assessments for Certificate of Waiver and PPMP laboratories. Figure 66-7 is a copy of the self-assessment checklist for physician offices in the State of Nevada.

# Index

Note: Page numbers followed by f indicate figures; those followed by t indicate tables.

- A**
- Abacavir, for HIV, 299
  - Abdominal examination, in urogynecologic workup, 377–378
  - Abdominal myomectomy, 199
  - Abdominal pain, in adolescents, 505–508, 507t
  - Abdominal pregnancy, 206t, 215–216, 215f, 215t
  - Abdominal pressure (Pabd), 382, 384f, 394f–400f
    - during voiding, 408f–410f
  - Abdominal wall metastases, after laparoscopy, 564
  - Abdominal wall pain, due to endometriosis, 163
  - Abdominal wall tenderness test, for chronic pelvic pain, 48
  - Abdominopelvic surgery, chronic pelvic pain due to, 44
  - Abnormal uterine bleeding (AUB), 91–96
    - causes of, 91–93, 92t
    - clinical features of, 91–93, 92t
    - diagnosis of, 93–94, 93f, 93t
    - due to endometrial carcinoma, 667
    - due to endometriosis, 162–163
    - epidemiology of, 91
    - hysteroscopic endometrial ablation for, 580–581
  - key points on, 91
  - and leiomyomas, 180, 181t, 184–185
  - with oral contraceptives, 837
  - in perimenopause, 880–884
    - algorithm for management of, 881–882, 883f
    - endometrial ablation for, 884
    - etiology of, 880, 880t
    - evaluation of, 880–882, 880t, 881t, 882f
    - hysterectomy for, 884
    - intrauterine systems for, 884
    - oral contraceptives for, 882–883, 882t
      - other benefits of, 884–886, 884t–886t, 885f
      - progestin therapy for, 883, 884t
    - treatment of, 94–96, 94t
  - Abortion
    - antimicrobial prophylaxis for, 236t
    - endometritis after, chlamydia and, 266
- Abscess(es)**
- Bartholin's gland, 252, 252t, 253f
  - labial, 250, 251f
  - pelvic
    - laparoscopy for, 551–552
    - postoperative, 315
    - due to surgical site infection, 323
    - tubo-ovarian
      - laparoscopy for, 552
      - in PID, 286–289, 289f–291f, 289t, 290–291, 291t
- Abstinence, for adolescents, 503**
- Abstinence syndrome, 57**
- Abuse. *See* Domestic violence.**
- Abuse Assessment Screen, 81, 81t**
- AC (doxorubicin [Adriamycin] and cyclophosphamide) regimen, for breast cancer, 602, 602t**
- Acanthosis nigricans, in polycystic ovary syndrome, 899**
- Accelerated partial breast irradiation, 601**
- Accessory mammary glands, 607**
- Accessory nipples, 607**
- Accidents**
- household and recreational, counseling on, 104–105, 105t
  - motor vehicle, 105, 105t
- Acetic acid, for colposcopy, 146–147, 146f–150f, 156**
- after menopause, 154–155, 155f
- Acetowhite epithelium, in colposcopy, 146–147, 146f–150f, 153f, 154f, 156**
- ACMI fluid monitoring system, 540f**
- ACMI hysteroscopic fluid management system, 540f**
- Acne, oral contraceptives for, 836**
- Acne inverse, 250–252, 251t**
- ACOG (American College of Obstetricians and Gynecologists)**
- breast cancer screening guidelines of, 612t
  - cervical cancer screening guidelines of, 652t
- Acquired immunodeficiency syndrome (AIDS). *See* Human immunodeficiency virus (HIV).**
- Acromegaly, infertility due to, 754, 759**
- Acrosome reaction test, 787**
- ACTH. *See* Adrenocorticotrophic hormone (ACTH).**
- Actinomycin D (dactinomycin)**
- for hydatidiform mole, 715
  - for malignant gestational trophoblastic disease, 722, 722t, 723, 723t
- ACTION (Adjuvant ChemoTherapy in Ovarian Neoplasm) trial, 703–704, 704t**
- Actiq (fentanyl)**
- for cancer pain, 733, 733t, 734
  - for chronic pelvic pain, 58t
- Activin**
- in menstrual cycle, 851
  - in puberty, 449
- Actonel (risedronate), for osteoporosis, 12, 13, 13t, 14f, 15f**
- Acute urethral syndrome, due to chlamydia, 265–266**
- Acyclovir, for genital herpes, 275–276, 276t**
- Addiction, 57, 730**
- pseudo-, 730
- Addison, Thomas, 917, 918t, 928**
- Addisonian crisis, 929–930, 930t, 931, 931t**
- Addison's disease**
- causes of, 928–929, 928t, 929t
  - clinical features of, 929–930, 930t
  - diagnosis of, 930–931
  - treatment of, 931–932, 931t, 932t
  - tuberculous, 928–929, 931
- Adenocarcinoma**
- of Bartholin's gland, 642
  - of vagina, 647–648
- Adenocarcinoma in situ (AIS), endocervical, 135–136**
- Adenoma(s)**
- adrenal
    - Cushing's syndrome due to, 923–924, 927
    - precocious puberty due to, 457
  - pituitary
    - Cushing's syndrome due to, 927
    - hyperprolactinemia due to, 805–807, 806f
    - male infertility due to, 780–781
- Adenomyomata, 573, 575f**
- Adenomyosis**
- chronic pelvic pain due to, 50t
  - menometrorrhagia due to, 91–92, 94, 96
- Adenosarcoma, uterine, 680, 680f, 681f**
- Adhesiolysis, 56, 522**
- hysteroscopic, complications of, 595t

- Adhesiolysis (*Cont.*)  
 laparoscopic, 549–550  
 complications of, 594t
- Adhesions  
 intracervical, due to hysteroscopy, 593  
 intrauterine  
   hysteroscopic lysis of, 578  
   due to hysteroscopy, 593  
   recurrent pregnancy loss due to, 799  
   secondary amenorrhea and, 819f, 827  
 labial, in pediatric patients, 489, 489f  
 pelvic  
   chronic pelvic pain due to, 53–54, 56  
     in adolescents, 522  
   formation of, 549–550  
   infertility due to, 752  
   due to PID, 286, 286f, 290
- ADJUVANT, 599
- Adjuvant ChemoTherapy in Ovarian Neoplasm (ACTION) trial, 703–704, 704t
- Adnexal mass, laparoscopy for, 554–555
- Adolescent(s), 481–509  
 chronic pelvic pain in, 519–525  
 behavioral component of, 519  
 differential diagnosis of, 520t, 521t, 522  
 history and physical examination for, 522, 523f–525f  
 pathophysiology of, 520–522, 520t, 521t  
 treatment of, 522  
 contraception for, 502–505, 502t, 503t, 505t–507t, 834  
 dysmenorrhea in, 505–508, 507t  
 endometriosis in  
   chronic pelvic pain due to, 521–522  
   diagnosis of, 165–166, 165f, 166f, 508  
   508f  
   treatment of, 508, 509f  
 gynecologic examination in, 485–488  
   confidentiality of, 488, 489f, 495f  
   pelvic, 485–488, 485t  
   screening questionnaire and record of, 488, 489f–495f  
   speculum for, 488, 496f  
 hirsutism in, 499–502, 500t, 501f  
 polycystic ovary syndrome in, 900  
 STDs in, 259
- Adrenal adenomas  
 Cushing's syndrome due to, 923–924, 972  
 precocious puberty due to, 457
- Adrenal androgen(s), secretion of, 920
- Adrenal androgen replacement therapy, for adrenal insufficiency, 932
- Adrenal carcinoma  
 Cushing's syndrome due to, 923–924, 927  
 precocious puberty due to, 457
- Adrenal cortical hormones, 917
- Adrenal crisis, 929–930, 930t, 931, 931t
- Adrenal disorder(s), 917–935  
 congenital adrenal hyperplasia as, 932–935, 933t  
 Cushing's disease as, 922, 923  
 Cushing's syndrome as, 922–928

 and leiomyomas, 179  
 and miscarriage, 754  
 and oocyte aneuploidy, 889  
 and ovarian reserve, 888  
 preconception counseling due to, 113, 114t  
 and urinary incontinence, 38, 38t, 41, 342–343  
 and venous thromboembolism, 868, 868t
- Aging, physiology of, 37–38, 38t, 39t
- AIDS (acquired immunodeficiency syndrome). *See* Human immunodeficiency virus (HIV).
- Air embolism, due to hysteroscopy, 593, 593t
- AIS (adenocarcinoma in situ), endocervical, 135–136
- AJCC (American Joint Committee on Cancer), 598, 599t, 641
- Akt gene, 745t
- Albumin, and ovarian hyperstimulation syndrome, 775

- Alcohol abuse  
counseling on, 103, 104t  
pseudo-Cushing's syndrome due to, 924
- Alcohol consumption  
during pregnancy, 118, 118t  
and recurrent pregnancy loss, 800
- Alcohol Use Disorders Identification Test (AUDIT), 103
- Aldara (imiquimod)  
for condyloma acuminatum, 281, 281t, 311  
for vulvar disorders, 222
- Aldosterone  
biosynthesis of, 919f  
secretion of, 919, 920
- Aldosterone synthetase, in steroidogenesis, 918t
- Aldosterone synthetase deficiency, 933t
- Alendronate (Fosamax), for osteoporosis, 12, 13, 13t, 14f, 15f
- Alesse (levonorgestrel/ethynodiol), for emergency contraception, 505t
- Alkalosis, hypokalemic, in Cushing's syndrome, 923, 925
- Allergic contact dermatitis, of vulva, 224
- Alloimmune factors, recurrent pregnancy loss due to, 799–800
- Allopregnanolone, in premenstrual syndrome/premenstrual dysphoric disorder, 20
- ALND (axillary lymph node dissection), 600
- Alpha-thalassemia, 115
- Alprazolam, for premenstrual syndrome/premenstrual dysphoric disorder, 25t, 30
- Alternative medicine, 71–77  
black cohosh as, 76, 76f  
chasteberry as, 72  
for chronic pelvic pain, 58–59  
dong quai as, 73  
evening primrose oil as, 72–73  
ginkgo as, 73  
phytoestrogens as, 73–76, 73f–75f, 74t  
and preoperative care, 77, 77t  
St. John's wort as, 71–72, 72f  
wild yam as, 76, 76f
- ALTS (ASC-US/LSIL Triage Study), 133–134, 151
- Alzheimer's disease, hormone therapy for, 868
- Ambulatory urodynamic testing, 385, 407
- Amenorrhea  
functional hypothalamic, 846  
primary, 476–477  
differential diagnosis of, 473f  
laboratory evaluation of, 476–477  
management of, 477–478  
secondary, 815–828, 816t  
due to adrenal tumor, 821, 826  
due to anorexia nervosa, 817
- Amenorrhea (*Cont.*)  
secondary (*cont.*)  
due to Asherman's syndrome, 827  
bone health with, 827  
due to cervical stenosis, 827  
classification of, 815, 816t  
clinical features of, 816–818  
due to congenital adrenal hyperplasia, 826  
due to Cushing's syndrome, 821–822, 826  
diagnosis of, 818–822, 818f–821f, 820t  
due to endometrial atrophy, 826–827  
due to endometritis, 827  
epidemiology of, 816  
etiology of, 815, 816, 817t  
due to hypergonadotropic hypoestrogenism, 823–824  
due to hyperprolactinemia, 804, 820–821, 821f, 824  
hypoestrogenic, 819f, 827  
hypothalamic, 817t, 822–823

due to chronic pelvic pain syndrome, 54, 54t  
clinical features of, 45–46  
depression and, 47, 54  
diagnosis of, 46–50  
diagnostic tests in, 50, 50t  
history in, 46–48  
laparoscopy in, 50, 59  
McGill Pain Questionnaire in, 47–48, 47t  
pain mapping in, 46, 46f, 48  
pain scales in, 46–47, 47f  
physical examination in, 46, 48–50, 48t, 49t  
disorders associated with, 44, 45t  
dyspareunia with, 45, 50t, 53
- Chronic pelvic pain (CPP) (*Cont.*)  
due to endometriosis, 43, 161–162  
in adolescents, 521–522  
diagnosis of, 50t, 52–53  
treatment of, 54–55  
epidemiology of, 43  
due to interstitial cystitis  
diagnosis of, 50t, 51, 51f, 52f  
treatment of, 55  
due to irritable bowel syndrome, 521t, 522  
diagnosis of, 50–51, 50t  
treatment of, 55–56  
due to leiomyomas, 185–186  
pathogenesis of, 44, 44t, 45t  
due to pelvic congestion syndrome, 50t, 53, 53f  
due to pelvic inflammatory disease, 43, 53  
risk factors for, 43–44  
treatment of, 54–59  
alternative or complementary, 58–59  
disease-specific, 54–56  
pain-specific, 56–58, 57t, 58t
- Chronic pelvic pain syndrome, 54, 54t
- Cigarette smoking  
counseling on, 102–103, 103t  
and ectopic pregnancy, 207  
and high-grade squamous intraepithelial lesions, 152  
and leiomyomas, 182  
passive, 102  
during pregnancy, 118  
and recurrent pregnancy loss, 800  
and urinary incontinence, 335
- Cimetidine, for hirsutism, 906
- Cimicifuga racemosa*, for premenstrual syndrome/premenstrual dysphoric disorder, 22t, 24
- Cimicifuga racemosa* rhizome, 76
- CIN. *See* Cervical intraepithelial neoplasia (CIN).
- CIOMS (Council for International Organizations of Medical Sciences), 871
- Ciprofloxacin  
for chancroid, 272t  
for donovanosis, 274  
for gonorrhea, 263t  
for pediatric vulvovaginitis, 497t
- Circular pattern, of breast palpation, 615, 615f
- Cisapride, for irritable bowel syndrome, 56
- Cisplatin (Platinol)  
adriamycin, cyclophosphamide (PAC)  
regimen, for fallopian tube carcinoma, 694  
for cervical cancer, 660, 661–662  
for endometrial carcinoma, 672  
etoposide, cyclophosphamide (PEC)  
regimen, for fallopian tube carcinoma, 694  
for fallopian tube carcinoma, 694

- Cisplatin (Platinol) (*Cont.*)  
 for malignant gestational trophoblastic disease, 723  
 for ovarian carcinoma, 704, 706, 707, 707t  
 for uterine sarcomas, 683  
 vinblastine, bleomycin (PVB) regimen, for malignant gestational trophoblastic disease, 723
- Citalopram, for premenstrual syndrome/premenstrual dysphoric disorder, 25t, 26, 28t
- Citrovorum factor  
 for ectopic pregnancy, 212, 212t  
 for malignant gestational trophoblastic disease, 723
- Clarithromycin, for pediatric vulvovaginitis, 497t
- Claus model, for breast cancer risk assessment, 610, 611
- Clear cell carcinoma(s)  
 of endometrium, 665  
 of vagina, 647
- Cleveland Clinic Incontinence Score, 356t
- CLIA (Clinical Laboratory Improvement Amendments) Act, 943–951, 947f–950f
- Clindamycin  
 for necrotizing fasciitis, 256  
 for PID, 289t  
 for postoperative infection, 319t, 320t, 323, 323t  
 in septic patient, 322t  
 for tubo-ovarian abscess, 289t, 291t
- Clinical breast examination (CBE), 614–616, 615f, 616f
- Clinical Laboratory Improvement Amendments (CLIA) Act, 943–951, 947f–950f
- Clips, for laparoscopic suturing, 533
- Clitoral therapy device (CTD), 68
- Clitoris, during puberty, 451t
- Clobetasol propionate, for lichen sclerosus, 227
- Clock face orientation, 485, 487f
- Clodronate, for cancer pain, 736
- Clomiphene citrate (CC, Clomid)  
 for female infertility, 760, 761, 825  
 for in vitro fertilization, 770, 770t  
 for male infertility, 792  
 for polycystic ovary syndrome, 902, 904, 905
- Clomiphene citrate challenge test (CCCT), 706–707  
 for in vitro fertilization, 769
- Clomipramine, for premenstrual syndrome/premenstrual dysphoric disorder, 25t
- Clonidine, for cancer pain, 732
- Clostridium difficile*, pseudomembranous colitis due to, 235
- Clotrimazole, for candidiasis, 255t
- CMF (cyclophosphamide, methotrexate, and fluorouracil) regimen, for breast cancer, 602, 602t
- CMS (Centers for Medicare and Medicaid Services), 944, 949
- c-myc* oncogene, 745t, 746
- CNBSS (Canadian National Breast Screening Study), 617
- CNS (central nervous system), with aging, 38
- CNS (central nervous system) tumor, precocious puberty due to, 455–456
- CO<sub>2</sub>. *See* Carbon dioxide (CO<sub>2</sub>)
- CO<sub>2</sub> laser vaporization, for cervical intraepithelial neoplasia, 138
- Coagulation disorders, menometrorrhagia due to, 92, 94, 95, 240
- Cocaine abuse, 104
- Coccodynia, 49
- Coccygeal muscle, 329, 330f
- Codeine  
 for cancer pain, 733  
 for chronic pelvic pain, 58t
- Coding, 937–939
- Coding Alert, 939
- Coding Institute, 939
- Coffee, during pregnancy, 118
- Cognition, in menopause, 861, 868
- Cognitive behavioral therapy (CBT), for premenstrual syndrome/premenstrual dysphoric disorder, 22t, 23
- Cognitive theories, of chronic pelvic pain, 520
- Cold knife cone, 156
- Cold knife conization, for cervical intraepithelial neoplasia, 138
- Colitis  
 pseudomembranous, due to antimicrobial prophylaxis, 235  
 ulcerative, chronic pelvic pain due to, 521t
- Collaborative Group on Hormonal Factors in Breast Cancer (CGHBC), 869
- Colon, endometriosis of, 169f, 175
- Colorectal cancer  
 hormone therapy and, 870  
 oral contraceptives and, 836
- Colporrhaphy  
 anterior, for urinary incontinence, 347  
 antimicrobial prophylaxis for, 236t
- Colposcope, 146, 146f, 156
- Colposcopy, 145–157  
 accuracy of, 145  
 acetic acid for, 146–147, 146f–150f, 156  
 after menopause, 154–155, 155f  
 assessment systems for, 149–150, 149t, 150f, 151t  
 of atypical vessels, 149, 153, 153f  
 of cervical cancer, 134, 153, 153f  
 challenges in, 155, 155f
- Colposcopy (*Cont.*)  
 after DES in utero exposure, 155  
 green filter for, 146, 146f  
 indications for, 145–146  
 with infection, 155, 155f  
 of internal border, 148–149  
 key terms for, 156–157  
 of leukoplakia, 146f, 148  
 Lugol's solution for, 147, 148f, 150f, 154  
 management after, 155–156  
 of microinvasive disease, 149, 150f, 153f, 154, 154f  
 of mosaic pattern, 146f, 148f, 149, 154f  
 of postmenopausal cervix, 154–155, 155f  
 postradiation, 155  
 in pregnancy, 153–154, 154f  
 procedure for, 146–149, 146f–149f  
 of punctations, 149, 152, 152f, 154f  
 satisfactory or adequate, 147–148, 148f, 149f, 157  
 of squamocolumnar junction, 147, 148f  
 of squamous intraepithelial lesions  
 high-grade, 147f, 149f, 150f, 152, 152f  
 low-grade, 147f, 150–151, 151f  
 of transformation zone  
 abnormal, 148–149, 156  
 normal, 148, 157  
 of vagina, 643
- Colposuspension, laparoscopic, for urinary incontinence, 349–350
- Comfort measures, for chronic pelvic pain, 59
- Communication, with older women, 39
- Complementary medicine, for chronic pelvic pain, 58–59
- Compliance, bladder (detrusor), 385–386, 386f, 387f
- Compression neuropathy, chronic pelvic pain due to, 50t
- Computed tomography (CT)  
 for Cushing's syndrome, 926  
 of fallopian tube carcinoma, 688, 689f, 690f  
 quantitative, for assessment of bone mass, 6–7  
 for secondary amenorrhea, 819, 820f
- Computer-aided detection, of breast cancer, 622–623, 623f
- Condoms  
 for adolescents, 504, 505t  
 for contraception, 831–832  
 for HIV prevention, 300, 302
- Condyloma acuminatum, 279–281  
 clinical appearance of, 279f, 306–308, 307f, 308f  
 colposcopic appearance of, 151, 151f  
 diagnosis of, 309f  
 treatment of, 281t, 310–311, 310t
- Condyloma latum  
 due to human papillomavirus, 307, 308f  
 due to syphilis, 280

- Condyllox (podofilox), for condyloma acuminatum, 281, 281t, 310
- Cone biopsy. *See* Conization.

 vulvar, 222, 222f, 223f  
**HT**. *See Hormone therapy (HT)*.  
**Human chorionic gonadotropin (hCG)**  
 in ectopic pregnancy, 209  
 with hydatidiform mole, 714, 715–716, 715f  
 and ovarian hyperstimulation syndrome, 775  
 phantom, 716  
 in secondary amenorrhea, 816  
**β-Human chorionic gonadotropin (β-hCG)-producing tumor**, precocious puberty due to, 456t, 457  
**Human immunodeficiency virus (HIV)**, 295–302  
 Addison’s disease with, 928, 929  
 chancroid with, 271  
 clinical manifestations of, 295–296, 300–302  
 condyloma acuminatum with, 280  
 contraception with, 302  
 diagnosis of, 298  
 discordant couples with, 302  
 epidemiology of, 296, 297f, 298t  
 gynecologic surgery with, 301  
 and high-grade squamous intraepithelial lesions, 152  
 and human papillomavirus, 300  
 natural course of, 295–296, 297f  
 Pap test with, 300  
 pathogenesis of, 296  
 prevention of, 299–300  
 risk factors for, 296  
 screening for, 298  
 STDs and, 259  
 syphilis with, 270t  
 transmission of, 296–297, 297f, 298t  
 treatment of, 298–299  
 virology and life cycle of, 295, 296f  
**Human leukocyte antigen (HLA)**, recurrent pregnancy loss due to, 799  
**Human menopausal gonadotropins (Repronex)**, 770  
**Human papillomavirus (HPV)**, 156, 305–313  
 and cervical cancer, 151, 305–306, 309f, 651–652, 653f  
 and cervical intraepithelial neoplasia, 122–125  
 clinical features of, 306–308, 307f, 308f, 308t  
 condyloma acuminatum due to, 279–281  
 diagnosis of, 308–309, 309f  
 DNA testing for, 141  
 education on, 312–313  
 epidemiology of, 305  
 HIV and, 300  
 koilocytosis due to, 150–151, 156  
 life cycle of, 124, 124f  
 natural history of, 122–125, 123f–125f, 312, 313t  
 Pap smear abnormalities due to, 308, 308t  
 pathogenesis of, 305–306, 306f  
 pitfalls and controversies over, 312–313  
 psychosocial issues with, 313  
 risk factors for, 305  
 structure of, 124, 124f  
 T-cell response to, 125  
 treatment of, 309–312, 310t  
 vaccines for, 313  
 virology of, 305, 306, 306f, 651–652, 653f  
 and vulvar cancer, 631–632  
 vulvar infection with, 222  
**Human papillomavirus (HPV) testing**, for atypical squamous cells, 654–655  
**Hunner’s ulcer**, 51  
**Huntington’s** 11, 76  
**Hycodan** (hydrocodone), for chronic pelvic pain, 58t  
**Hydatidiform mole (HM)**, 711–717  
 androgenetic, 712  
 biparental, 712  
 classification of, 711–713, 712t  
 clinical diagnosis of, 714, 714f  
 clinical features of, 713–714, 713t  
 complete  
   clinical features of, 713, 713t  
   diagnosis of, 714, 714f  
   features of, 712t  
   karyotype of, 711–712  
   pathology of, 711, 712f  
 epidemiology of, 711, 712t  
 follow-up of, 715–717, 715f, 717f  
 hyperthyroidism with, 912  
 natural history of, 714  
 partial, 712–714, 712t, 713f, 713t  
 pregnancy after, 716  
 risk factors for, 711, 712t  
 treatment of, 714–715  
 in twin pregnancy, 714  
**Hydergine** (ergoloid mesylates), for hyperprolactinemia, 807t, 810

- Hydradenitis suppurativa, vulvar, 225f
- Hydration, for ovarian hyperstimulation syndrome, 775
- Hydrocodone (Hycodan, Vicodin, Lortab, Lorcet), for chronic pelvic pain, 58t
- Hydrocortisone  
for adrenal insufficiency, 931, 931t, 932t  
for congenital adrenal hyperplasia, 934
- Hydrodistention, of bladder, for interstitial cystitis, 55
- Hydromorphone (Dilaudid)  
for cancer pain, 733, 733t, 734  
for chronic pelvic pain, 58t
- Hydrops tubae profluens, 688
- Hydrosalpinx  
and in vitro fertilization, 768–769  
laparoscopy for, 552–553, 554f  
due to PID, 290
- 11 $\beta$ -Hydroxylase, in steroidogenesis, 918t, 919f
- 11 $\beta$ -Hydroxylase deficiency, 933t, 934  
precocious puberty due to, 457
- 17 $\alpha$ -Hydroxylase deficiency, 933t, 935
- 17 $\alpha$ -Hydroxylase/17,20 lyase, in steroidogenesis, 918t
- 18-Hydroxylase, in steroidogenesis, 919f
- 18-OH-Hydroxylase, in steroidogenesis, 919f
- 21-Hydroxylase, in steroidogenesis, 918t, 919f
- 21-Hydroxylase deficiency, 932, 933t  
diagnosis of, 934  
prenatal, 934  
heterozygote, 934  
late-onset, 933–934  
precocious puberty due to, 457, 461  
salt-wasting form of, 932–933, 933t  
simple virilizing form of, 932, 933t
- 17-Hydroxyprogesterone, in congenital adrenal hyperplasia, 902, 902t
- 3 $\beta$ -Hydroxysteroid dehydrogenase (3 $\beta$ -HSD), in steroidogenesis, 918t, 919f
- 3 $\beta$ -Hydroxysteroid dehydrogenase (3 $\beta$ -HSD) deficiency, 933t, 935
- Hydroxyurea  
for cervical cancer, 658  
for malignant gestational trophoblastic disease, 723
- Hymen, 484, 484f–487f  
annular, 485f  
crescentic, 484f  
fimbriated, 486f  
imperforate, 486f  
injury of, 513, 514  
microporefate, 486f  
during puberty, 451t  
redundant, 485f  
septate, 486f
- Hymenal tag, 487f
- Hyperandrogenism  
amenorrhea due to, 477  
in polycystic ovary syndrome, 895–896
- Hypercalcemia, due to adrenal insufficiency, 930
- Hypercalciuria, idiopathic, 11
- Hypercortisolism. *See* Cushing's syndrome.
- Hyperemesis gravidarum, 912
- Hyperforin, 71
- Hypergonadotropic hypoestrogenism, 823–824
- Hyperhomocysteinemia, recurrent pregnancy loss due to, 800, 800t
- Hypericin, 71
- Hypericum perforatum*, 71–72, 72f  
for premenstrual syndrome/premenstrual dysphoric disorder, 22t, 24
- Hyperkalemia, due to adrenal insufficiency, 930
- Hyperprolactinemia, 803–812  
and bone loss, 804  
causes of, 804–805, 805t  
clinical features of, 804, 804t  
delayed puberty due to, 475  
dysfunctional uterine bleeding due to, 96  
epidemiology of, 803  
evaluation of, 805–807, 806f  
female infertility due to, 753, 761  
female sexual dysfunction in, 62–63  
male infertility due to, 779–780, 788t  
management of, 807–812  
individualized, 810–811  
irradiation in, 810  
medical, 807–811, 807t, 808f, 809f  
duration of, 811–812  
observation in, 807, 811  
surgical, 810
- pathologic, 805, 805t  
pharmacologic, 805, 805t  
physiologic, 805, 805t  
physiology of, 803–804, 804f  
vs. polycystic ovary syndrome, 902, 902t  
and pregnancy, 810–811  
secondary amenorrhea due to, 804, 820–821, 821f, 824
- Hypertension  
in Cushing's syndrome, 923  
and endometrial carcinoma, 666  
pregnancy with, 117  
screening for, 108, 108t
- Hyperthyroidism, 911  
clinical course and progression of, 915  
clinical features of, 913, 913t  
diagnosis of, 913–914  
fetal, 912, 913  
with hydatidiform mole, 715  
incidence of, 911  
infertility due to, 754, 759  
menometrorrhagia due to, 92, 95  
pathology of, 912  
during pregnancy, 914, 916  
screening for, 106–107, 107t  
secondary amenorrhea due to, 824–825
- Hyperthyroidism (*Cont.*)  
thyroid function in, 912t  
treatment of, 914
- Hypoactive sexual desire disorder, 61, 64–65, 65f
- Hypoadrenalinism, 928–932  
causes of, 928–929, 928t, 929t  
clinical features of, 929–930, 930t  
diagnosis of, 930–931  
primary (Addison's disease), 928–929, 928t, 929t  
secondary (ACTH deficiency), 928t, 929, 930  
treatment of, 931–932, 931t, 932t
- Hypoestrogenism, hypergonadotropic, 823–824
- Hypoestrogenic amenorrhea, 819f, 827
- Hypogastric neurolysis, for cancer pain, 731–732, 732f
- Hypogonadotropic hypogonadism  
delayed puberty due to, 475  
male infertility due to, 780–781, 788t  
secondary amenorrhea due to, 817t
- Hypokalemic alkalosis, in Cushing's syndrome, 923, 925
- Hyponatremia  
due to adrenal insufficiency, 930  
related to hysteroscopy, 592–593
- Hypo-osmotic swelling test, 785–787
- Hypophysectomy, transsphenoidal  
for Cushing's syndrome, 927  
partial, 810
- Hypothalamic amenorrhea, 817t, 822–823  
functional, 846
- Hypothalamic anovulation, infertility due to, 753
- Hypothalamic disorders, delayed puberty due to, 470t
- Hypothalamic hamartoma, precocious puberty due to, 455–456, 465t
- Hypothalamic-pituitary-adrenal axis  
suppression, due to corticosteroids, 918, 921, 929
- Hypothalamic-pituitary-gonadal (HPG) axis  
and male factor infertility, 779–780, 780f  
in puberty, 446, 447f, 449, 449t
- Hypothalamus, in menstrual cycle, 815, 843–847, 847f
- Hypothyroidism, 911  
clinical course and progression of, 915  
clinical features of, 913, 913t  
congenital, 911, 912–913, 915–916  
diagnosis of, 913–914  
female infertility due to, 754, 759  
fetal, 912, 913  
incidence of, 911  
male infertility due to, 781  
in newborn, 914  
pathology of, 912–913  
precocious puberty due to, 457–458, 465t

Hypothyroidism (*Cont.*)  
 during pregnancy, 915  
 recurrent pregnancy loss due to, 798  
 risk factors for, 911  
 screening for, 106–107, 107t  
 secondary amenorrhea due to, 820, 824  
 thyroid function in, 912t  
**Hyskon** (dextran 32%), for hysteroscopic surgery, 539t, 540  
 complications of, 593  
**Hysterectomy**  
 for abnormal uterine bleeding, during perimenopause, 884  
 antimicrobial prophylaxis for, 236t  
 for cervical intraepithelial neoplasia, 140  
 demographics of, 558  
 for dysfunctional uterine bleeding, 96  
 for endometrial carcinoma, 670, 672  
 for endometriosis, 54  
 for hydatidiform mole, 715  
 hysteroscopic, 571t  
 indications for, 558  
 laparoscopic, 558–562, 560f, 561f  
   supracervical, 562  
   total, 559–562, 560f, 561f  
   radical, 562  
 laparoscopically assisted vaginal, 558–559  
   radical, 562  
 for leiomyomas, 198, 198t  
 for malignant gestational trophoblastic disease, 721  
 for menorrhagia, 95–96  
 postoperative infection after, 315–317  
 pregnancy after, 216  
 radical  
   for cervical cancer, 657  
   laparoscope-assisted vaginal, 562  
   total laparoscopic, 562  
 tamoxifen and, 572t  
 for tubo-ovarian abscess, 291t  
 and urinary incontinence, 342  
 urogenital fistulas due to, 413–415, 414t, 415t, 417  
 vaginal  
   laparoscope-assisted radical, 562  
   laparoscopically assisted, 558–559  
 vaginal cancer after, 644–645  
**Hysterosalpingography (HSG)**  
 antimicrobial prophylaxis for, 236t  
 of endometrial polyps, 570, 570f  
 for leiomyomas, 189  
 for secondary amenorrhea, 819, 819f  
 for tubal factor infertility, 757  
 for uterine factor infertility, 756, 756f  
**Hysteroscopes**, 569  
 flexible, 537, 538f  
 rigid, 537, 538f, 539f  
**Hysteroscopic hysterectomy**, 571t  
**Hysteroscopic instrumentation**, 537–540  
 availability of, 540  
 distention media for, 538–540, 539t

**Hysteroscopic instrumentation** (*Cont.*)  
 fluid pumps and fluid monitors as, 540, 540f  
 hysteroscopes as  
   flexible, 537, 538f  
   rigid, 537, 538f, 539f  
   rectoscopes as, 537–538, 539f  
**Hysteroscopic myomectomy**, 571–575, 571t, 572f–576f  
**Hysteroscopic polypectomy**, 570–571, 570f, 571f, 571t  
 complications of, 594t, 595t  
**Hysteroscopic sterilization**, 578–580, 579f, 580f  
**Hysteroscopic surgery**, 570–582  
 distention media for, 538–540, 539t  
 complications related to, 591–593, 592f, 592t  
 for endometrial ablation/resection, 580–581  
 for endometrial cancer, 581–582, 581f  
 fluid management system for, 540, 540f, 547, 547f  
 instrument layout for, 547, 547f  
 lights for, 544, 546f  
 for lysis of intrauterine adhesions, 578  
 operating table for, 544, 544f  
 personnel for, 543–544  
 positioning for, 545–546  
 for proximal tubal occlusion, 580  
 for resection/incision of uterine septum, 575–578, 576f, 577f  
 room setup for, 543–547, 544f–547f  
**Hysteroscopy**  
 for abnormal uterine bleeding, during perimenopause, 881  
 complication(s) of, 591–595  
 air embolism as, 593, 593t  
 associated with distention media, 591–593, 592f, 592t  
 associated with entry, 591, 591t  
 bleeding as, 593  
 infection as, 593  
 intrauterine and intracervical adhesions as, 593  
 by patient characteristics, 594, 594t  
 pregnancy-associated, 593–594, 594t  
 procedural and postoperative, 593–594, 593t–595t  
 by procedure, 594, 594t, 595t  
 diagnostic, 569–570  
 for endometrial carcinoma, 667  
 of leiomyomas, 191  
 for uterine factor infertility, 756, 756f  
**Hysterosonography (HSG)**  
 for abnormal uterine bleeding, during perimenopause, 881  
 of endometrial polyps, 570, 570f  
 for in vitro fertilization, 768  
 of leiomyomas, 190, 190f, 571–572, 573f  
**Hysterosonography (HSG)** (*Cont.*)  
 for secondary amenorrhea, 819, 819f  
 for tubal factor infertility, 757  
**I**  
**IARC** (International Agency for Research on Cancer), 130  
**Ibandronate** (Boniva), for osteoporosis, 12–13, 13t  
**IBS**. *See* Irritable bowel syndrome (IBS).

 hysteroscopic endometrial resection for, 581  
 and leiomyomas, 180, 181t, 184–185  
 oral contraceptives for, 95, 836  
 perioperative management of, 240  
 treatment of, 94–96, 94t  
 Menstrual cycle, 843–856  
 anovulatory, 854, 856f  
 endometrium in, 852, 853f–855f

- Menstrual cycle (*Cont.*)  
 estradiol in, 849–850, 850f, 851, 851f  
 follicular phase of, 843, 844f, 847–851,  
 849f–852f  
 FSH and LH in, 844f  
 during follicular phase, 847–851,  
 849f–852f  
 during luteal phase, 852  
 during ovulation, 851  
 release of, 844–847, 847f, 848f  
 variations in, 854  
 GnRH in, 843–847, 844f, 847f  
 hypothalamus in, 843–847, 847f  
 inhibin, activin, and follistatin in, 850–851,  
 851f, 852f  
 insulin-like growth factors in, 851  
 luteal phase of, 843, 844f, 851–852  
 insufficient, 854, 855f  
 normal, 815–816, 856f  
 oocyte in, 843, 845f, 846f  
 ovary in, 849–851, 849f–852f  
 overview of, 843, 844f  
 ovulation in, 843, 844f, 849, 851  
 in perimenopause, 879–880  
 pituitary in, 843, 847–849, 848f  
 in polycystic ovary syndrome, 898, 899f  
 progesterone in, 851, 851f, 852  
 proliferative phase of, 843, 844f, 852,  
 853f, 855f  
 secretory phase of, 843, 844f, 852, 853f,  
 855f  
 variations in, 854–855, 856f
- Menstrual irregularities  
 with HIV, 301  
 and leiomyomas, 180, 181t, 184–185  
 in perimenopause, 879–880  
 in polycystic ovary syndrome, 898, 899f
- Menstrual period, final, 875, 876f
- Menstruation  
 isolated, 466  
 reflux, 160
- Meperidine, for cancer pain, 733t
- Meropenem, for postoperative infection, 320t
- MESA (microsurgical epididymal sperm aspiration), 792, 792f
- Mesterolone, for male infertility, 792
- Metastasis(es)  
 abdominal wall, after laparoscopy, 564  
 of malignant gestational trophoblastic disease, 723, 724f  
 to ovaries, 701  
 to vagina, 643
- Metastatic bone disease, pain due to, 731
- Metastatic breast carcinoma, 603–604, 604t
- Metastatic cervical cancer, 660–662, 661f
- Metastatic choriocarcinoma, 718
- Metastatic endometrial carcinoma, 670, 672
- Metastatic fallopian tube carcinoma, 689
- Metastatic uterine sarcomas, 681, 681f, 682f
- Metformin  
 for dysfunctional uterine bleeding, 96  
 for hirsutism, 502, 906  
 for infertility, 760–761  
 for polycystic ovary syndrome, 903–905  
 with insulin resistance, 825
- Methadone (Dolophine)  
 for cancer pain, 734–735  
 for chronic pelvic pain, 58t
- Methimazole (MTZ), for hyperthyroidism, 914
- Methotrexate (MTX)  
 for breast cancer, 602, 602t  
 for ectopic pregnancy, 212–213, 212t,  
 213t  
 for hydatidiform mole, 715  
 for malignant gestational trophoblastic disease, 721–723, 722t, 723t
- Methotrexate, adriamycin, cyclophosphamide (MAC) regimen, for malignant gestational trophoblastic disease, 722
- Methylphenidate, for cancer pain, 736
- Methylprednisolone  
 for cancer pain, 735  
 potency equivalents for, 921t
- Methyltestosterone, for female sexual dysfunction, 67
- Metronidazole  
 for Bartholin's gland abscess, 252  
 for hidradenitis suppurativa, 251  
 for pediatric vulvovaginitis, 497t  
 for PID, 289, 289t  
 for postoperative infection, 319, 319t,  
 320t, 323, 323t  
 in septic patient, 322t  
 for trichomoniasis, 277, 277t  
 for tubo-ovarian abscess, 289t, 291t
- Metrorrhagia, 91  
 causes of, 91–92, 92t  
 clinical features of, 91–92  
 diagnosis of, 93–94, 93f, 93t  
 physiologic, 91  
 treatment of, 94–96, 94t
- Metyrapone, for Cushing's syndrome, 927
- Metyrapone test, for Cushing's syndrome, 925–926
- MHA-TP (microhemagglutination assay for antibody to *T. pallidum*), 269
- MI. *See* Myocardial infarction (MI).
- Miacalcin (calcitonin), for osteoporosis, 13t,  
 14f, 15, 15f, 866
- Miami pouch reconstruction, 661f
- Miconazole nitrate, for candidiasis, 255t
- Microadenoma, 806
- Microbiologic factors, recurrent pregnancy loss due to, 800, 801t
- Microflora, and postoperative infection, 315–317, 317t
- Microhemagglutination assay for antibody to *T. pallidum* (MHA-TP), 269
- Microsatellite(s), 745
- Microsatellite instability (MSI), 745, 746f
- Microsurgical epididymal sperm aspiration (MESA), 792, 792f
- Mifepristone, for endometriosis, 55
- Migraine headache, with oral contraceptives, 837–838
- Milk letdown, 609
- Milk lines, 607
- Million Women Study, 869
- Mineralocorticoid(s), secretion of, 919–920
- Mineralocorticoid replacement, for adrenal insufficiency, 932, 932t
- Minilaparotomy, retractors for, 534, 535f
- Minimally invasive surgery (MIS). *See also* Hysteroscopic surgery; Laparoscopic surgery  
 setup for, 543–547, 544f–547f
- Mini-mental status examination, 378, 379t
- Minimum necessary rule, 941
- Minipill, 840, 841t
- Minors, confidentiality of, 943
- Mirapex (pramipexole), for hyperprolactinemia, 807t, 810
- Mirena. *See* Levonorgestrel intrauterine contraceptive systems (LN-IUS, Lng-20 IUS, Mirena).
- Mirtazapine, for SSRI-induced sexual dysfunction, 63
- MIS (minimally invasive surgery). *See also* Hysteroscopic surgery; Laparoscopic surgery
- Miscarriage, 797  
 etiology of, 797–800, 799t–801t  
 with leiomyomas, 187, 187t, 189  
 maternal age and, 754  
 recurrent, 797–801  
 clinical course and progression of, 800–801, 801t  
 diagnosis and treatment of, 798–800, 799t–801t  
 pathogenesis of, 797–798  
 primary vs. secondary, 797  
 risk factors for, 797  
 risk of, 797
- Mismatch repair genes, 744–745
- Misoprostol, prior to hysteroscopy, 591
- Mitolactol, for cervical cancer, 661
- Mitotane, for Cushing's syndrome, 927
- Mixed gonadal dysgenesis, male infertility due to, 783
- MLH1 gene, 742t, 744, 744t, 745
- MLH2 gene, 742t, 744, 744t, 745
- MLH3 gene, 742t, 744, 745
- MLH6 gene, 742t, 744, 745
- MMK (Marshall-Marchetti-Krantz) procedure, for urinary incontinence, 347
- MMMTs (malignant mixed mesodermal tumors), of fallopian tubes, 692f

- Molar pregnancy. *See* Hydatidiform mole (HM).
- Mole, invasive, 717
- Molimina, 20
- Molluscum contagiosum, 278–279
- Monistat nitrate, for candidiasis, 255t
- Monitors, for laparoscopic surgery, 527, 528f, 545f
- Monsel's solution, 156–157
- Montgomery tubercles, 608
- Mood change, in menopause, 860–861
- Mood disorders, and cancer pain, 731
- Morbidity, in older women, 38, 38t
- Morcellator, for laparoscopic surgery, 533, 533f
- Morphine (MSIR, MS Contin)
- for cancer pain, 733, 733t, 734
  - for chronic pelvic pain, 58t
- Morphine pump, for cancer pain, 732
- Mortality, in older women, 38, 39t
- Mosaic pattern, 157
- colposcopy of, 146f, 148f, 149, 154f
- Motor vehicle accidents, 105, 105t
- MPA. *See* Medroxyprogesterone acetate (MPA).
- MPC (mucopurulent cervicitis), 264–265, 265f
- in PID, 287, 287f
- MRI. *See* Magnetic resonance imaging (MRI).
- MRV (magnetic resonance venography), of deep venous thrombosis, 238–239
- MS Contin (morphine)
- for cancer pain, 733, 733t, 734
  - for chronic pelvic pain, 58t
- MSI (microsatellite instability), 745, 746f
- MSIR (morphine)
- for cancer pain, 733, 733t, 734
  - for chronic pelvic pain, 58t
- MTX. *See* Methotrexate (MTX).
- MTZ (methimazole), for hyperthyroidism, 914
- Mucolipidosis IV, 115
- Mucopurulent cervicitis (MPC), 264–265, 265f
- in PID, 287, 287f
- MUCP (maximum urethral closure pressure), 401, 403f
- Müllerian duct agenesis, infertility due to, 755
- Multichannel urethrocytometry, 392–401, 394f–400f
- Multifactorial conditions, 114
- Multiorgan syndrome, male infertility due to, 782t, 783
- Multiple endocrine neoplasia type I, 742t
- Multiple endocrine neoplasia type II, 742t
- Multiple pregnancy, with in vitro fertilization, 775
- Multiple sclerosis
- female sexual dysfunction in, 62
  - urologic symptoms of, 378
- Musculoskeletal causes, of chronic pelvic pain, 45t, 520–521, 521t

 for dysfunctional uterine bleeding, 96  
 for endometrial hyperplasia, 667–668  
 for endometriosis, in adolescents, 508  
 with GnRH agonists, 194–195  
 for hypothalamic amenorrhea, 822  
 for menorrhagia, 95  
 in oral contraceptives, 834, 835  
 for polycystic ovary syndrome, 825  
 for premature ovarian failure, 823

Progesterin subdermal implants, for adolescents, 504

Progesterin-containing IUD, for endometrial hyperplasia, 668

Progesterin-only contraceptives, 839–840  
 for adolescents, 503–504

Prolactin (PRL), 803  
 biologic actions of, 803  
 and delayed puberty, 474  
 in female infertility, 753, 761  
 in immunocompetence, 803  
 during lactation, 803, 805  
 in male infertility, 779–781, 787, 788t  
 during pregnancy, 803, 805  
 and progesterone, 803  
 regulation of, 803–804, 804f  
 in secondary amenorrhea, 816t  
 structure of, 803

Prolactin-inhibiting hormone, 608, 609

Prolactinomas, 805–806, 806f  
 and breastfeeding, 811  
 female infertility due to, 753  
 irradiation of, 810  
 male infertility due to, 781  
 malignancy in, 810  
 and pregnancy, 811  
 secondary amenorrhea due to, 820–821, 821f, 824  
 surgical resection of, 810

Prolapse, assessment of, 376t, 378, 378f

Proliferative phase, of menstrual cycle, 843, 844f, 852, 853f, 855f

Promensil, 75, 75f

Promoter methylation, 739

Prone knee-chest position, for pediatric patients, 482, 483f

Pro-opiomelanocortin (POMC), 917

PROPI mutations, delayed puberty due to, 475

Propoxyphene (Darvon, Darvocet), for chronic pelvic pain, 58t

Propylthiouracil (PTU), for hyperthyroidism, 914

PROS (Pediatric Research in Office Settings) Study, 445, 445t, 446t

Prostaglandin E<sub>1</sub>, for female sexual dysfunction, 68

Protease inhibitors (PIs), for HIV, 298, 299

Protein C deficiency, recurrent pregnancy loss due to, 800t

Protein S deficiency, recurrent pregnancy loss due to, 800t

Prothrombin mutation, recurrent pregnancy loss due to, 800, 800t

Proto-oncogenes, 740, 741

Provider-Performed Microscopy Procedure (PPMP) Laboratory Certification, 945, 949, 949f, 951

Pseudoaddiction, 730

Pseudo-Cushing's syndromes, 923t, 924

Pseudohermaphroditism  
 female, 476  
 male, 781

Pseudomembranous colitis, due to antimicrobial prophylaxis, 235

Pseudomenopausal treatment, for endometriosis, 170–171

Pseudoprecocious puberty, 455, 456, 466

Pseudopregnancy therapy, for endometriosis, 170

Psittacosis, 263

Psoriasis, vulvar, 223, 226f

PSTT (placental site trophoblastic tumor), 719

Psychiatric illnesses, female sexual dysfunction due to, 63

Psychological dependence, 57

Psychosocial history, for chronic pelvic pain, 48

Psychostimulants, for cancer pain, 736

Psychotherapy  
 for cancer pain, 731  
 for chronic pelvic pain, 58  
 for irritable bowel syndrome, 56  
 for premenstrual syndrome/premenstrual dysphoric disorder, 22t, 23

PTEN (phosphatase and tensin homolog deleted on chromosome 10) gene, 742t, 746t, 747–748, 747t

PTH (parathyroid hormone)  
 and osteoporosis, 10  
 for osteoporosis, 13t, 14f, 15f, 16, 866

PTHrP (parathyroid hormone-related protein), during pregnancy and lactation, 17

PTR (pressure transmission ratio), 404f

PTU (propylthiouracil), for hyperthyroidism, 914

Pubarche, 449  
 in females, 449t, 450, 450f, 469, 470f  
 median age of, 469, 470f  
 in males, 451–452, 452f, 452t  
 premature, 456t, 458, 460–461  
 in polycystic ovary syndrome, 900

Puberty, 443–466  
 age of onset of, 444f, 469, 470t  
 biochemical exposures and, 454–455  
 current trends in, 445, 469, 470t  
 determinants of, 454–455, 454t  
 genetic factors in, 454, 454t  
 historical trends in, 443–445, 444f, 444t, 445t  
 nutrition and, 454  
 obesity and, 454, 454t  
 racial differences in, 444t, 445, 445t, 470t  
 bone age and, 469, 470t  
 bone density and, 453  
 changes in body composition at, 453  
 clinical signs of, 449–455  
 in females, 449–451, 448f, 449t, 450f, 451t  
 in males, 451–452, 452f, 452t  
 contemporary studies on, 445–446, 445t, 446t  
 controversies over, 465–466

**Puberty (Cont.)**

- controversies over (*cont.*)
  - historical, 443
  - re-evaluation of, 445–446
- delayed, 469–479
  - clinical features of, 471
  - constitutional, 470t, 471
  - differential diagnosis of, 471, 472f
  - distribution of, 444f
  - etiology of, 470–471, 470t
  - laboratory evaluation of, 471–476, 474t
  - management of, 477–478
  - psychosocial aspects of, 477
- duration of, 443, 445
- early, 443, 445, 455, 466
  - constitutional, 466
- endocrinology of, 446–449, 447f, 449t, 469
- key terms for, 466
- leptin and, 454
- precocious, 443, 455–466
  - central, 455–456
  - defined, 455, 466
  - differential diagnosis of, 455–456, 456t
  - treatment of, 462–464, 463t, 465t
- classification of, 455, 455t
- contrasexual, 466
  - historical, 443
  - re-evaluation of, 445–446
- diagnosis and evaluation of, 459–462
  - differential, 456t
  - flowchart for, 459f
  - history in, 460
  - laboratory studies in, 461–462, 461t, 462t, 463f
    - physical examination in, 460–461
  - distribution of, 444f
  - “early” vs., 443, 455
  - family male, 457
  - GnRH-dependent, 455t
  - GnRH-independent, 455t
  - incomplete, 456, 458–459
  - isolated, 456t, 458–459, 466
    - treatment of, 465t
  - isosexual, 466
  - management and treatment of, 462–464, 463t, 465t
  - medical conditions associated with, 454t
  - peripheral, 456–457, 466
    - differential diagnosis of, 457, 456t, 457t
      - treatment of, 465t
  - prognosis for, 464, 465t
  - pseudo-, 455, 456, 466
  - psychosocial impact of, 464–465
  - slowly progressive or nonprogressive, 466
  - somatic growth in, 452–453, 453f
  - Tanner staging of, 443
    - female, 449–450, 450f
    - male, 451–452, 452f

Pubic bone stabilization sling, for urinary incontinence, 350, 350f

Pubic hair growth, 449
 

- in females, 449t, 450, 450f, 469, 470f
  - median age of, 469, 470f
  - in males, 452, 452f, 452t
  - premature, 456t, 458, 460–461
- Pubic louse, 278

Pubocervical fascia, 326f–328f, 327, 330f, 331, 331f
 

- detachment of, 333

Pubococcygeus muscles, 329, 330, 330f and continence, 342

Puborectalis muscle
 

- and fecal continence, 356, 357f–359f
- in pelvic support, 329, 330f
- and urinary continence, 342

Puborectalis sling, 356, 359f

Pubourethral ligaments, 327

Pubovaginal slings, for urinary incontinence, 347, 351

Pucp (urethral closure pressure), 383, 384f
 

- maximum, 390, 402f

Pudendal nerve, 729f
 

- in sexual response, 62

Pudendal nerve terminal motor latencies (PNTML), for fecal incontinence, 361, 363–364, 364f

Pudendal neuralgia, 226f

PUF (pelvic pain urgency/frequency) questionnaire, 51, 52f

Pulmonary complications, of gynecologic surgery, 243–246

Pulmonary edema, postoperative, 245

Pulmonary embolism, postoperative, 237–239, 237t, 246

Pulmonary insufficiency, acute, with hydatidiform mole, 715

Punctations, colposcopy of, 149, 152, 152f, 154f, 157

Pura (urethral pressure), 382–383, 384f, 385f, 394f–400f
 

- maximum, 403f

PVB (cisplatin, vinblastine, bleomycin) regimen, for malignant gestational trophoblastic disease, 723

Pves (vesical pressure), 382, 384f, 394f–400f
 

- during voiding, 408f–410f

Pyelonephritis, in older women, 41

Pyoderma, 249–250
 

- fistulans, 250–252, 251t

Pyosalpinx, due to PID, 290

Pyospermia, 787

Pyridoxine, for premenstrual syndrome/premenstrual dysphoric disorder, 22t, 23

**Q**

Q-tip test, in urogynecologic workup, 379–380, 381f

Quality assurance, federal regulations on, 943–951, 947f–950f

Quality control, for in vitro fertilization, 776

Quality of life enhancement, with cancer pain, 727, 728f

Quantitative computed tomography, for assessment of bone mass, 6–7

Quinagolide (Norprolac), for hyperprolactinemia, 807t, 810

**R**

Racial background, preconception counseling due to, 114–115

Racial differences
 

- in breast cancer, 609
- in leiomyomas, 179–180
- in onset of puberty, 443–445, 444t, 445t, 470t

Radiation dysplasia, 157

Radiation exposure, and uterine sarcomas, 677

Radiation therapy
 

- for breast cancer, 600–601
  - postmastectomy, 600
- for cervical cancer, 657–659, 660
  - colposcopy after, 155
- for endometrial carcinoma, 669–671, 672
- for fallopian tube carcinomas, 694
- female sexual dysfunction after, 63–64
- for ovarian carcinoma, 705
- for prolactinomas, 810
- rectovaginal fistula due to, 437
- for uterine sarcomas, 683
- for vaginal carcinoma, 647
- for vulvar cancer, 636, 638f, 640–641, 641t

Radical hysterectomy
 

- for cervical cancer, 657
- laparoscopically assisted vaginal, 562
- total laparoscopic, 562

Radical mastectomy, 599
 

- modified, 599

Radical vulvectomy, 639–641, 640f, 640t, 641f

Radioimmunoassays, for adrenal insufficiency, 931

Radiosensitizers, for cervical cancer, 658

Raloxifene (Evista)
 

- for breast cancer, 598
- for osteoporosis, 13t, 14, 14f, 15, 15f, 866

Random perireareolar fine-needle aspiration, 626

RANKL, in bone remodeling, 5f

Rapid plasma reagin (RPR) test, 269, 270

RAS genes, 741

Rb (retinoblastoma) protein, in cervical cancer, 652

Recombinant follicle-stimulating hormone (rFSH, Gonal-F, Follistim), 770, 770t, 771

Records, retention of, 943  
 Recreational injuries, counseling on, 104–105, 105t  
 Rectal examination, 326  
 Rectal hyperactivity artifact, in cystometry, 395f  
 Rectal pain, due to endometriosis, 162  
 Rectoanal inhibitory reflex, 356, 361, 362f  
 Rectocele, 332, 334  
 Rectoscopes, gynecologic, 537–538, 539f  
 Rectovaginal fascia, 327–328, 328f, 331  
     detachment of, 334  
 Rectovaginal fistula(s), 426–439  
     with anal sphincter defects, 434, 434f–436f  
     classification of, 431  
     clinical features of, 434  
     complicated, 437  
     with Crohn's disease, 437  
     diagnosis of, 434, 434f  
     epidemiology of, 431–434  
     irradiation-induced, 437  
     management of, 434–437, 434f–439f  
     multiple, 434, 434f  
     risk factors for, 431–434  
 Rectovaginal septum, 327f, 330f, 331  
 Rectum  
     anatomy of, 356, 357f  
     endometriosis of, 167f, 168f, 175  
 Recurrent pregnancy loss, 797–801  
     clinical course and progression of, 800–801, 801t  
     diagnosis and treatment of, 798–800, 799t–801t  
     pathogenesis of, 797–798  
     primary vs. secondary, 797  
     risk factors for, 797  
 Red blood cell transfusions, perioperative, 239–240  
 Red clover, isoflavones in, 75  
 "Red degeneration," of leiomyomas, 189  
 Red lesions, 223t  
 5 $\alpha$ -Reductase, in steroidogenesis, 919  
 5 $\alpha$ -Reductase deficiencies, male infertility due to, 781  
 Reflex testing, in urogynecologic examination, 379  
 Reflexology, for chronic pelvic pain, 58  
 Reflux menstruation, 160  
 Reichstein, T., 918t  
 Reid's colposcopic index, 149–150, 149t, 150f  
 Reifenstein's syndrome, male infertility due to, 781  
 Relative value units, and coding, 939  
 Relaxation therapy, for chronic pelvic pain, 58  
 Reliability, of test, 100  
 Religious treatments, for chronic pelvic pain, 59  
 Remifemin, 76

Renal failure, male infertility due to, 781  
 Renal manifestations, diabetes mellitus with, coding of, 937–938  
 Renal system, with aging, 37–38  
 Renin, secretion of, 920  
 Renin-angiotensin system, 920  
 Renin-angiotensin-aldosterone axis, 919–920  
 Repronex (human menopausal gonadotropins), 770  
 Requip (ropinirole), for hyperprolactinemia, 807t, 810  
 Rescue medications, for cancer pain, 729  
 Research, consent for, 943  
 Respiratory system, with aging, 37  
 RET oncogene, 742t  
 Retinoblastoma (Rb) protein, in cervical cancer, 652  
 Retinol oversupplementation, during pregnancy, 116  
 Retractors, for minilaparotomy, 534, 535f  
 Retrograde ejaculation, male infertility due to, 784, 792  
 Retroperitoneal lymphadenectomy, laparoscopic, 562–564, 563f  
 Retropubic suspensions, for urinary incontinence, 347–348, 348f  
 Retropubic transvesical vesicovaginal fistula repair, 421, 427f  
 Retzius space, 565f  
 Reverse transcriptase inhibitors, for HIV, 298, 299  
 rFSH (recombinant follicle-stimulating hormone), 770, 770t, 771  
 Rh<sub>0</sub>D antigen, with hydatidiform mole, 715  
 Rhabdomyosarcoma, vulvovaginal, in pediatric patients, 499, 500f  
 Rimostil, 75, 75f  
 Ringer's solutions, for hysteroscopic surgery, 539, 539t  
 Risedronate (Actonel), for osteoporosis, 12, 13, 13t, 14f, 15f  
 Risk assessment, in breast cancer screening, 610–612, 610f, 611f, 611t  
 Robotics, for laparoscopic surgery, 534, 536f  
 Rokitansky-Küster-Hauser syndrome, 476–477  
 Room setup, for minimally invasive surgery, 543–547, 544f–547f  
 Ropinirole (Requip), for hyperprolactinemia, 807t, 810  
 Rosewater's syndrome, male infertility due to, 781  
 Rosiglitazone, for polycystic ovary syndrome, 904  
 Rowntree, L. G., 918t  
 RPR (rapid plasma reagin) test, 269, 270  
 RU 486, for leiomyomas, 195  
 Rubella, during pregnancy, 118  
 Rubin and Barbo system, for colposcopic assessment, 150, 150f, 151t

**S**  
 Sacral plexus, 729f  
 Sacral spinal nerve stimulation, for fecal incontinence, 370–372  
 Safety, with domestic violence, 82, 83t  
 Saline infusion sonography (SIS)  
     for abnormal uterine bleeding, during perimenopause, 881, 882t  
     for menometrorrhagia, 93–94  
 Saline infusion sonohysterography (SIS), for secondary amenorrhea, 819, 819f  
 Salpingectomy  
     for ectopic pregnancy, 212  
     laparoscopic, 551, 552f, 553f  
 Salpingitis  
     due to chlamydia, 266  
     oral contraceptives and, 835  
     in PID, 287, 290  
 Salpingitis isthmica nodosa (SIN)  
     and ectopic pregnancy, 206  
     infertility due to, 752  
 Salpingocentesis, for ectopic pregnancy, 214  
 Salpingo-oophorectomy  
     for *BRCA1/BRCA2* mutations, 744  
     for endometriosis, 54  
     for premenstrual syndrome/premenstrual dysphoric disorder, 25t, 30  
 Salpingostomy  
     for ectopic pregnancy, 212  
     laparoscopic, 550–551, 551f, 552f  
 Salvage chemotherapy, for malignant gestational trophoblastic disease, 723  
 Sanctura (trospium), for urinary incontinence, 337, 337t, 343  
 Sarafem (fluoxetine), for premenstrual syndrome/premenstrual dysphoric disorder, 24–25, 25t, 28t  
 Sarcoma(s)  
     botryoides, 648  
     in pediatric patients, 499, 500f  
     ovarian, 708  
     uterine, 677–684  
         adeno-, 680, 680f, 681f  
         carcino- (malignant mixed müllerian), 677, 678, 678f, 680, 682  
         classification of, 677, 678t  
         clinical features of, 678–680, 678f–681f, 679t  
         diagnosis of, 680–682, 682f  
         endometrial stromal, 679–680, 680f  
         epidemiology, risk factors, and pathogenesis of, 677  
         key points on, 677  
         leiomyo-, 678–679, 679f, 679t, 680–681, 682–684  
         metastatic, 681, 681f, 682f  
         prognosis for, 684  
         treatment of, 682–684, 683t  
         vaginal, 648  
 Sarcoptes scabiei, 277–278
